Abstract

This study reports simple and straightforward methods for synthesizing new bivalent β-carboline compounds using L-tryptophan as a starting material with 1,4-dibromobutane as a dimerization linker. The synthetic route began with coupling L-tryptophan with formaldehyde via Pictet-Spengler condensation to afford tetrahydro-β-carboline, **T1** as the key intermediate. The reaction proceeded with decarboxylation of **T1** using potassium dichromate with acetic acid to afford β-carboline, **T2**. Subsequent alkylation of **T2** using 1,4-dibromobutane as the linker yielded intermediate **T3**, followed by dimerization to furnish the new bivalent β-carboline, **T4**. ^{1}H and ^{13}C NMR confirmed all the synthesized compounds. In addition, this study includes the proposed mechanism for the synthesis of a new bivalent β-carboline compound.

Keywords: synthesis, bivalent β-carboline, L-Tryptophan, Pictet-Spengler condensation, dimerization

Abstrak

Kajian ini melaporkan kaedah mudah dan secara terus untuk mensintesis sebatian baru bivalen β-karbolin menggunakan L-tryptofan sebagai bahan pemulaan dengan 1,4-dibromobutana sebagai penghubung dimerisasi. Laluan sintesis bermula dengan gandingan L-tryptofan dengan formaldehid melalui pemeluwapan Pictet-Spengler untuk mendapatkan tetrahidro-β-karbolin, **T1** sebagai kunci perantaraan. Tindak balas diteruskan dengan pendekarboksilan **T1** menggunakan kalium dikromat dengan asid asetik untuk menghasilkan β-karbolin, **T2**. Seterusnya alkilasi **T2** menggunakan 1,4-dibromobutana sebagai penghubung menghasilkan perantara **T3**, diikuti dengan dimerisasi untuk menghasilkan bivalen β-karbolin baharu, **T4**. Semua sebatian yang disintesis disahkan dengan ^{1}H NMR dan ^{13}C NMR. Sebagai tambahan, kajian ini merangkumi mekanisma yang dicadangkan untuk sintesis sebatian bivalen β-karbolin baharu.

Kata kunci: sintesis, bivalen β-Karbolin, L-Tryptofan, pemeluwapan Pictet-Spengler, dimerisasi

Introduction

β-carbolines are derived from a large group of heterocyclic compounds known as Norharmane (Figure 1), which have a 9H-pyrido[3,4-*b*]indole structural unit [1]. Furthermore, β-carboline can be classified as a synthetic and naturally occurring indole alkaloid with varying degrees of aromaticity that possess a planar tricyclic pyrido[3,4-*b*]indole ring system [2,3,4]. The core skeleton of β-carboline consists of a pyridine ring fused to an indole backbone (Figure 1).

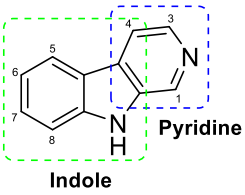

Figure 1. Core skeleton of β-carboline structure

β-carboline is a natural constituent found in plants, human tissues, body fluids, marine life, insects, and mammals [1]. Furthermore, β-carboline is also distributed in fungi and foods with broad pharmacological properties, including sedative, antithrombin, antimalarial, anti-HIV, and anti-inflammatory [5,6]. In addition, previous studies have reported that β-carboline, with its widespread biological properties, is commonly studied for its antitumor activity [7].

β-carboline alkaloid can be isolated from the seeds of a plant named *Peganum harmala,* which belongs to the family of Zygophyllaceae [4,7,8]. Other names for *Peganum harmala* include harmal, African rue, and Syrian rue. It is a perennial herbaceous, glabrous plant that can grow in semi-arid rangeland and sandy soils, especially in the Mediterranean region of North Africa and the Middle East [9]. β-carboline derivatives extracted from this plant are used mainly to treat various diseases, including asthma and jaundice. Despite its toxicity level, *Peganum harmala* has been used to treat a range of human ailments, as the health benefits outweigh the detrimental effects [10].

Interestingly, bivalent β-carboline alkaloids (Figure 2) elicited substantially greater bioactivity than the corresponding monomers. Thus, this suggests that bivalent compounds have better therapeutic potential and thus should be studied in future research [11].

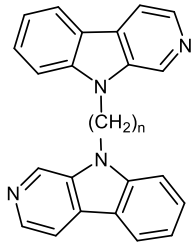

Figure 2. Example of a bivalent β-carboline structure

The bivalent β-carboline structure has two β-carboline monomers linked at positions-1, -2, -3, and -9 by carbon chains, heteroatoms, heterocyclic, amide esters, or amino-groups [11]. In addition, a previous study discovered that bivalent β-carboline elicited anticancer properties via a suitable linker, significantly improving activity by 100- to 500-fold over the corresponding monomers [5,12]. The improvement in anticancer activity might have occurred as the bivalent compound was more favourable to intercalating into DNA [5]. Therefore, bivalent β-carboline was expected to have significantly higher antitumor potency *in vitro* and *in vivo* than the corresponding monomers [12].

There are numerous reports of bivalent β-carboline derivatives. Daoud et al. investigated the anticancer activity of the bivalent β-carboline derivative B-9-3 (**1**) (Figure 3), which demonstrated potent anticancer activity against three cancer cell lines with IC_{50} values ranging from 3.58 μM–10.89 μM [13]. Chen et al. reported the synthesis and anticancer activity of a series of novel N^9-heterobivalent β-carboline (**2**) and (**3**) with strong cytotoxic activities against six cancer cell lines with IC_{50} values lower than 20 μM (Figure 3) [1].

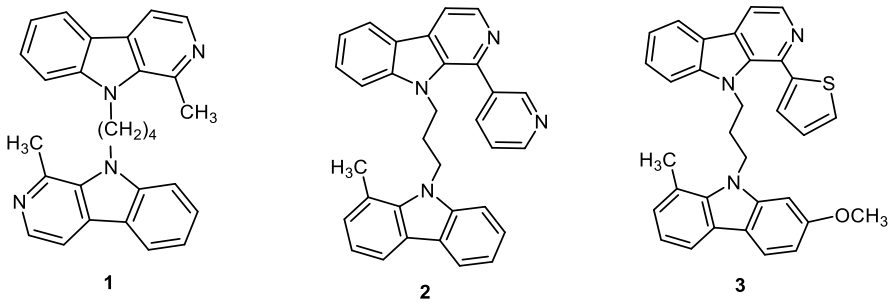

Figure 3. Reported bivalent β-carboline derivatives

Bivalent β-carboline, linked by suitable linkers, could significantly improve DNA-binding affinity as the dimerized compounds can bind to DNA through bis-intercalation mode, causing significant changes in DNA double helix structure [7,14,15]. The structural-activity relationships of the bivalent β-carboline compound indicated a few factors that determined antitumor activity; the common β-carboline moiety was very crucial for antitumor activity, the length of the linker affected antitumor potencies, four to six methylene units were more favourable, and the linker position in positions-1,-2,-3, and -9 were beneficial [14,16]. The problem statement that this study addresses is the importance of developing new anticancer drugs as cancer is currently one of the leading causes of major health problems worldwide. Thus, this study aims to synthesize a new bivalent β-carboline compound using the suitable length of 1,4-dibromobutane in position-9 in the four-step method using commercially available L-tryptophan as a starting material. The bivalent β-carboline was characterized using ^{1}H- and ^{13}C-NMR.

Materials and Methods

This section will describe a sequential decarboxylation and aromatization of tetrahydro-β-carboline-3-carboxylic acid **T1** to furnish β-carboline **T2**. This was followed by the dimerization reaction of the monomer β-carboline to form a new bivalent β-carboline **T4**.

Synthesis of tetrahydro-β-carboline (T1)

Tetrahydro-β-carboline-3-carboxylic acid (**T1**) was prepared through Pictet-Spengler condensation of L-tryptophan (**1**, 2.0 g, 9.8 mmol) with 37% formaldehyde (**2**, 0.98 mL, 32.63 mmol). The reaction started with 3 hours of stirring of L-tryptophan (**1**) and NaOH (0.4 g, 10 mmol) in a specific amount of water (200 mL). Then, 37% formaldehyde (**2**) was added to the solution, and it continued to reflux for 3 hours at room temperature. Upon completion, the reaction mixture was neutralized with glacial acetic acid, and the product was filtered off, washed well with water, and dried overnight.

Synthesis of β-carboline (T2)

Next, we attempted the decarboxylation-aromatization of tetrahydro-β-carboline-3-carboxylic acid (**3**, 1 g, 4.6 mmol) by stirring it in water (100 mL) at 100°C. The reaction continued to stir and heat with $K_2Cr_2O_7$ (9.5 g, 32 mmol) and acetic acid as a base (10 mL). Then, the reaction mixture was cooled by running it under tap water. Upon completion, sodium sulfite was added as a removing oxidizing agent. This was followed by the addition of 2.5 M NaOH drop by drop until it reached pH 7. The solution was extracted with ethyl acetate, and the combined organic layer was collected, washed with water and brine, and dried over anhydrous sodium sulfate. Lastly, the solution was evaporated. Yellowish solid, yield 47%, m.p. 199°C. ^{1}H-NMR (400 MHz, MeOD-d_4): δ 8.77 (s, 1 H), 8.26 (d, J = 5.5 Hz, 1 H), 8.17 (d, J = 7.8 Hz, 1 H), 8.08-8.07 (m, 1 H), 7.55-7.54 (m, 2 H), 7.27-7.23 (m, 1 H); ^{13}C NMR (101 MHz, MeOD-d_4): δ 137.0, 132.7, 129.1, 128.4, 121.4, 120.8, 119.5, 114.8, 111.5.

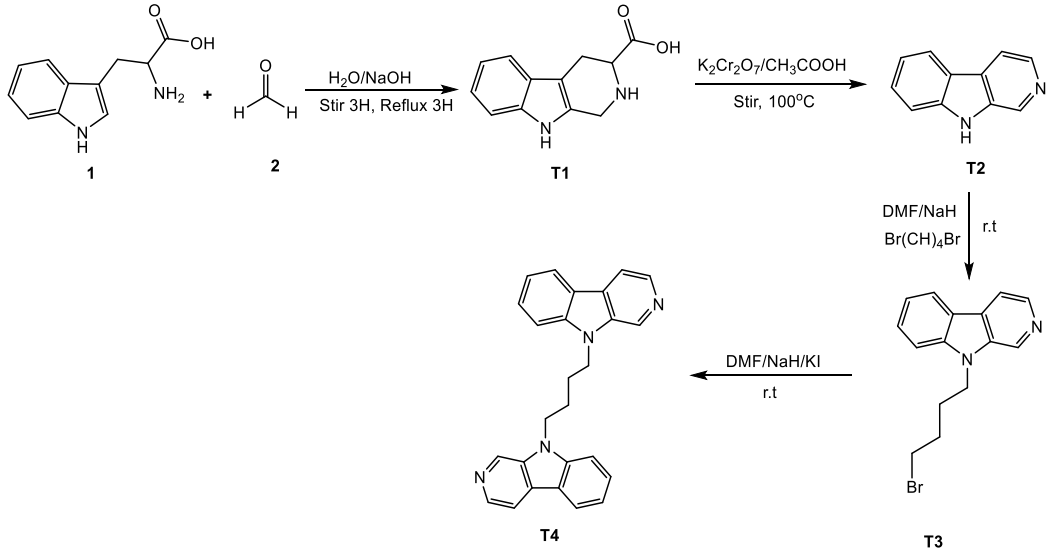
Synthesis of intermediate bivalent β-carboline (T3)

The intermediate **T3** was prepared by stirring β-carboline (**T2,** 0.5 g, 2.96 mmol) in anhydrous DMF (15 mL) at room temperature for 30 minutes, then 60% NaH dispersed in mineral oil (0.23 g, 5.92 mmol) and

appropriate 1,4-dibromobutane (0.7 mL, 5.92 mmol) was added. The reaction mixture continued to stir at room temperature, and upon completion, the mixture was poured into water, extracted with ethyl acetate, and washed with water and brine. Next, it was dried under anhydrous sodium sulfate, filtered, and evaporated. The final result of the reaction was an oily product. Dark brownish oil product, yield 98%, m.p. 188°C. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.39 (d, *J* = 5.9 Hz, 1 H), 8.31-8.27 (m, 2 H), 7.85 (d, *J* = 7.3 Hz, 1 H), 7.69 (d, *J* = 8.7 Hz, 2 H), 7.49 (d, *J* = 7.8 Hz, 1 H), 3.50 (d, *J* = 12 Hz, 2 H), 3.43 (d, *J* = 5.9 Hz, 2 H), 2.03-2.00 (m, 4 H); ^{13}C NMR (101 MHz, $CDCl_3$): δ 144.6, 136.2, 132.9, 132.3, 130.8, 123.5, 122.6, 119.6, 117.3, 111.2, 60.3, 44.4, 33.9, 29.7.

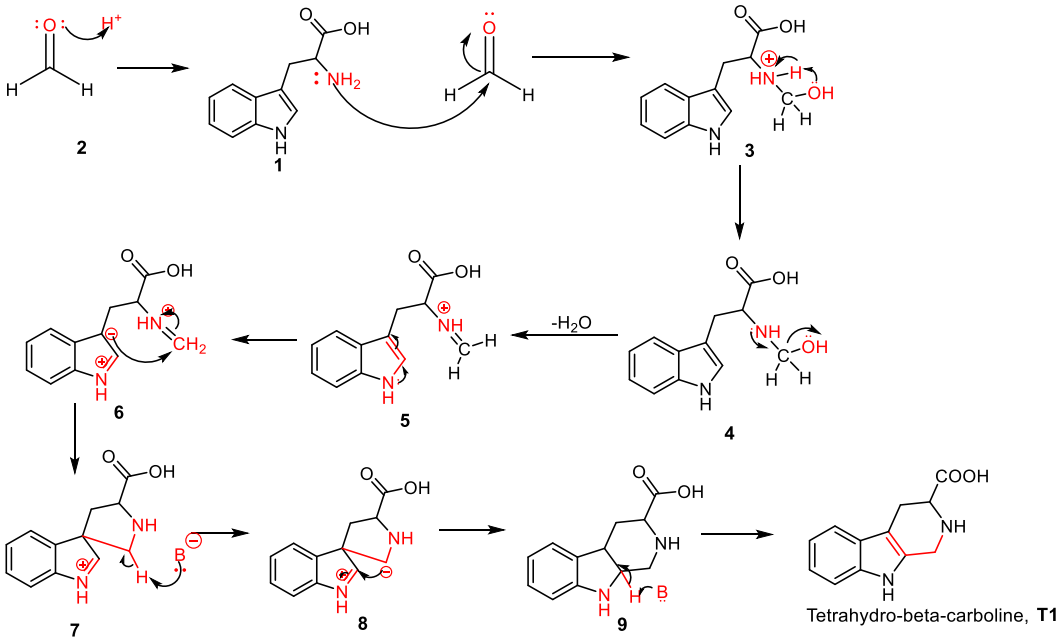
Synthesis of bivalent β-carboline (T4)

β-carboline (**T2**, 0.18 g, 1.09 mmol) in anhydrous DMF (6 mL) was added by stirring to a solution of intermediate (**T3**, 0.5 g, 1.64 mmol), 60% NaH dispersed in mineral oil (0.21 g, 5.49 mmol), potassium iodide (0.91 g, 5.49 mmol) in anhydrous DMF (10 mL). Next, intermediate **T3** was further reacted to form bivalent β-carboline **(T4)**. The reaction mixture was stirred at room temperature until the reaction was completed, and then it was poured into ice-cold water. After that, the reaction mixture was extracted with ethyl acetate and washed with water and brine. The combined organic layer was dried over anhydrous sodium sulfate, Na_2SO_4, and filtered. The purification process was conducted using column chromatography (DCM/MeOH 100:1 as the eluent) to furnish bivalent β-carboline **(T4)**. Dark brownish oil product, yield 13%, m.p. >270°C. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.93 (s, 2 H), 8.45 (d, *J* = 5.5 Hz, 2 H), 8.19 (d, *J* = 8.2 Hz, 2 H), 8.10 (d, *J* = 5.5 Hz, 2 H), 7.70-7.66 (m, 2 H), 7.52 (d, *J* = 8.4 Hz, 2 H), 7.36 (t, *J* = 7.5 Hz, 2 H), 5.06-5.00 (m, 4 H), 4.47 (t, *J* = 7.3 Hz, 4 H); ^{13}C NMR (101 MHz, $CDCl_3$): δ 143.3, 138.1, 137.5, 133.8, 132.0, 129.9, 122.6, 120.7, 118.5, 115.5, 110.1, 43.5.



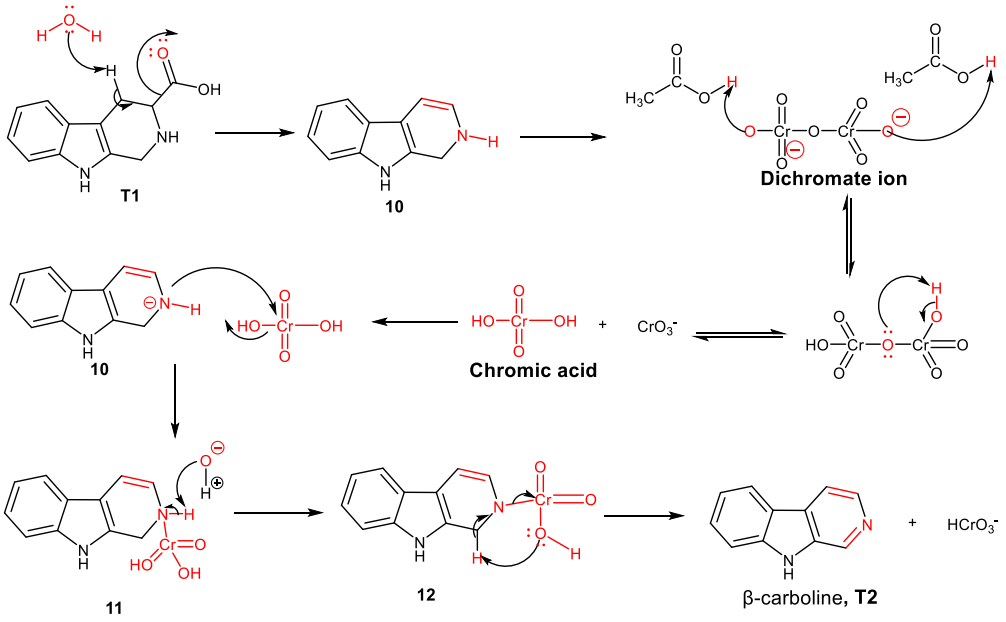
Results and Discussion

The desired bivalent β-carboline **(T4)** synthesis was performed in a four-step method starting from L-tryptophan **(1)** as outlined in Scheme 1. Firstly, the tetrahydro-β-carboline **(T1)** was prepared from the successful reaction of Pictet-Spengler condensation of L-tryptophan **(1)** with formaldehyde. The reaction was further reacted to form β-carboline **(T2)** with a 47% yield via decarboxylation by using potassium dichromate in the presence of acetic acid. Next, the β-carboline structure was alkylated at position-9 by the action of the strong base, NaH in anhydrous DMF, followed by the addition of 1,4-dibromobutane to successfully afford intermediate **T3** with a 98% yield. The intermediate **T3** was present in an oily product form. Finally, the intermediate **T3** was further reacted with β-carboline **(T2)** with a strong base, NaH in solvent anhydrous DMF, in the presence of potassium iodide. The reaction was carried out at room temperature to successfully afford the targeted compound, bivalent β-carboline **T4** (13%). The bivalent β-carboline **(T4)** underwent a purification process using column chromatography and furnished the oily product. ^{1}H NMR and ^{13}C NMR were utilized to characterize the chemical structures of all synthesized compounds in this study.

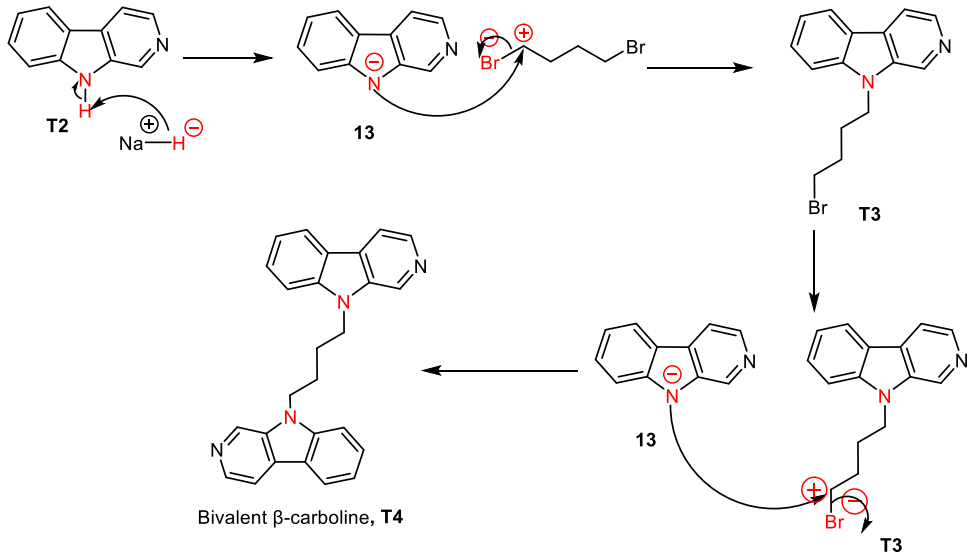


The proposed mechanism for the Pictet-Spengler condensation of L-tryptophan forming tetrahydro-β-carboline **T1** was outlined in Scheme 2. Initially, the mechanism started with the production of an iminium ion **3**, followed by the formation of an imine intermediate **5**, Schiff base, which removed H_2O. Next, the imine intermediate **5** underwent 6-endo-trig cyclizations involved in the base's action, forming a new ring, and the final product was tetrahydro β-carboline **(T1)**.

The proposed mechanism of the oxidation-decarboxylation of tetrahydro-β-carboline **(T1),** which produces β-carboline **(T2)**, is outlined in Scheme 3. Based on Scheme 3, the first step of the mechanism involved abstracting protons from tetrahydro-β-carboline **(T1)** by water. Then a new bond was formed: the double bond and functional group -COOH were removed, forming compound **10**. On the other hand, potassium dichromate that has been treated with acetic acid formed a chromic acid known as the common oxidizing agent for the oxidation reaction. Then, the strong nucleophile site of compound **10** attacked the electrophile site of chromic acid-water repeated proton abstraction in compound **11**. Next, the nucleophile site of -OH was abstracted proton from the α-carbon of compound **12**, forming a new bond. This double bond formed a new aromatic pyridine ring which successfully formed β-carboline **(T2)**.



Lastly, the proposed mechanism for the new bivalent of β-carboline **(T4)** is outlined in Scheme 4. The mechanism started with the strong base, NaH, that abstracted protons from β-carboline (T2), producing a strong nucleophile site of compound **13**. Then, the strong nucleophile of N in compound **13** attacked the electrophile of C from the 1,4-dibromobutane, and it removed bromine since it is a good leaving group. Finally, the intermediate of bivalent β-carboline **(T3)** was successfully formed with NaBr. The intermediate bivalent β-carboline **(T3)** further reacted with the monomer β-carboline **(T2)** by the same reaction mechanism as the intermediate bivalent β-carboline **(T3)** to form a symmetrical structure of bivalent β-carboline **(T4)**.



Scheme 1. Overall synthetic route for new bivalent β-carboline compound **T4**

Scheme 2. Proposed mechanism for the Pictet-Spengler condensation of L-tryptophan forming tetrahydro-β-carboline (**T1**)

Scheme 3. Proposed mechanism for the oxidation-decarboxylation of tetrahydro-β-carboline (**T1**) forming β-carboline (**T2**)

Scheme 4. Proposed mechanism for dimerization of β-carboline (**T4**)

Conclusion

In summary, this study has successfully synthesized a new bivalent β-carboline compound **(T4)** from the starting material L-tryptophan **(1)** with a 13% yield. The synthesis reaction is simple and straightforward, using commercially available, safe, and cheaper chemicals. Moreover, the mechanism for the synthesis route of the new bivalent β-carboline compound **(T4)** has been

proposed in this study for future reference. Future studies will evaluate the *in vitro* cytotoxicity potential of T4 in various cancer cell lines to determine its potential as an anticancer agent.

Abstract

An understanding of the mechanism of chemical reactions is needed to optimize the reaction process and improve performance. The adsorption of reactant molecules, formation of reaction intermediates, and finally the distribution of products depend on the composition and surface structure of the catalyst. This research work deployed Fourier transform infrared (FTIR), high performance liquid chromatography (HPLC), and gas chromatography (GC) to identify the mechanism of Sm/Mn/Ru (60:35:5)/Al_2O_3 catalyst. The envisioned methanation reaction initially follows the Langmuir Hinselwood mechanism with the adsorption of CO_2 and H_2 gases on the catalyst surface. From the gaseous product, only methane peak was observed. Meanwhile, from the liquid product, methanol peak is observed at retention time 20 mins which accordance with standard methanol. Therefore, the final products acquired from the methanation reaction of Sm/Mn/Ru (60:35:5)/Al_2O_3 catalyst are CH_4, CH_3OH and H_2O.

Keywords: methanation, hydrogenation, samarium oxide, catalyst, mechanism

Abstrak

Pemahaman kepada mekanisme tindak balas kimia adalah perlu untuk mengoptimumkan proses tindak balas dan meningkatkan prestasi. Penjerapan molekul reaktan, pembentukan perantaraan tindak balas, dan taburan produk pada asasnya bergantung kepada komposisi dan struktur permukaan pemangkin. Kerja penyelidikan ini menggunakan inframerah transformasi Fourier (FTIR), kromatografi cecair prestasi tinggi (HPLC), dan kromatografi gas (GC) untuk mengenal pasti mekanisma mangkin Sm/Mn/Ru (60:35:5)/Al_2O_3. Tindak balas metana yang dipostulatkan adalah mengikut mekanisma Langmuir Hinselwood yang pada mulanya melibatkan penjerapan gas CO_2 dan H_2 pada permukaan mangkin. Daripada produk gas, hanya puncak metana

diperhatikan. Manakala, daripada produk cecair, puncak metanol diperhatikan pada minit ke 20 masa tahanan mengikut larutan piawai metanol. Oleh itu, produk akhir yang diperoleh daripada tindak balas metana mangkin Sm/Mn/Ru (60:35:5)/Al_2O_3 ialah CH_4, CH_3OH dan H_2O.

Kata kunci: metanasi, penghidrogenan, samarium oksida, pemangkin, mekanisma

Introduction

Nowadays, catalytic methanation reaction has been widely explored in order to convert CO_2 gas to CH_4 gas by reducing emission of greenhouse gases using metal oxide. The most conventional metal oxide catalyst used are nickel, cobalt, manganese, copper, iron and lanthanide element. The catalytic ability of metal oxide catalyst deteriorates after several hours of reaction time due to the carbon forming process. The formation of carbon can be avoided by adding a dopant to the metal oxide catalyst [1]. Rosid et al. revealed that dopants and metal-based oxides have varying functions in hydrogenation reactions [2]. The metal-based oxide incites the reaction via combining with CO_2 molecules to form carbonate species on the surface, while the dopant split the H_2 molecules and provides the H atoms required for further hydrogenation of the carbonate to form methane [3].

Carbon dioxide (CO_2) adsorption happens during carbonate species and carrier-related formate formation in H_2 presence [4, 5]. Many studies have proposed varying CO_2 methanation mechanisms. The first proposed mechanism refers to CO_2 reaction in a carrier, while H (ads) species generated in metals yield formate intermediate (COOH) at the interface of metal support. The CO (ads) species generated by formate are hydrogenated to methane [6]. Meanwhile, on second proposed mechanism, CO_2 (ads) and O (ads) dissociated directly on the metal surface. Subsequently, CO (ads) become hydrogenated to CH_4. The dissociation of CO (ads) denotes the rate determining step of the reaction [7].

Other than that, Marc. et al. also pointed out that the methanation process consists of three steps, of which the first step is to adsorb CO_2 on the catalyst chemically [8]. The second step is to separate CO_2 into surface-absorbed CO and O, and the final step is species reaction to separate it from H_2. The particular reaction process is known as Langmuir-Hinselwood mechanism [9]. However, most of the proposed mechanism involved alkaline earth metal dan transition metal which showed the formation of carbonate and formate species during reaction. Therefore, in this study the mechanistic study has been conducted over lanthanide element, which is samarium oxide catalyst in order to identify the mechanism pathway and product formed during the reaction occur. This study was conducted using FTIR, GC and HPLC for identification of product and by-product formed in methanation reaction.

Materials and Methods

Catalyst preparation

The catalyst was prepared by aqueous incipient wetness impregnation method. 5 g of samarium(III) nitrate was firstly weighed in a beaker and dissolved in a small amountof distilled water, then mixed together with a solution of $RuCl_3.xH_2O$ and $Mn(NO_3)_2.4H_2O$ salts according to the desired ratio. The catalyst solutions were stirred continuously for 30 minutes before 7 g of alumina was added to it. After that, the coated alumina was aging at 80 – 90 ^oC for 24 hours followed by calcination at 1000 ^oC for 5 hours using a ramp rate of 10 ^oC/min to remove all the metal counter ions and water present in the catalyst. Lastly, the sample was labelled as Sm/Mn/Ru (60:35:5)/Al_2O_3. All chemicals used in this study were purchased from Sigma Aldrich.

Catalytic screening

A gas mixture consisting of CO_2 and H_2 with a molar ratio of 1: 4 was continuously passed through the catalyst at a flow rate of 50.00 cm^3/min. Prior to starting the catalyst test, the reaction gas was introduced into the microreactor system without passing through the catalyst as a calibration. Then, the reaction gas was passed through a catalyst and the temperature is raised from room temperature (RT) to

400°C using FTIR Nicolet Avatar 370 DTGS spectrophotometer. The percentage of CO_2 conversion calculation is shown in Equation 1.

$$\% \text{ of } CO_2 \text{ conversion} = \frac{\text{Peak Area of } CO_2 \text{ calibration} - \text{Peak Area of } CO_2 \text{ conversion}}{\text{Peak area of } CO_2 \text{ calibration}} \times 100 \quad (1)$$

Mechanistic study

First, the catalyst was ground and placed in a glass tube, while air pre-treatment was executed for 30 minutes at 100 °C for catalyst sample activation. When the sample cooled to ambient temperature, H_2/CO_2 gas was installed into the microreactor system with the temperature increased to 400 °C. The product stream was gathered in a sample cell equipped with a KBr window and scanned through an in-situ Nicolet Avatar FTIR 370 DTGS spectrophotometer. Then, FTIR was used to analyze the catalyst powder to identify adsorbed materials on the catalyst surface. The liquid product of the reaction and methanol standard were analyzed by HPLC (Rezex ROA-Organic Acid), and methanol was detected using a 300 mm × 7.8 mm ID column with a refractive index (RI) detector. Meanwhile, gas products were analyzed by Hewlett Packard 6890 series gas chromatograph with Flame Ionization Detector (FID) and methane production was determined using an Equation 2.

$$\% \text{ Yield of } CH_4 = \frac{[CH_4] \text{ from GC}}{\% \text{ Conversion of } CO_2} \times 100\% \quad (2)$$

Results and Discussion

Marwood et al. and Sharma et al. confirmed the direct decomposition of CO_2 into CO and O [10, 11]. In this study, it seems that the direct decomposition of CO_2 is demonstrated. This proposal is very consistent with the fact that, as described by Solymosi et al. formate was not detected in excessive supports containing low concentrations of OH groups [12]. This was ascribed to hydrogen present in the reaction that hindered CO intermediates formation, thus yielding formate species.

Products analysis

Potential Sm/Mn/Ru (60:35:5)/Al_2O_3 catalyst reveal catalytic routes for methane as main product, methanol and water as a by-product. In this study, it seems that the direct decomposition of CO_2 is demonstrated. The FTIR spectrum of the gaseous product is presented in Figure 1. The spectrum shows that the peak is close to 2351 cm^{-1} due to the CO_2 stretching mode. At the same time, the stretching mode of CH_4 band at the wavenumber of 3014 cm^{-1} and C-H deformation mode at 1310 cm^{-1} [13] can be clearly detected starting at 250 ^oC reaction temperature. From the figure, it can be observed that no methane peak was appeared at room temperature (RT) and 100 ^oC indicating the absence of methane gas produced during the reaction. When the reaction temperature was raised to 400 ^oC, the highest CH_4 gas was formed with around 69% detected by GC-FID. This show that methane formation is advantageous at high reaction temperature [14]. No band of 3300-3600 cm^{-1} of water was observed in the FTIR spectrum because the silica trap system used in the reactor functions as adsorbed water. Interestingly, no CO intermediate was formed as there is no CO peak around 2080 cm^{-1} was detected. This shows that CO_2 gas is directly converted into CH_4 gas without producing CO gas as an intermediate.

As can be observed in Table 1, no methane gas was formed at room temperature (RT) and 100 ^oC of reaction temperature which agreed with the absence of methane peak (~3000 cm^{-1}) in FTIR spectra in Figure 1. However, when increasing reaction temperature to 200 ^oC, about 6% of CH_4 gas was formed from 65.52% of CO_2 conversion. This means that 59.09% of the reacted CO_2 was attained as a by-product. At a reaction temperature of 250 ^oC, the catalyst formed 20% CH_4 gas. Upon raising the reaction temperature to 400 °C (maximum value), the best 69% CH_4 gas was formed

as detected by GC-FID. Although CO_2 conversion is 100%, but the CH_4 gas formed only 69%. This might due to formation of methanol as side product for the catalysts (Refer Figure 2) as confirmed by HPLC analysis which showed the presence of peak at 20 minutes compatible with the retention time of standard methanol. As qualitatively, the presence of methanol was confirmed in the water product. This is because the peak area of 1.708 x 10^6 at 20.038 minutes coincided with the peak of standard methanol (not shown) at 19.122 minutes.

Methanation mechanism

The hydrogenation methanation adhered to the Langmuir-Hinshelwood mechanism, which reflected CO_2 and H_2 gases adsorption on the surface of catalyst. All CO_2 adsorption, dissociation, and reaction of the resolved species with H_2 had been established from in-situ FTIR experiments without any carbonate adsorption peak at 1760 and 1570 cm^{-1}. The FTIR spectra for catalyst during reaction is depicted in Figure 3. The spectra exhibited two broad O-H peak around 3443 and 1637 cm^{-1} corresponded to stretching and bending of adsorbed water on Al_2O_3 support [15, 16]. According to Narain et al., a peak band was noted at 1639 cm^{-1} for the similar temperature due to O-H bending derived from H_2O [17]. Initially, CO_2 and H_2 molecules were drawn to the catalyst surface (Step I) and directly coordinated the C atoms to generate inorganic carboxylate as proposed in Figure 4. The peak at 1116 cm^{-1} assigned to the CO species observed during the attachment of CO_2 to the catalyst surface at reaction temperature, 100°C [10]. This suggested the arrangement of C atoms attached to the catalyst surface (Step II). The adsorbed H_2 molecule was dissociated to active H atom species, and this was followed by CO_2 gas dissociation, as reported by Haldor [18] in Step III. The continuous flow of H_2 gas on the catalyst connects with oxygen atoms at the lone pair of electrons with higher electronegativity to form water (step IVa). This was supported with intense peak in the FTIR at reaction temperature, 200°C. A little peak at 1397 cm^{-1} was also observed at 200°C that correspond to the methoxy group (H_3C-O) as suggested in step IVb. Solymosi et al. described the peak around 1397 cm^{-1} on the catalyst surface foremost to the formation of methanol as a by-product [12]. When increased the reaction temperature to 250 – 300°C, the peak at 2892-2926 cm^{-1} was appeared which suggested free carbon from step III react directly with hydrogen to produce methane (step V). The intensity of C-H peak decreased at 350°C indicating that almost all CHx was released as CH_4 gas. At a reaction temperature of 400°C, all peak C-H groups disappeared which resulted higher CH_4 formation at this reaction temperature with 69% as stated in Table 1. This signifying the conversion of all species to CH_4, H_2O, and CH_3OH as the final yields.

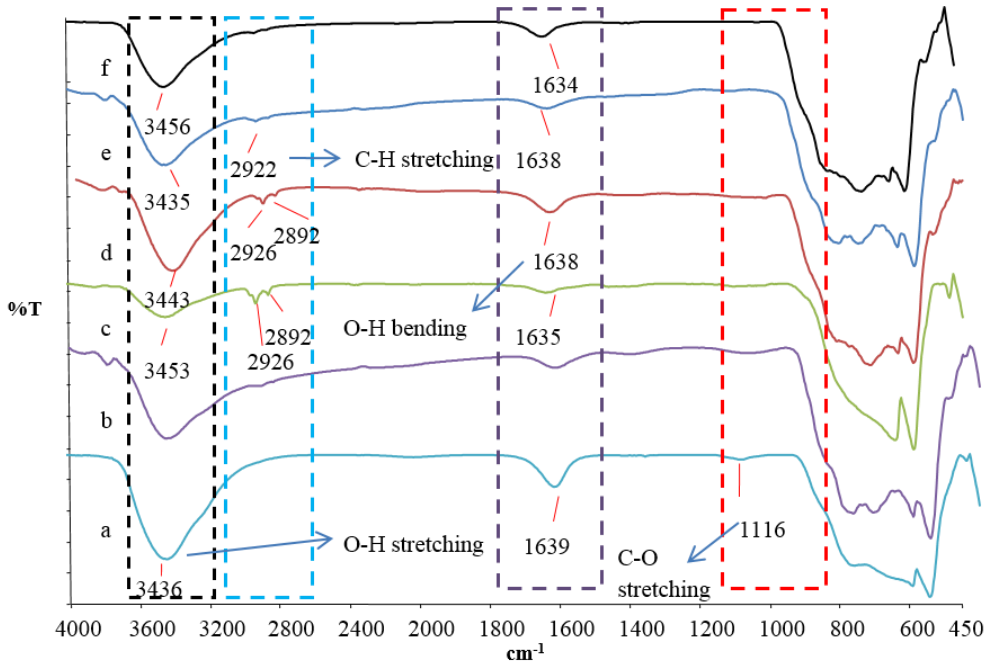

Figure 3. FTIR spectra of Sm/Mn/Ru (60:35:5)/Al_2O_3 catalyst surface at (a) 100ºC, (b) 200ºC, (c) 250ºC, (d) 300ºC, (e) 350ºC, and (f) 400ºC reaction temperature

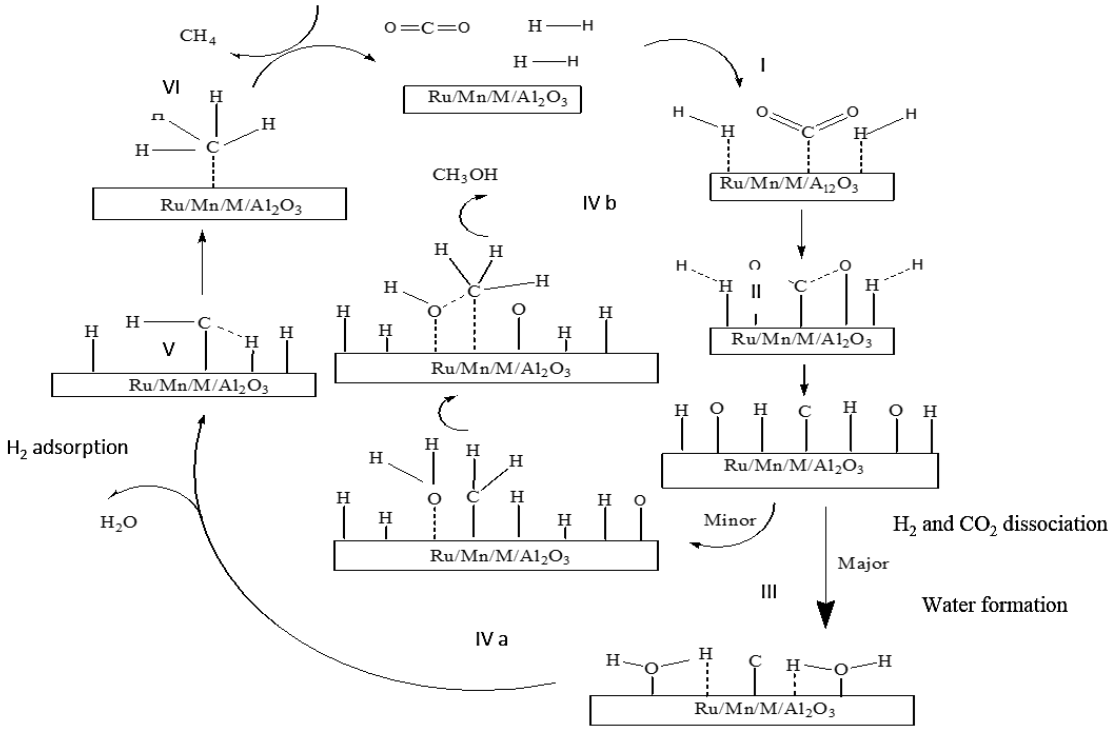

Figure 4. Proposed mechanism of M/Mn/Ru (60:35:5)/Al_2O_3, (M= Sm) calcined for 5 hours at 1000 ºC

Conclusion

This evaluation revealed compliance with the Langmuir Hinselwood mechanism, where CO_2 gas is first adsorbed, and then H_2-reactive gas is adsorbed on the catalyst surface. Based on the mechanistic approach, CH_4 was formed at temperature of 250 ºC and CO_2 peak was gradually decrease when the reaction temperature increased. The CO_2 conversion at 400ºC is 100%, with CH_4 formation of 69%. The others percent conversion was side products which are water and methanol, as detected by HPLC.

Abstract

Downstream processing of trypsin synthesis, which includes purification, is a major issue due to high complexity of the bio-suspension itself and the stress sensitivity of the desired target molecules. Therefore, an affinity membrane was fabricated in this study using polysulfone polymers and modified by chitosan to enhance biofouling resistance. To determine the optimum conditions for maximum trypsin adsorption and desorption during affinity ultrafiltration process, elution buffers and pH were investigated using various types of displacing salts (potassium chloride, KCl; sodium chloride, NaCl; magnesium chloride, $MgCl_2$; calcium chloride, $CaCl_2$) and elution pH (pH 4, 5, 6, 7, 8). The result showed that the buffer using KCl was identified as the best displacing salt as it recovered the highest trypsin of 78.84%, with a purification fold of 1.31. Trypsin recovery increased to 92% and 1.20 purification fold when the experiments were at pH 8. These buffers dissolved the interference chemical bonds comprising trypsin-trypsin inhibitor interactions and restore target trypsin to the permeate stream in an active state for maximum trypsin recovery. The information provided in this study represents a possible future avenue for developing an affinity membrane system.

Abstrak

Pemprosesan hiliran sintesis tripsin, yang termasuk penulinan, adalah isu utama kerana kerumitan bio-pengampaian itu sendiri dan kepekaan tekanan molekul sasaran yang dikehendaki. Oleh itu, membran afiniti telah direka dalam kajian ini menggunakan polimer polisulfon dan diubahsuai oleh kitosan untuk meningkatkan rintangan bio-kotoran. Untuk menentukan keadaan optimum untuk penjerapan tripsin maksimum dan penyahjerapan semasa proses ultrafiltrasi perkaitan, penimbal pengeluat dan pH telah

disiasat menggunakan pelbagai jenis garam pengganti (kalium klorida, KCl; natrium klorida, NaCl; magnesium klorida, $MgCl_2$; kalsium klorida, $CaCl_2$) dan pH pengeluatan (pH 4, 5, 6, 7, 8). Hasilnya menunjukkan bahawa penimbal menggunakan KCl dikenal pasti sebagai garam pengganti terbaik kerana ia perolehan tripsin tertinggi sebanyak 78.84%, dengan lipatan penulenan 1.31. Perolehan tripsin meningkat kepada 92% dan 1.20 lipatan penulenan apabila eksperimen berada di pH 8. Penimbal ini telah melarutkan ikatan kimia yang menganggu yang terdiri daripada interaksi perencat tripsin-tripsin dan memulihkan tripsin sasaran ke aliran menelap dalam keadaan aktif untuk perolehan maksimum tripsin. Maklumat yang disediakan dalam kajian ini mewakili jalan masa depan yang mungkin untuk membangunkan sistem membran afiniti.

Introduction

Affinity ultrafiltration membranes have unfolded a new avenue in membrane technology due to the ability of membranes to bind specifically to target molecules/proteins via a specific interaction. This type of membrane results from a combination of two separation processes, namely affinity adsorption and ultrafiltration. It comprises the use of affinity ligands attached to the crosslinked or activated membrane matrix covalently. Ligands are bound to the target enzyme with different adsorption mechanisms and degrees of specificity, depending on the type of ligand used. This system conducts affinity adsorption and ultrafiltration in stages in ultrafiltration modules or separate systems [1].

The recent literature on the development of affinity chromatographic membranes describes highly diversity for proteins and enzyme purification in particular [2]. In fact, several recent studies have reported the rapid development of affinity membranes for protein recovery which increased gradually due to the need of this protocol to obtain high protein quality [3-6]. To meet the growing market demand for this enzyme, commercial production should focus either on innovating alternative procedures or modifying existing methods with slight improvement [7]. Based on the studies described above, affinity membrane chromatography has great potential to isolate a single protein fraction from protein mixture.

The target enzymes can be dissociated from the enzyme-ligand complex and passed through the affinity membranes by applying a suitable elution buffer on the system at the same operating pressure. Various buffers and conditions can be utilised for these studies; affinity-bound enzyme elution and elution using high-concentration salt solution are widely used [8]. This elution buffer breaks the connections between the target enzyme and ligand, lowers its binding affinity and forces the desired enzyme into the permeate stream.

Trypsin is one of the most well-known proteases and consists of serine endopeptidases [9]. Trypsin has a wide range of applications due to its strong proteolytic function and specificity of action, including its use as a critical intermediary in the manufacture of insulin, cell culture applications, research and production of recombinant proteins for clinical use, debriding agent in the wound care market, and oral treatment for inflammatory edema, hematoma and pain associated with diabetes [10, 11, 12].

In most cases, elution buffers were selected at random, most likely due to convenience or prior experience, although the final aim was to achieve a functional eluate [13]. However, several investigations have shown that elution conditions can substantially impact both the yield and specific activity of eluted products [14, 15]. The selected displacing salts are ensured to be soluble, non-denaturated, stable, transparent, ionic at relevant pH, pH stable, non-hazourdous and available [16].

The main benefit of ultrafiltration techniques over conventional separation methods such as chromatography, electrophoresis and conventional affinity separation is the high product throughput. Furthermore, ultrafiltration technologies are considerably easier to scale up, simple to clean and run, and relatively compact in design [17]. Although the use

of ultrafiltration is widespread, its potential in protein fractionation application has not been fully realised in the biotechnology industry due to lack of knowledge on the separation mechanism concepts and membrane fouling [18]. As a result, this study was conducted to determine the most efficient approach to increase the use of unltrafiltration in the biotechnology industry.

This study provides fundamental knowledge in designing a highly specific affinity ultrafiltration membrane for trypsin purification under proper pressure to selectively eliminate target enzyme-ligand complex as a retentate and simultaneously, other unbound impurities flow through membrane pores. Selectivity of polysulfone as a membrane material was due to its strong and thermally stable characteristics. The integration of chitosan with polysulfone was hypothesized to produce a hydrophilic segment on the membrane surface which can be an ideal method to combine both the advantages of hydrophilic and hydrophobic membranes. The use of ligands to support materials using activator (glutaraldehyde) can enhance the performance of affinity membranes. It is crucial to determine the best conditions for the trypsin recovery protocol; therefore, this study was conducted to identify the effects of displacing salt and pH of the buffer solution in separation process. In conclusion, with the integration of affinity chromatographic and high-performance ultrafiltration concept, it is believed that affinity ultrafiltration membrane will become common in the near future especially for protein and enzyme recovery.

Materials and Methods

Chemicals and raw materials

Membranes were produced using a ternary casting solution including polysulfone (PSf) as the polymer, N-methyl-2-pyrrolidone (NMP) as the solvent (provided by Merck), and water (H_2O) as the non-solvent. In this study, N-Methyl-2-Pyrrolidone (NMP) from MERCK Schuchard OHG, Germany, was used as a solvent for PES. As a coagulation medium, distilled water was employed. Fluka trypsin (Mw = 25 000 g/mol) was used as the target enzyme in this study. Trypsin inhibitor type III (ovomucoid) and trypsin (Mw = 25 000 Dalton) purchased from Sigma Aldrich were used for affinity ligand and adsorption study, respectively. Chitosan particle (Sigma Aldrich) was used for hydrophilic modification of asymmetric PSF membrane. Glutraraldehyde (Sigma Aldrich) was used for membrane activation to develop the affinity membranes. N-α-benzoly-L-arginine p-nitroanilide (BAPNA) was used for enzyme activity. Sodium acetate acetic acid buffer (solution), acetic acid solution, potassium chloride (KCl), sodium chloride (NaCl), calcium chloride ($CaCl_2$), and magnesium chloride ($MgCl_2$) were purchased from Sigma Chemical Co. (St Louis, Missouri) for affinity ultrafiltration experiments. All materials utilised in this study were of analytical grade.

Preparation of affinity membrane

For PSf membrane preparation, the weight of the binary dope was determined at 70 g. Then, 85 (wt.%) NMP was heated at 60 ˚C in a reactor flask for 10 minutes. The solvent was then gently infused with 15 (wt.%) polymer (PSf) until all polymers were dissolved and stirred at 300 to 400 rpm for about 8 hours at a constant temperature of 600 ˚C using a WiseStirTM Digital Overhead Stirrer from DAIHAN Scientific, Co., Ltd. To eliminate trapped air bubbles, the resulting polymer solution was immersed in an ultrasonic bath for about 3 hours. The prepared binary dope was then titrated with water as a non-solvent to produce the ternary dope and the stirrer was set to stir at a moderate speed. The presence of a drop of water that changed the colour of the binary dope solution indicated that the cloud point was achieved, and the volume of water titrated was recorded. The polymer solvent mixture was mixed again until all the components utilised were completely dissolved. Finally, the finished dope solution was put into a Schott bottle.

The affinity membrane (CH/PSf-60) was prepared with simple dry/wet phase inversion technique using an electrically casting machine at shear rate of 200 s^{-1} and then immersed directly into a coagulation bath for 24 hours. For surface modification, a native PSf membrane was immersed into the chitosan solution (0.1 wt.% in acetic acid with pH 5) for 60 minutes to deposit chitosan particles onto the membrane surface and dried in ambient air. The dried membrane was

then neutralized with NaOH solution (0.1 M in 50% of water-ethanol mixture) for 30 minutes to ensure that all chitosan acetate was converted to chitosan. To prevent osmotic cracking and to remove the remaining NaOH, the membrane was rinsed with 50% v ethanol solution for 3 times, and followed by washing with distilled water and stored in distilled water before use.

The membrane support (CH/PSf-60) was cut to an area of 14.6 cm^2 and incubated in an incubation shaker for 150 min in a reacting solution containing different amounts of 25 vol% glutaraldehyde (GTA) aqueous solution in 0.1 M sodium chloride and 0.1 M sodium acetate-acetic acid buffer (pH 7.4). From the reaction, excess glutaraldehyde was removed from the membrane by washing three times with 2 M acetic acid. The trypsin inhibitor was immobilized onto the active membrane for 180 minutes, and the adsorption capacity was measured every 30 minutes. The CH/PSf-60 membrane was referred to as an affinity membrane.

Affinity ultrafiltration experiment

A dead-end cell with a processing volume of 300 mL, and an effective permeation membrane area of 14.6 cm^2 was used for affinity ultrafiltration. This solution was drawn across the membrane using compressed nitrogen at a pressure of 5 bar. A washing step with 0.1 M phosphate buffer was used to eliminate unbound trypsin and contaminants. For the elution step, the bound trypsin was subsequently desorbed from the affinity membrane using 0.01 M Tris-HCl buffer with various displacing salts, namely KCl, NaCl, $CaCl_2$ and $MgCl_2$, and pH (pH 4, 5, 6, 7, 8). When the enzymes were firmly attached to the affinity membrane, it may be beneficial to pause the flow for 15 min after adding the eluent before proceeding with the elution. This phase allows additional time for dissociation to occur, which assists in the recovery of bound trypsin. The total protein content of the eluate was determined using the Bradford assay and trypsin activity.

Determination of total protein and enzyme activity

Protein concentration was calculated using Bradford method with Bovine Serum Albumin (BSA) as the standard. Using a UV-Vis spectrophotometer, absorbance and concentrations were determined by dissolving each 100 µL sample in 5 mL of Bradford reagent. The experiment was repeated with trypsin as the sample. Trypsin activity was assessed with minor changes [19] [12]. As a chromogenic substrate, BAPNA was utilised. Analiquot of the enzyme solution of 200 µL was added to the pre-incubated reaction mixture containing 1000 µL of BAPNA solution (dimethyl sulfoxide) and 200 µL of 0.05 M Tris-HCl. The mixture was incubated at 40°C for 10 min. The enzymatic process was halted by adding 200 µL of 30% (v/v) acetic acid and then centrifuged at 8000x g for 3 min at room temperature. Due to the production of p-nitroaniline, absorbance was used to assess trypsin activity at 410 nm using Equation 1.

$$q = \frac{(C_0 - C)\,V}{A} \quad (1)$$

where q is the amount of trypsin adsorbed onto the membrane ($mg.ml^{-1}$), C_0 and C are the total protein in the initial solution and the aqueous phase after adsorption, respectively ($mg.ml^{-1}$), V is the volume of the aqueous solution (ml), and A is the area of the membranes in the adsorption medium (cm^2).

Results and Discussion

Characteristics of affinity membrane

As seen in Figure 1(a), affinity membrane generally employs two separation concepts, namely affinity adsorption and ultrafiltration. It comprises the use of affinity ligands attached to the crosslinked or activated membrane matrix covalently. Depending on the ligand utilised, the ligands are attached to the target enzyme through different adsorption methods and specificity. Then, for ultrafiltration separation, a buffer media with sufficient pressure selectively excludes the target enzyme-ligand complex as a retentate while allowing other unbound contaminants to flow through the membrane pores. The target enzymes can be separated from the enzyme-ligand combination and processed through an amplification process. By introducing an appropriate elution buffer to the system at the same operating pressure, the target enzymes can be dissociated from the enzyme-ligand complex and passed through the affinity membranes. Figure 1(b) shows the schematic diagram of the developed affinity

membrane consisting of 15% PSf membrane. The PSf membrane underwent surface modification with chitosan to produce membrane hydrophilicity followed by an activation process using glutaraldehyde and immobilised using trypsin inhibitor as ligand.

The separation method of the affinity membrane is based on the affinity characteristics of the desired solute molecules. The selection of suitable membrane is one of the important elements influencing the separation performance of affinity ultrafiltration membrane. Large pore sizes and high porosity membrane matrix are necessary to avoid fouling while also allowing larger pollutants to flow through the membrane during the washing phase. The hydrophilic properties of the CH/PSf membrane enhances its ability to immobilise ligands and transmit trypsin during affinity ultrafiltration. Figure 2 depicts the surface morphology of native PSf 15 and affinity membrane after trypsin inhibitor was effectively adsorbed onto the CH/PSf membrane by glutaraldehyde activation.

Membrane activation with glutaraldehyde results in crosslinking, stabilising the membrane structure during ligand immobilisation [20]. As a result, this affinity membrane has rough and porous surface structure which improves the surface area, minimises mass transfer resistance and facilitates enzyme molecule diffusion. This results in a low diffusional resistance situation in the membrane, which contradicts to the packed bed affinity column, in which significant pressure drops constantly occur [21].

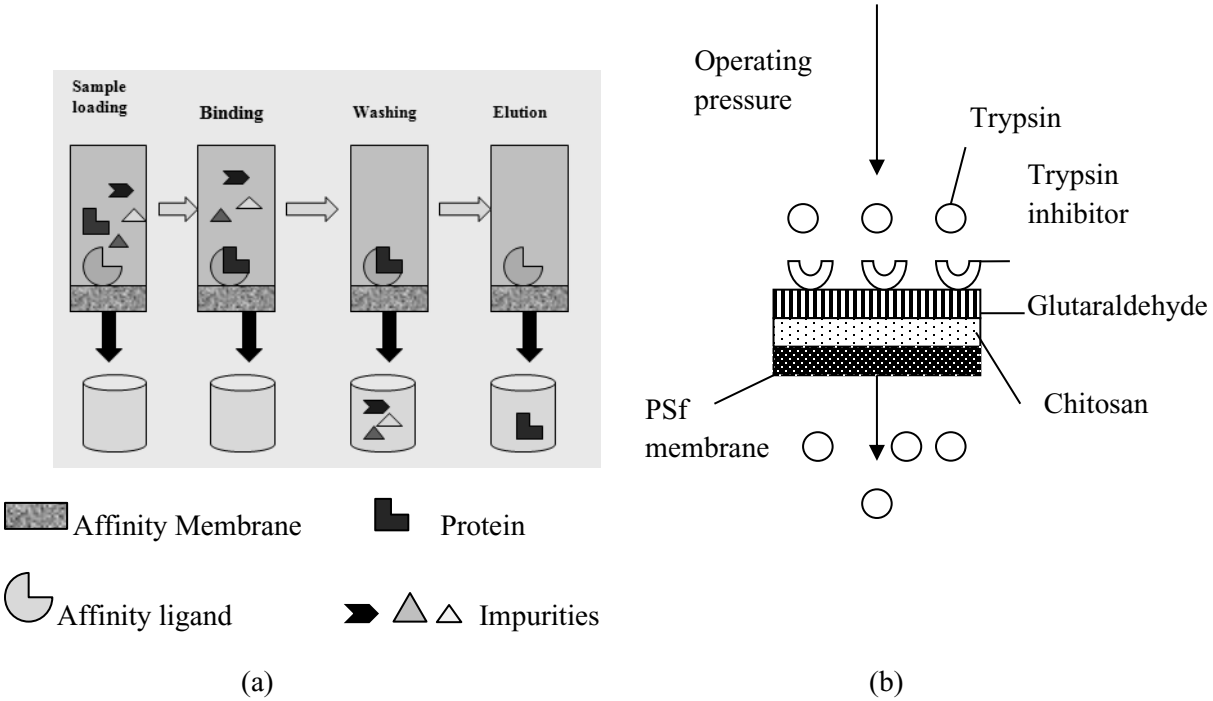

Figure 1. Graphical image of (a) protein purification protocols using affinity chromatographic membrane developed, and (b) synthesis of affinity membrane

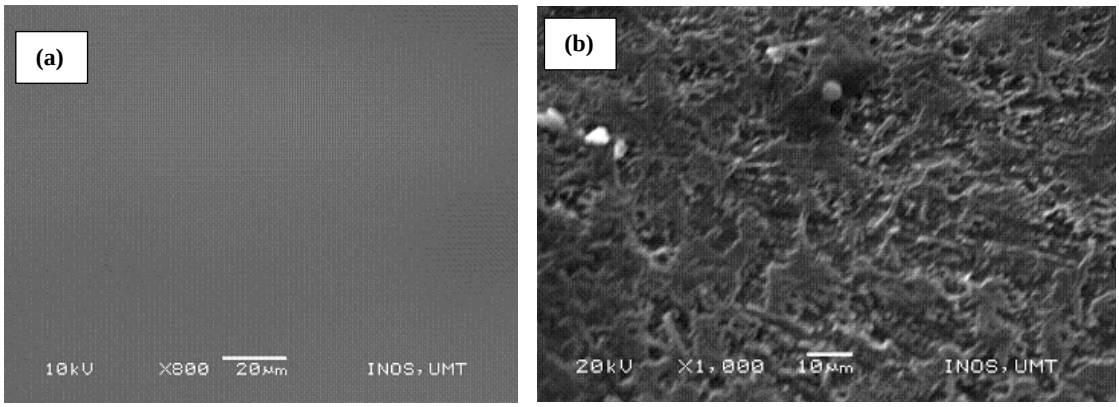

Figure 2. Surface morphology of (a) native membrane (PSf 15), and (b) affinity membrane (CH/PSf-60)

Figure 3 depicts the native membrane (PSf 15) and the affinity membrane by ATR-FTIR. The spectra represented the group of main compounds associated with the native membrane (PSf 15). After incorporating with chitosan, the band stretching was less intense due to the thin layer formation on the PSf 15 membrane. This band revealed the presence of O-H and N-H_2 groups in chitosan in affinity membrane (CH/PSf-60) ranging between 3200 and 3600 cm^{-1} [22,23]. The O–H stretching vibration peak (v=3200 to 3600 cm^{-1}) was reduced by crosslinking CH/PSf with glutaraldehyde (Figure 2 (b)). The wavelength at 2873 cm^{-1} exhibited C-H stretching due to aldehyde as well as duplet adsorption with peaks ascribed to the alkyl chain [24]. The band at 1657 cm^{-1} could be attributed to >C=O stretching (amide I) of the N-acetyl group in chitosan particles and a wavelength of 1722 cm^{-1} may be attributed to the presence of ethylenic chain [7].

The appearance of aldehyde peaks in the affinity membrane spectrum was due to the incomplete reactivity of glutaraldehyde with the chitosan OH groups during crosslinking network formation. As a bifunctional crosslinking, one aldehyde group may form a hemiacetal structure with hydroxyl groups of CH/PSf polymer chain while the other is unreacted associated with a certain conformation. The addition of a small amount of GTA may increase crosslinking chain with the formation of intermolecular covalent bonds between ligands and membrane (CH/PSf-60) via the availability of free amine group in affinity membrane (CH/PSf-60) [25]. Moreover, as a bi-functional reactive agent capable of reacting with the surface –OH groups of membrane and the amines groups of enzyme inhibitor, GTA could efficiently alleviate strong interaction between ligand and matrix apart from its ability to sustain ligand immobilization to be more resistant to pH changes and ionic strength.

Effect of displacing salt in elution buffer

Other impurities and unbound molecules of the desired enzyme were removed using appropriate buffer solution during the washing stage. Although affinity chromatography membrane aims to target enzymes from their affinity ligands, an equally important aspect of this purification technique is the ability to release and recover isolated targets in active form.

A list of buffers and conditions can be applied for this recovery process, or the elution of affinity-bound enzymes using high-concentration salt solution [8] is commonly used. This elution buffer disrupts the interactions between the target enzyme and the ligand to reduce the binding affinity between them and force the desired enzyme in the permeate stream. In most cases, elution buffer options are targeted to obtain a functional eluate [26]. However, a number of studies

have demonstrated that elution conditions can significantly influence both the yield and specific activity of the eluted products [27].

In this study, four displacing salts (KCl, NaCl, $MgCl_2$ and $CaCl_2$) with 0.05 M ionic strength were added to the elution buffer to determine the ionic species that could enhance the dissociation of enzyme-ligand complex and trypsin transmission through affinity membrane. The results presented in Figures 4 and 5 exhibited a series of trypsin recovery in increasing order: $CaCl_2$ < NaCl < $MgCl_2$ < KCl. The main component in the adsorption mechanism is the affinity of positively charged trypsin and negatively charged sites on the membrane surface. The ionic bonding of this enzyme-ligand interaction can be affected by changing the physicochemical environment controlled by the displacing salts.

The pH 7 condition provided a favorable environment for trypsin adsorption with the help of electrostatic interaction that has dominated the adsorption. Trypsin was best adsorbed onto the affinity membrane with low positive charge as the electrostatic interactions between enzyme molecules decreased as the membrane increased. Moreover, in this favourable physicochemical environment, the amine groups of the trypsin molecules can undergo protonation to NH_3^+ [3], and these protonated amino groups on the surface of trypsin enhanced the electrostatic interaction between trypsin and affinity membrane. This observation is in agreement with the previous findings who found that the maximum adsorptive capacity of trypsin occureds around pH 7 [28].

The presence of displacing salts influenced the ionic strength of the elution buffer solution when KCl-HCl was added and then disrupted the electrostatic interaction of enzyme-affinity ligands, thus ionic exchange process occurred. K^+ cation is more electropositive, then the enzyme-ligand complex was dissociated and permeated through the membrane. Therefore, the trypsin recovery by KCl-HCl was highest at 78.8% with 1.31 purification fold. The properties of high chaotropic effect and salting of K^+ may destabilize the bonding between trypsin and trypsin inhibitor, leading to enhanced trypsin transmission [16].

The findings were attributed to different elution strengths of displacing ions during competition with trypsin in the affinity system. The trypsin recovery using the displacing salts such as NaCl-HCl, $MgCl_2$ and $CaCl_2$ were 65.0%, 69.3% and 40.6%, respectively. Compared to Ca^{2+}, Mg^{2+} with higher charge density is a better charge acceptor, thus it is expected to bind more tightly to the protein binding sites [29]. From the experimental observations, the addition of $CaCl_2$ converted the buffer solution to a cloudy solution, resulting in lower total protein readings and trypsin activity. This finding may be explained due to the formation of metal-enzyme complexes interaction. Calcium is a cosmotropic ion that can promote hydrophobic interaction with trypsin and may retain this enzyme on the membrane surface after elution [30]. Moreover, trypsin was assumed to have two binding sites, and the primary site has high affinity for calcium ions. This interaction has considerably stabilized the enzyme against denaturation [31] and was achieved by a conformational shift in the trypsin molecule, resulting in a more compact structure [32]. This change broke the bonding between trypsin and its ligand, and reduced trypsin transmission during the elution process.

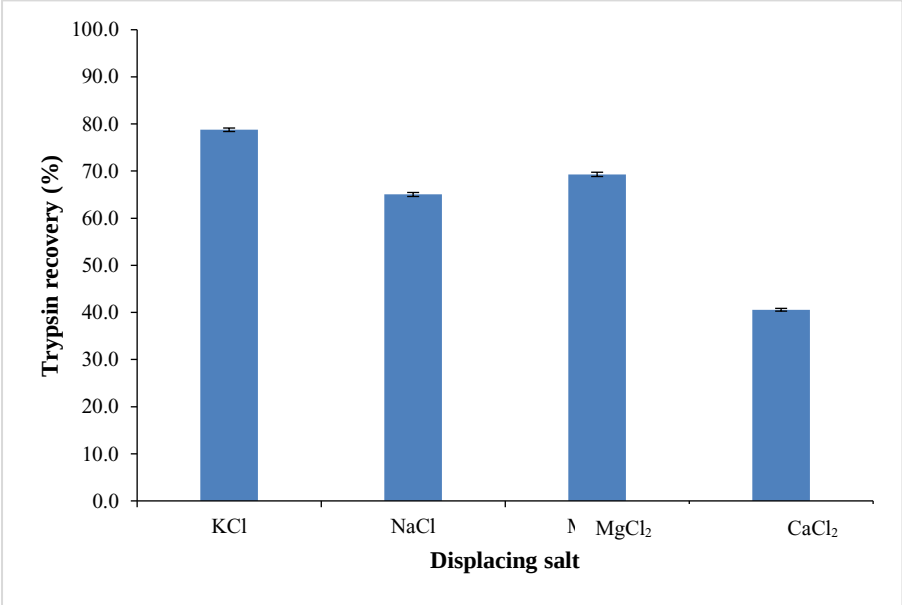

Figure 5. Effect of displacing salts on trypsin recovery activity and data are presented as mean ± standard error (SE), $n = 3$

Effect of elution pH

The adsorption behaviour in this study occurred mostly due to electrostatic interaction, and it is important to consider electrostatic interaction between trypsin molecules as well as between trypsin and membranes. pH can induce alteration in spatial structure of the

trypsin to affect the affinity of trypsin [33]. A small change in the pH of the solution can alter the electrical charge on proteins as well as membrane due to ionization or deionization of various acidic/basic groups on protein and membrane surface, which can cause either repulsive or attractive interactions [34]. The protein activity can be observed in Figures 6 and 7. The ionization of the charged groups on the ligand and/or the bound trypsin alters as the pH changes. This transition may directly influence the binding sites, reduce their affinity, or cause indirect changes in affinity through conformational changes.

Since the optimum adsorption of trypsin occurred at pH7, the trypsin recovery at this condition was 73.6%. This could be due to the fact that the electrostatic attraction of enzyme-ligand was strong and retained on the affinity membrane. Based on the optimum adsorption at pH 7, the pH of the elution buffer should be higher to break down the bonding of the enzyme and its ligand. Using an elution buffer at pH8, trypsin permeated into the membrane and resulted in about 92.0% recovery and 1.2 purification fold. An increase in the pH of elution buffer (pH 8) increased the dissociation of the sulfonic functional group of membranes and created a negative charge of the membrane. Therefore, electrostatic repulsion between enzyme-ligand was disrupted and thus trypsin dissociation occurred. An increase in the surrounding negative charge will cause the trypsin-ligand instability on the affinity membrane, increase the electrostatic repulsion and lead to high protein (trypsin) in eluent [35]. High OH^- anion will trigger enzyme aggregation as the net charge of the enzyme surface becomes zero. Therefore, there is no electrostatic repulsive force between trypsin-ligand [36]. The reduction of enzyme adsorption under alkaline pH could be attributed to the electrostatic repulsion between enzyme-membranes [37] and is responsible for lower adsorption, where thermodynamic entropy difference is the only force inducing the adsorption [38].

At lower pHs (6, 5 and 4), the decrease in protein activity due to trypsin recovery was 66.7%, 55.6%, and 50%, respectively. However, at extreme pH (acidic), the protein will be denatured [39]. Therefore, during the measurement of trypsin activity, the conformational changes of the trypsin molecules (denatured trypsin) at acidic pH affect the proper binding of the enzyme to the substrate, resulting in loss of the activity of the recovered trypsin in the permeate [40].

Conclusion

To conclude, this study suggests that the CH/PSf-60 membrane is the most appropriate membrane for trypsin separation. Furthermore, the modification of membrane with chitosan solution is a potential technique to mitigate fouling and improvemembrane lifespan as an excellent matrix material for developing an affinity membrane for trypsin separation and purification. Although the affinity membrane was well prepared, the physicochemical environment of the enzyme solution was also considered to obtain the greatest adsorption capacity. KCl as the displacing salt in the elution buffer solution was the optimum condition for trypsin recovery (78.8%). The recovery increased to 92% by setting the elution buffer pH at pH8. This study proved that the condition of elution buffer significantly influenced the degree of dissociation between the target enzyme and the affinity ligand, and enhanced the separation and purification performance. Thus, the fundamental chemical properties involved in the adsorption and desorption of proteins should be prioritized to develop affinity membrane protocols. The knowledge proposed in this study could be a good pathway for developing affinity membrane systems in the future.

Abstract

The biomimetic method, which relies on natural resources such as plant extracts, bacteria, and fungi, offers an alternative for synthesizing silver nanoparticles (AgNPs). The use of biomimetic method for synthesizing AgNPs have various benefits including cost effectiveness, low toxicity, and suitabiity for biomedical application. This study synthesizes plant mediated nanoparticle using *Eleusine indica* to determine its antibacterial activity. *Eleusine indica* methanol extract is treated with 1 mM of silver nitrate at room temperature (25-27 °C) for 24 hours. The resulting product is characterized using UV-Vis spectroscopy and transmission electron microscope (TEM). UV-Vis absorption spectroscopy displays a strong resonance centered on the surface of AgNPs at approximately 413 nm. Physical appearance of AgNPs as characterized by transmission electron microscopy (TEM) showed formation of AgNPs with average particle size of 20 nm. In the antibacterial activity of the synthesized AgNPs, minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) assays are performed. The plant mediated AgNPs has predicted bacteriocidal activity according to the ratio of MBC to MIC values against selected Gram-positive and Gram-negative bacteria. In this study, plant mediated AgNPs has been successfully synthesized by reduction of silver nitrate with *Eleusine indica* leaves methanol extract.

Abstrak

Kaedah biomimetik yang bergantung kepada sumber alam seperti ekstrak tumbuhan, bakteria dan kulat, menawarkan alternatif dalam sintesis nanopartikel perak (AgNPs). Penggunaan kaedah biomimetik dalam sintesis AgNPs mempunyai pelbagai kelebihan termasuk keberkesanan kos, ketoksikan yang rendah, dan kesesuaian dalam kegunaan biomedik. Objektif kajian ini adalah untuk mensintesis nanopartikel perak diperantara tumbuhan menggunakan *Eleusine indica* dan menentukan aktiviti antibakteria. Ekstrak metanol *Eleusine indica* telah dirawat dengan 1 mM larutan perak nitrat pada suhu bilik (25 – 27 °C) selama 24 jam. Sampel telah

dicirikan menggunakan spektroskopi UV-Vis dan mikroskopi transmisi elektron (TEM). Spektroskopi penyerapan UV-Vis menunjukkan resonans berpusat yang kuat atas permukaan AgNPs pada kira-kira 413 nm. Rupabentuk fizikal AgNPs yang dicirikan melalui mikroskopi transmisi elektron (TEM) menunjukkan pembentukan AgNP dengan purata saiz partikel 20 nm. Aktiviti antibakteria nanopartikel perak perantaraan-tumbuhan yang disintesis telah diasai melalui penentuan kepekatan perencatan minimum (MIC) dan kepekatan bakterisidal minimum (MBC). Gabungan nanopartikel perak perantaraan-tumbuhan diramal mempunyai aktiviti bacteriosidal berdasarkan nisbah nilai MBC kepada MIC terhadap bakteria Gram positif dan Gram negatif bakteria. Dalam kajian ini, AgNPs perantaraan-tumbuhan telah berjaya disintesis melalui penurunan perak nitrat dengan ekstrak metanol daun *Eleusine indica*.

Kata kunci: nanopartikel perak perantaraan-tumbuhan, *Eleusine indica*, analisa UV-Vis, mikroskopi transmisi elektron, aktiviti antibakteria

Introduction

Nanotechnology is developing - rapidly in the growing field with the applications of science and technology for the purpose of making new nanoscale materials [1]. Communication, electronics, chemistry, physics, robotics, biology, and medicine can benefit from nanotechnology research [2]. Different forms of nanoparticles (NPs) such as copper, zinc, titanium, magnesium, gold, alginate and silver have emerged, but silver NPs have proven to be the most effective since they have strong antimicrobial efficiency against bacteria, viruses and other eukaryotic microorganisms [1]

Conventional methods for synthesizing AgNPs, such as physical and chemical procedures, involved the usage of heavy equipment, substantial amounts of energy consumption, highly toxic and hazardous chemical compounds that can cause biological hazards and therefore, they are not environmentally sustainable and they are unsafe [3]. As a result, biomimetic nanoparticle syntheses or plant-mediated silver nanoparticles are often used because they are simple, cost-effective, environmentally friendly, and they are easily reproduced [4]. AgNPs synthesized in a biomimetic method - useful in a variety of fields, including optoelectronic devices [5], catalytic activities [6], and the food packaging industry [7]. AgNPs is has also be regarded as the agent of wound-healing, antioxidant, antimicrobial, antiviral, and anticancer [8].

Synthesis methods using either plant extract or fruit extract have several advantages over other biological approaches. This includes no requirement in cell culture that can take more time to produce which can scale up the synthesis process [9]. Plant extracts contain a wide range of metabolites that can act as capping and stabilizing agents and thus avoids the need to add these agents from other sources [3]. There are other studies whereby plant-mediated AgNPs have been investigated for the antibacterial properties such as using *Rhazya stricta* [10] and *Azhadirachta indica* [11] to synthesis AgNPs. This study aims to add the possibility of *Eleusine indica* as a plant candidate to synthesize AgNPs. *Eleusine indica* or locally known as sambau has been known to possess antioxidant, antibacterial and antiviral activities among others [12,13]. Thus, it is a good potential for producing AgNPs against bacterial candidates known to be pathogenic. The strategy involves the reduction of silver nitrate and the methanol extract of *Eleusine indica* which can be used as a reductant as well as a stabilizer. The synthesized AgNPs is evaluated for its physical characteristics and antibacterial activity against four pathogenic microorganisms.

In this study, an extract of *Eleusine Indica* is used in the synthesis of plant-mediated AgNPs, and the relation between AgNPs and the extract's metabolites, and evaluate its antibacterial properties The characterization of synthesized AgNPs is analyzed with the use of UV-Vis spectroscopy and transmission electron microscopy (TEM).

Materials and Methods

All the reagents purchased were of laboratory grade and used as received. Silver nitrate ($AgNO_3$) were purchased from R&M Chemicals, US. Methanol was purchased

from Sigma Aldrich, Germany. (3-[4,5-dimethylthiazol-2-yl]-2,5 diphenyl tetrazolium bromide) (MTT), Mueller Hinton agar and nutrient broth was obtained from Universiti Kebangsaan Malaysia. The fresh leaves of *Eleusine indica* were collected in Kuala Pilah, Negeri Sembilan. Authentication of this species was done by Forest Research Institute Malaysia (FRIM) where voucher specimen (FRI-51486) was deposited. Deionized water was used throughout the experiment.

Extractions of *Eleusine indica*

About 250 g of ground dried *Eleusine indica* leaves was soaked in 2500 mL of methanol for 72 hours at room temperature by using maceration technique [14]. The sample was filtered and concentrated by using rotary evaporator. The extract was placed in a fume hood until almost dried to obtain *Eleusine indica* methanol extract and kept in a vial for further analysis.

Biomimetic synthesis and characterization of silver nanoparticles

The biomimetic method was followed by Lee and Jun [15] with some modification. About 10 mL of *Eleusine indica* methanol extract was added drop by drop into 30 mL of 1 mM silver nitrate solution and was allowed to be reacted at room temperature for 24 hours at 25-27 ºC. The appearance of yellowish-brown color of the solution indicates the formation of silver nanoparticles [16]. The formation of plant-mediated AgNPs was analyzed using UV-Vis spectroscopy and TEM.

Characterization of plant-mediated silver nanoparticles

Physicochemical properties of the synthesized plant-mediated silver nanoparticles were characterized using UV-Vis spectra and TEM analysis. The UV-Vis spectra analysis was conducted using a UV 2450 Shimadzu double-beam spectrophotometer, operated at a resolution of 2 nm in the range from 300 to 500 nm. The formation of AgNPs was confirmed by transmission electron microscopy (TEM). TEM analysis of AgNPs was performed using a Philips CM12 instrument operated at an accelerating voltage at 80 kV. The size distribution of the AgNPs was calculated from the TEM images by measuring the diameter in nm of approximately 50 nanoparticles.

Evaluation of antibacterial activity

The antibacterial potential of the synthesized plant-mediated silver nanoparticles was determined using minimum inhibitory concentration (MIC) and Minimum Bactericidal Concentration (MBC) assays [17]. In the assay, four bacteria were tested with two Gram-positive bacteria (*Staphylococcus aureus*, *Bacillus subtilis*) and another two Gram-negative bacteria (*Escherichia coli*, *Enterobacter aerogenes*). MIC assay was performed in triplicate in a 96-well microtiter plate. Serial double dilutions of plant-mediated silver nanoparticles (AgNPs) varying from 100% to 1.562 % in nutrient broth were prepared in the MIC assay. Each dilution (100 µL) was dispensed into the wells and then 100 µL of the bacterial suspension in nutrient broth was incubated at 37ºC for 24 hours. After 24 hours, 10 µL of 0.2 mg/mL (MTT) solution was added into each well and incubated for another 2 hours. The solution color change from pale yellow to red/purple, which indicated biologically active bacteria [18]. MBC is the determination of the lowest concentration without colony growth on the agar plates. This was determined by plating 10 µL from each well that showed no growth on a Mueller Hinton agar plate. Plates was then incubated for further 24 hours at 37°C. Lowest concentration that shows no colony growth was determined as MBC.

Results and Discussion

Extractions of Eleusine indica

Dried ground Eleusine indica leaves was used in this study in order to enhance the surface area and optimize the extraction process (Figure 1). The percentage yield of the crude extract was calculated and presented in Table 1.

Methanol extraction resulted in moderate weight and percentage yield of Eleusine indica. Methanol is a polar solvent that can extract most of the key phytochemical compounds [19]. Compared with aqueous solvent, methanol solvent has less polarity which gives more efficiency in term of extraction because of its capability in degradation of cell wall. Thus, methanol provides excellent capability in extraction of secondary metabolites such as phenolics, glycosides, tannins, flavonoids, saponins, steroids and alkaloids [20, 21].

These secondary metabolites have polyhydroxy group that are suitable in reducing metal ions to nanoparticles [22]. According to Iberahim et al. [23], Eleusine indica methanol extract have several groups of metabolites including phenolics, glycosides, flavonoids and terpenoids. These metabolites substantiate the selection of Eleusine indica in this study to potentially act as reducing and stabilizing agent in the synthesis of AgNPs.

Table 1. Percentage yield of *Eleusine indica* crude extract

Type of Crude Extract	Weight of Sample (g)	Weight of Crude (g)	Percentage of Crude Extract (%)
Methanol	250	13.3	5.32

Biomimetic synthesis and characterization of silver nanoparticles

Formation of silver nanoparticles in this study is monitored by color change. Figure 2 shows the color changes when the Eleusine indica methanol extract was mixed with a 1 mM $AgNO_3$ solution and treated at room temperature for 24 hours. The appearance of a yellowish solution in the reaction vessel indicated the formation of AgNPs due to excitation of surface plasmon resonance in the AgNPs [24,25].

Characterization of silver nanoparticles

Ultraviolet-visible spectroscopy (UV-Vis) and transmission electron microscopy (TEM) were used to characterize the synthesized AgNPs. As illustrated in Figure 3, the surface plasmon resonance of the AgNPs is centered at approximately 413 nm, indicating the presence of AgNPs in the solution. AgNPs are known to exhibit a UV-Visible absorption maximum in the range of 400-500 nm because of surface plasmon resonance [26]. The conduction band and valence band in AgNPs are relatively close to one other, allowing the electrons to travel freely. The collective oscillation of electrons of silver nano particles in resonance with the light wave produces a surface plasmon resonance (SPR) absorption band, which is caused by these free electrons [27]. According to Kerker [28], the absorbance of AgNPs depends mainly upon size and shape. thus, this will affect the absorbance of AgNPs that obtained.

The morphology and size distribution of plant-mediated AgNPs was analyzed using TEM micrograph. The TEM image in Figure 4 (left) shows that the particles are almost spherical. The particles size histograms of the plant-mediated AgNPs (Figure 4-right) suggest that the particles diameter is within the range of 10 nm to 55 nm

with an average size of 20 nm. Silver nanoparticles, in particular, have varying scale sizes depending on the type of plant extracts used [16]. For example, the silver nanoparticles synthesized using Plumbago auriculata leaves has average size between 15 to 30 nm [29]. [30] found that AgNPs synthesized using Datura stramonium leaf extract has average size of 15 to 20 nm. Based on the theory of quantum restraint, a smaller wavelength leads to a higher energy of the wave and a smaller particle size [31].

It has been reported that Eleusine indica extract contains 12 metabolites such as hydroxycinnamic acid, naringenin (flavanones), *2(3,4-dihydroxyphenyl)-7-hydroxy-5-benzenepropanoic acid,* antraquinone, caffeic acid derivative, caffeoyl glucose, hydroxybenzoic acid derivatives methyl 2-[cyclohex-2-en-1-yl(hydroxy)methyl]-3-hydroxy-4-(2-hydroxy ethyl)-3-methyl-5-oxoprolinate (aglycone) from the flavonoid and phenolic groups [12]. Active oxygen found in phenols, flavonoids, and triterpenoic acid can donate electrons into AgNPs to reduce silver precursors [32]. This reduction of silver ions to silver nanoparticles could be possibly due to -OH groups in flavonoids such as quercetin, which can be released during the tautomeric change of flavonoids from the enol to keto type that releases reactive hydrogen atoms that are responsible for the reduction of silver nanoparticles [33]. Figures 5 show the possible mechanism of reduction of silver ions to AgNPs by naringenin (flavonone) molecule.

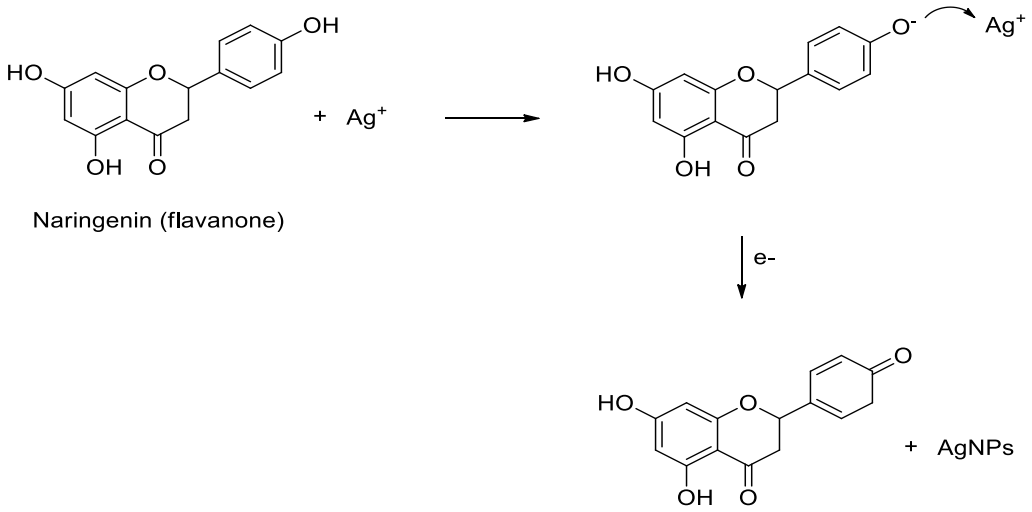

Figure 5. The proposed mechanism for the formation of plant-mediated AgNPs

Antibacterial activity of silver nanoparticles

The efficacy of AgNPs as promising antimicrobial has been experimentally tested against a wide range of medically important planktonic and sessile pathogenic microorganisms including bacteria, viruses, champignons, lichens and yeasts [34, 35]. In this study, the plant-mediated silver nanoparticles were tested against Gram-positive bacteria and Gram-negative bacteria. Table 2 shows the MIC and MBC test of synthesized silver nanoparticles against *Staphylococcus aureus*, *Bacillus subtilis*, *Escherichia coli* and *Enterobacter aerogenes*.

Based on the MIC and MBC values, the synthesized nanoparticle suggest the display of bacteriocidal potentials. The formal definition of a bactericidal agent is the ratio of MBC to MIC is ≤ 4, while a bacteriostatic agent has an MBC to MIC ratio of > 4 (CLSI). AgNPs antibacterial effects may be determined by the characteristics of certain bacterial species and the type of metabolite present in the plant [36] as well as the size

ranges and shapes of the AgNPs [27]. Theoretically, upon interaction with bacteria, nanoparticles bind with bacterial membrane which causes changes to both its physical and chemical nature. Nevertheless, the normal physiological process such as respiration and permeability of cells will be compromised [37]. Besides, the formation of various reactive nitrogen and oxygen species can be induced by nanoparticles that generates oxidative stress on DNA, and other important cell constituents which disrupt the overall functioning of bacterial cells.

Table 2. MIC and MBC test of silver nanoparticles synthesized by *Eleusine indica* against four bacteria

Bacteria	**MIC (µg/mL)**	**MBC (µg/mL)**	**MBC to MIC Ratio**
Staphylococcus aureus	12.5	12.5	1
Bacillus subtilis	1.56	1.56	1
Escherichia coli	6.25	12.5	2
Enterobacter aerogenes	3.13	6.25	2

Conclusion

In conclusion, the biomimetic method was demonstrated as a simple, safe, cost-effective, and ecofriendly preparation of AgNPs using *Eleusine indica* methanol extract. The synthesized plant-mediated AgNPs gave UV-Vis reading at 413 nm and have an average particle size of 20 nm. They showed potential antibacterial activity against Gram-positive and Gram-negative bacteria including *Staphylococcus aureus*, *Bacillus subtilis*, *Escherichia coli* and *Enterobacter aerogenes*. Thus, application of these synthesized AgNPs based on the findings may lead to valuable discoveries in various fields, including medical devices and in the pharmaceutical and biomedical industries. Toxicity studies of these AgNPs using human pathogens may open the door to a new range of antibacterial agents and the possibility to the use of AgNPs as antiviral agents.

Acknowledgement

The authors would like to acknowledge Ministry of Education for the financial support under Fundamental Research Grant Scheme (FRGS/1/ 2019/STG01/UITM/ 02/10) and Universiti Teknologi MARA, Negeri Sembilan Branch, Kuala Pilah Campus, Negeri Sembilan; Faculty of Applied Sciences, Universiti Teknologi MARA, Shah Alam Selangor; Faculty of Science & Technology and CRIM, Universiti Kebangsaan Malaysia, Bangi Selangor for providing the research facilities. Abstract

Solvents are an unavoidable part of pharmaceutical and chemical manufacturing/synthesis, most of them are toxic or hazardous. The study on toxic solvent replacement is ongoing over the world. Researchers are trying to overcome the hazardous issues that can be possible using the mixture of hydrogen bond donor (HBD) and hydrogen bond acceptor (HBA) solvent as a safe/recommended solvent mixture. This study presents the possibility for the replacement/limitation of dipolar aprotic solvent in drug synthesis using solvent-pair mixture where the Kamlet-Taft (KT) parameter works as a tool to alternate the uses of such types of toxic solvents. It has been simplified here among the many methods and equations of the KT approach. The polarity (π*), basicity (β), and acidity (α) of 10 pure solvents and 16 solvent-pair mixtures were measured spectroscopically, utilizing well-suited dyes or indicators. The highest absorption wavenumber value of indicators in the solution was selected and the simplified KT equations were used to determine the solvent properties (π*, β, α). Solvent mixtures were classified as per the solvent selection guideline of GSK2016 and CHEM21. Four pure solvents (tetrahydrofuran, dimethylformamide, dimethylsulfoxide, and acetone) exhibited low KT acidity, high KT basicity, and high KT polarity. Eight aqueous solvent mixtures (water-acetone, water-ethanol, water-isopropyl alcohol, water-dimethylsulfoxide, water-dimethylformamide, water-tetrahydrofuran), and two non-aqueous solvent mixtures (ethanol-dimethylformamide, ethanol-dimethylsulfoxide) showed low KT acidity and high KT basicity. Solvent classification by composite score showed that four solvent mixtures were as recommended and 5 mixtures were near to recommended solvent among 16 solvent mixtures. KT parameter was a simplified approach to determine which mixture can bind with active pharmaceutical ingredients (API) that is indicated by KT solvatochromic properties and solvent classification.

Abstrak

Pelarut adalah bahagian yang tidak dapat dielakkan dalam pembuatan/sintesis farmaseutikal dan kimia, kebanyakannya beracun atau berbahaya. Kajian mengenai penggantian pelarut toksik sedang dijalankan di seluruh dunia. Penyelidik berusaha mengatasi masalah berbahaya yang mungkin dilakukan dengan menggunakan campuran pelarut penderma ikatan hidrogen (HBD) dan pelarut

ikatan hidrogen (HBA) sebagai campuran pelarut yang selamat/disyorkan. Kajian ini menunjukkan kemungkinan penggantian/pembatasan pelarut aprotik dipolar dalam sintesis ubat dengan campuran pasangan pelarut di mana parameter Kamlet-Taft (KT) berfungsi sebagai alat untuk mengganti penggunaan jenis pelarut toksik tersebut. Ini telah dipermudahkan di sini antara banyak kaedah dan persamaan pendekatan KT. Kekutuban (π*), asas (β), dan keasidan (α) daripada 10 pelarut tulen dan 16 campuran pasangan pelarut telah diukur dengan menggunakan spektroskopi, berdasarkan pewarna atau indikator yang sesuai. Nilai penyerapan gelombang tertinggi dari indikator dalam larutan dipilih dan persamaan KT digunakan untuk menentukan sifat pelarut (π*, β, α). Campuran pelarut dikelaskan mengikut garis panduan pemilihan pelarut GSK 2016 dan CHEM21. Empat pelarut tulen (tetrahidrofuran, dimetilformamida, dimetilsulfoksida, dan aseton) menunjukkan keasidan KT rendah, asas KT tinggi, dan kekutuban KT tinggi. Lapan campuran pelarut berasaskan air (air-aseton, air-etanol, air-isopropil alkohol, air-dimetilsulfoksida, air-dimetilformamida, air-tetrahidrofuran), dan dua campuran pelarut tidak berasaskan air (etanol-dimetilformamida, etanol-dimetilsulfoksida) menunjukkan keasidan KT rendah dan asas KT yang tinggi. Penggolongan terhadap 16 campuran pelarut berdasarkan skor komposit menunjukkan empat campuran pelarut adalah seperti yang disyorkan dan 5 campuran pelarut hampir dengan yang disyorkan. Parameter KT adalah pendekatan yang dipermudah untuk menentukan campuran mana yang dapat mengikat dengan bahan aktif farmaseutikal (API) yang ditunjukkan oleh sifat solvatochromic KT dan klasifikasi pelarut.

Kata kunci: parameter Kamlet-Taft, pelarut berbahaya, campuran pasangan pelarut, pelarut aprotik dipolar, sintesis ubat

Introduction

In 1976, Kamlet and Taft introduced a model to measure the solvatochromic properties, known as Kamlet-Taft parameters [1]. In 1997, Marcus brought some modifications in the measurement of KT parameters [2]. Various equations and indicators were used to calculate the KT parameters (KT acidity, KT basicity, and KT polarity) so that the appropriate result is obtained by averaging [3]. The most used indicators were N, N-dimethyl-4-nitroaniline, 4-nitro anisole, and N,N-dimethyl-3-nitro aniline for π* value; 4-nitroaniline, 4-nitrophenol, 4-aminoacetophenone and (tetramethyl ethylenediamine)(acetylacetonato)copper(II) perchlorate for β value; Cis-bis-(1,10-phenan throline)dicyanoiron(II), 2,6-dichloro-4-(2,4,6-triphenyl-1-pyridinio) phenolate, and 2,6-diphenyl-4-(2, 4, 6-tripheny-1-pyridinio) phenoxide/ phenolate for α value. The indicators were utilized in KT measurement because their UV variations are higher than the UV-Vis cutoff (310 nm) of the cyclic ketone [4]. In analysis, many specific equations are used to calculate the KT parameters that were prepared based on the indicators [2,5], and the concentration of the indicator greatly affects the result [6].

Solvents are categorized into four major types; recommended, problematic, hazardous, and highly hazardous based on health, safety, environment, and global harmonized system (GHS) hazards statements [7]. Most used solvents are hazardous as per the recommendation of the international conference on harmonization (ICH), Pfizer, GSK, and Sanofi [8,9], as shown in Table 1. Recently, KT parameters have been used to investigate the replacement/limitation of hazardous solvents using solvent-pair mixtures in synthetic chemistry. Most of the HBD-HBA solvent mixtures exhibit as solvent of recommended and problematic category [7,10,11], they can be applied in API [4,11] and non-API chemical [5,12,13] synthesis. The maximum use of safe solvents can minimize the health risks and negative impacts on the environment, which can be the most effective way to limit the use of hazardous solvents [14-17]. However, many methods; KT solvatochromic parameters using COSMO-RS [18], KT parameters using solvate ionic liquids [19] were more complex. Taking into consideration the advancement of the KT parameters in synthetic chemistry, the measurement technique has been simplified for determining the solvatochromic parameters. The 16 solvent-pair mixtures and 10 pure solvents were analyzed to determine the probability of application in replacing dipolar aprotic solvents (dimethylformamide, dimethylacetamide, N-methyl-2-pyrrolidone, pyridine etc.).

Table 1. Recommendation from Pfizer, GSK, Sanofi, and ICH regarding the use of the following solvents

Most Used Organic Solvents	**Concern in Use (Comment) [8, 9]**			
	Pfizer	**GSK**	**Sanofi**	**ICH**
Dimethylformamide (DMF)	Undesirable	Major issues	Substitution requested	To be limited
Dimethylacetamide (DMAC)	Undesirable	Major issues	Substitution requested	To be limited
N-methyl-2-pyrrolidone(NMP)	Undesirable	Major issues	Substitution requested	To be limited
Dichloromethane (DCM)	Undesirable	Major issues	Substitution advisable	To be limited

Pyridine	Undesirable	No comment	Substitution advisable	To be limited
Diisopropyl ether (IPE)	Undesirable	Major issues	Substitution advisable	Unknown

Materials and Methods

Materials

Analytical reagent (AR) grade methanol (MeOH 99.9%), acetone (Ace 99.8%), tetrahydrofuran (THF 99.8%), dimethyl sulfoxide (DMSO 99.9%), and calcium chloride anhydrous (99.9%) were received from Merck KGaA, Germany. Ethanol (EtOH 99.8%) was purchased from HmbG chemicals, Malaysia. HPLC grade acetonitrile (ACN 99.99%), AR grade dichloromethane (DCM 99.9%) were purchased from QREC (Asia), Malaysia. AR grade dimethylformamide (DMF 99.99%), and isopropyl alcohol (iPrOH 99.99%) were received from Fisher Scientific, UK. Three solvatochromic indicators were purchased: N, N-dimethyl-4-nitroaniline 98% as indicator 1 from Alfa Aesar through Permula chemicals, Malaysia; 4-nitro aniline 99% (Indicator 2) and Reichardt's dye 90% or 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridinio) phenolate 90% as indicator 3 from Sigma-Aldrich. To avoid humidity contamination or light degradation, the samples and indicators were weighted cautiously. A microbalance (Brand: Mettler Toledo; model: AX-205) was used to prepare the samples by mass with an uncertainty of ±1×10-4 g.

Analytical condition of KT parameters

Organic solvents were dried to free residual water before analysis using calcium chloride anhydrous. Indicator concentration in the solvent was from 0.03 mM to 0.05 mM (for indicator 1 & 2) and 0.1 mM (for indicator 3). The indicator and solvent were mixed properly before analysis to limit a variety of UV absorption to 0.5-1.2. The desired UV spectra of the solution were determined at a resolution of 0.2 nm using a double beam UV-Vis spectrophotometer (Shimadzu, UV-1800). Every UV-Vis spectrum was performed in triplicate. During the UV analysis, the temperature has been controlled at 25±0.1 °C using a temperature controller (Shimadzu, TCC-240A).

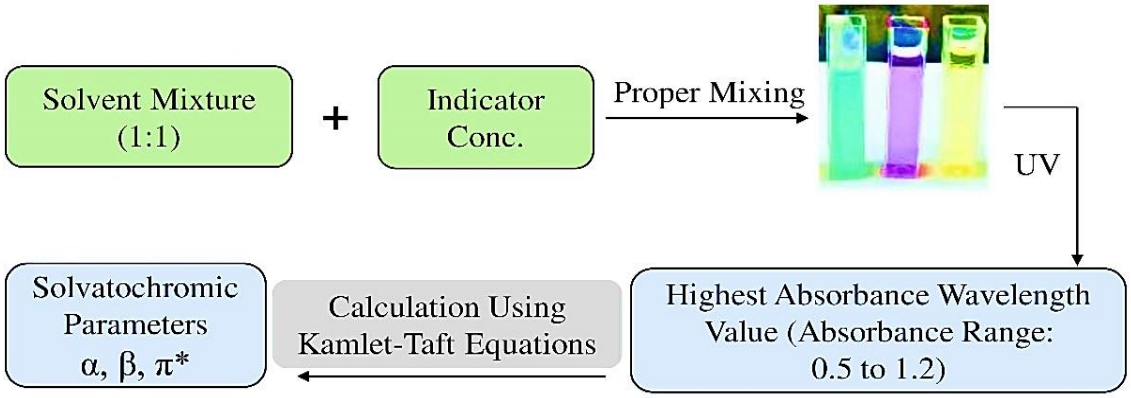

Figure 1. Measurement overview of solvatochromic parameters (π*, β, α) using the KT theory

Measurement equation of KT parameters

Three solvatochromic parameters i.e., KT polarity, KT basicity, and KT acidity were measured according to the original approach of KT theory using three equations (equation S1 to equation S3) [3,4]. The absorption wavenumber (V_{max}) from the highest wavelength value of the analytical sample was converted into KiloKaiser unit (1KK = 1000 cm^{-1}) to calculate the equations (1-3).

Statistical analysis

Experimental results were expressed as mean (n = 3) with uncertainty values and the data was analyzed using ANOVA and Dunnett's t-test in SPSS (version 20). *P values of 0.05 or less were regarded as significant.

Results and Discussion

The values of the measured wavenumbers (Vmax) and the obtained KT parameters have been expressed in Table 2 and Table 3. The absorbance range was established among the samples confined within 0.5 to 1.2. A total of ten pure solvents were analyzed to determine π*, β, and α. At the same time, sixteen mixed (HBD-HBA) solvents were also analyzed, involving eight aqueous and eight non-aqueous solvent pairs. In pure solvents, EtOH, MeOH, H_2O, iPrOH showed a high KT acidity and low KT polarity, whereas, DCM, ACN showed a low KT basicity. On the other hand, Ace, ACN, DMSO, DMF, and THF showed low acidity. In other words, the recommended solvents showed a high KT acidity, low KT basicity, and low KT polarity. In contrast, maximum problematic and hazardous solvents showed low KT acidity, high KT basicity, and high KT polarity except for DCM, iPrOH, and MeOH. Almost similar findings have been reported in the literature [20, 21].

Among the 16 mixed solvents, only four solvent mixtures i.e., H_2O-EtOH, H_2O-iPrOH, H_2O-DMSO, EtOH-DMSO were exhibited as recommended solvents, and the other 12 solvent mixtures were demonstrated as problematic in which 5 solvent mixtures (H_2O-Ace, EtOH-Ace, MeOH-Ace, H_2O-CAN, EtOH-CAN) showed as near to recommended solvent, as shown in Table 4. Eight aqueous (H_2O-MeOH, H_2O-Ace, H_2O-EtOH, H_2O-CAN, H_2O-iPrOH, H_2O-DMSO, H_2O-DMF, H_2O-THF) and two non-aqueous solvent mixtures (EtOH-DMF, EtOH-DMSO) showed a low KT acidity, low KT basicity, and high KT polarity. On the contrary, other non-aqueous solvent mixtures (EtOH-CAN, EtOH-Ace, EtOH-THF, MeOH-Ace, MeOH-DMF, MeOH-THF) showed a high KT acidity, low KT polarity, and low KT basicity, tabulated (Table 3). Similar results were found in the literature and previous work [6,11,12]. The solvent ranking was required for the application of mixed solvents that was prepared based on the GSK2016 and Innovative Medicines Initiative CHEM21 (IMI-CHEM21) solvent selection guideline [22]. The ranking of mixed solvents was ascertained from the minimum value of the GSK health and safety scores of HBA solvent using the equation (S4) [22].

Prat et al. and Byrne et al. stated that the commonly used solvents in drug synthesis and processing are hazardous, such as DMF, DMSO, NMP, DMAC, and pyridine, which are from dipolar aprotic solvents (HBA). IMI-CHEM21, GSK, Pfizer, ICH guidelines suggested that those solvents should be substituted/limited with safe solvents due to their toxic activities [7-9]. American Chemical Society (ACS) and Green Chemistry Institute (GCI) were investigating to replace such solvents in synthetic chemistry [23]. Duereh et al. stated that API has both HBD and HBA sites and dipolar aprotic (HBA) solvents have low KT acidity, high KT basicity, and high KT polarity. HBA solvents could easily create a strong chemical binding with the HBD site of API for these chemical properties [5].

Duereh et al. studied with 52 solvent mixtures and they reported that combinations of HBD-HBA allow the binding with API because solvent mixtures show low KT acidity, high KT basicity, and high KT polarity properties. For that, the solvent mixture can be used for the replacement of dipolar aprotic solvent. Although strong binding with API depends on physicochemical properties of solvent mixture. All mixtures who exhibited low KT acidity and high KT basicity, they are also capable to bind with the HBD site of API, can be selected for drug synthesis [4, 11, 13]. The solvent ranking was prepared to know which mixture is hazardous or problematic and which is recommended before being applied in synthesis. However, pure recommended solvents typically showed high acidity that is not capable to bind with the API. Therefore, when the solvent-pair mixtures show low KT acidity ($\alpha \approx 0$), high KT basicity ($\beta > 0.6$), and high KT polarity ($\pi^* > 0.6$), they offer a strong binding with the API [3, 11].

Indicator 1: Polarity (π^*) = $(28.10 - V_{max1}) / 3.52$ (1)

Indicator 2: Basicity (β) = $(0.984V_{max1} + 3.49 - V_{max2}) / 2.759$ (2)

Indicator 3: Acidity (α) = $(1.318V_{max1} - 47.7 + V_{max3}) / 5.47$ (3)

Composite score = $\sqrt{}$ (Safety score x Health score) (4)

Keys: Recommended solvent-pairs (green highlight) = score 7-10, problematic solvent-pairs (yellow highlight) = score 4-7, hazardous solvent-pairs (red highlight) = score 0-4 are score ranges adopted from IMI-CHEM21 [7]

Conclusion

The Kamlet-Taft analytical approach was simple and efficient to measure the KT acidity, basicity, and polarity of solvents or solvent mixtures. However, the proper mixing and temperature control of the solvent and indicator was the prerequisite to get the correct result in KT analysis. The ranking of HBD-HBA combinations facilitated to find out a suitable solvent mixture to substitute hazardous solvents in drug synthesis. The highest yield was found when the solvent creates a strong interaction with the HBD site of API. It is possible if the solvent mixture carries low KT acidity and high KT basicity. The maximum use of this methodology could bring a revolutionary change in synthetic chemistry.

Abstract

The dengue virus (DENV) has posed a serious global threat to human health for the past few decades. However, there are still no clinically approved antiviral drug available for the treatment of DENV. Cinnamic acid and its derivatives have attracted great attention due to their broad range of pharmacological properties. The present study aimed to synthesize and investigate the affinity of cinnamic acid derivatives against DENV. Six cinnamic acid derivatives (AC1-AC6) were synthesized by the reaction of substituted cinnamoyl chloride with the corresponding alcohol and amine. The structures of the compounds were confirmed by using ^{1}H and ^{13}C Nuclear Magnetic Resonance (NMR) and mass spectrometry. The synthesized compounds were then simulated for molecular docking to investigate their binding affinity to the protein target of DENV-2 NS2B/NS3 protease. The in-silico study reveals that the compound AC5 has the highest binding affinity and fit into the allosteric pocket of DENV-2 NS2B/NS3 serine protease with van der Waals interaction, C-H bonding and a few pi interactions such as π-cation, π-lone pair, π-π T-shaped as well as π-alkyl interaction.

Keywords: cinnamic acid, synthesis, anti-dengue virus, docking

Abstrak

Virus denggi (DENV) memberikan ancaman sejagat yang serius dalam kesihatan manusia sejak beberapa dekad yang lalu. Walau bagaimanapun, masih belum ada ubat anti-virus yang diluluskan secara klinikal bagi rawatan DENV. Asid sinamik dan terbitannya telah menarik banyak perhatian oleh kerana sifat farmakologi yang mempunyai julat yang luas. Kajian ini bertujuan untuk mensintesis dan menyiasat afiniti terbitan asid sinamik terhadap DENV. Enam terbitan asid sinamik (**AC1-AC6**) telah disintesis dengan tindakbalas penukargantian sinnamoil klorida dengan alkohol dan amina. Struktur sebatian telah disahkan dengan menggunakan ^{1}H dan ^{13}C Resonans Magnet Nukleus (NMR) dan spektrometer jisim. Sebatian yang telah disintesis kemudian disimulasikan dengan mengedok molekul untuk mengkaji sifat afiniti dengan protein sasaran iaitu protease DENV-2

NS2B / NS3. Kajian in-siliko mendedahkan bahawa sebatian **AC5** mempunyai afiniti pengikatan tertinggi dan dapat memasuki poket alosterik DENV-2 NS2B / NS3 protease serin dengan interaksi van der Waals, ikatan C-H dan beberapa interaksi pi seperti π-cation, π -lone pair, π-π berbentuk T dan juga interaksi π-alkil.

Kata kunci: asid sinamik, sintesis, anti-virus denggi, mengedok

Introduction

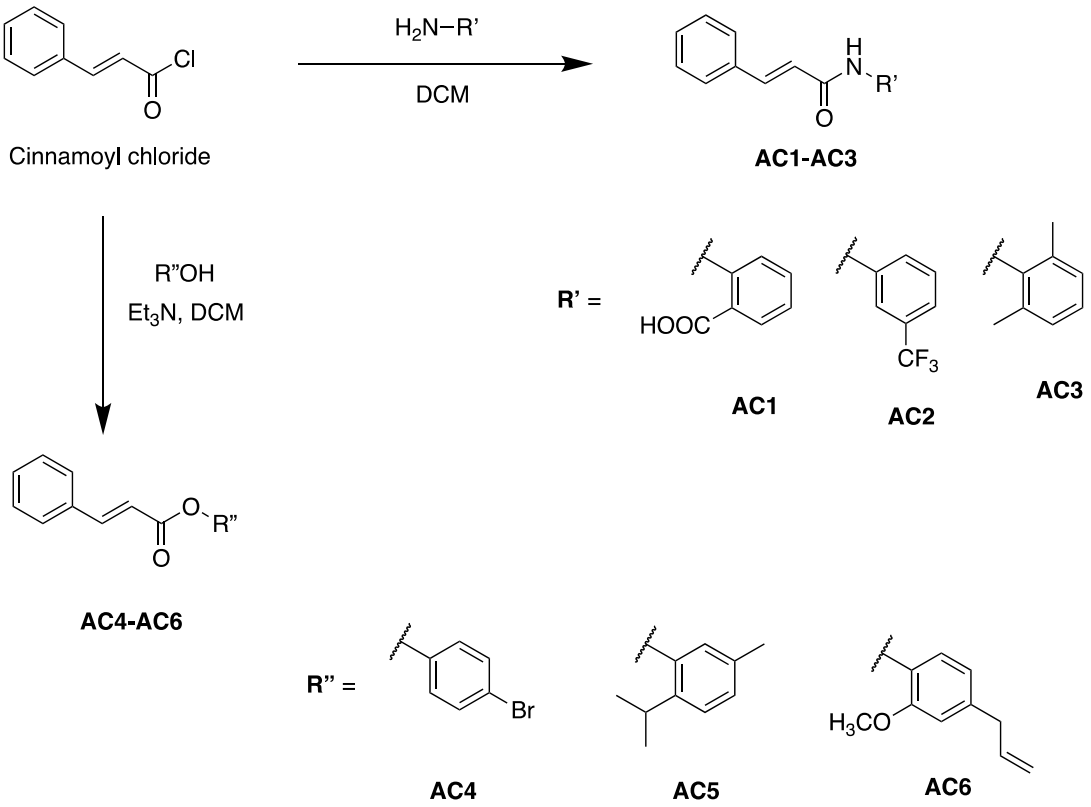
Dengue virus (DENV), the most significant virus in the *Flaviviridae* family with the highest morbidity and mortality rates, has been a serious global threat in the past few decades. The latest statistics from the World Health Organization (WHO) has shown an increasing trend of DENV infection throughout Malaysia with 127,407 reported cases in 2019. Despite this alarming issue, there is currently no effective vaccine nor antiviral treatment available for dengue patients. Prevention against DENV infection largely depends on controlling the mosquito vectors as well as on the use of the natural remedies. This underscores an urgent need to discover and develop a novel antiviral agent that is safe and effective in controlling dengue infection.

Cinnamic acid has gained a lot of interest due to its simple structure with great potential of pharmacological properties. It is a group of aromatic carboxylic acids, appearing naturally in the plant kingdom. Cinnamic acids occur in all green plants as well as the reproductive organs of flowering plants [1]. Cinnamic acids with varied substitution on the aryl ring, and their esters have been identified in natural bee products including honey and propolis [2]. It is also readily available from coffee beans, tea, cocoa, apples, tomatoes, and cereals [3]. It is a safe and extensive source of material due to its natural and low toxicity properties.

Cinnamic acid and its related molecules have a variety of biological activities, such as anticancer, antimalarial, antimicrobial and antioxidant [4,5]. Recently, cinnamic acid was reported to be an effective antiviral drug against Zika virus (ZIKV) [6]. It was found that cinnamic acid possessed anti-ZIKV properties against the post-entry stage of the ZIKV replication cycle, and inhibited RNA-dependent RNA polymerase (RdRp) activity. Additionally, cinnamic acid was also reported to have an excellent activity against *Tobacco mosaic virus* (TMV) in which most target compounds in this research exhibited good anti-plant virus activities [7]. One of the cinnamic acid derivatives also significantly inhibits hepatitis C virus (HCV) replication via the induction of oxidative stress [8].

Despite their rich medicinal tradition and remarkable biological activities, cinnamic acid derivatives and their potentials remained underutilized for several decades. Currently, the antiviral activity of cinnamic acid related molecules against dengue virus infection has never been experimentally addressed despite of its well-known therapeutic potential. In this study, six cinnamic acid derivatives have been synthesized and simulated for molecular docking to investigate their binding interactions to the protein target of DENV-2 NS2B/NS3 protease. Overall, this study demonstrated that cinnamic acid would be an excellent potential candidate for the development of antiviral drugs against DENV.

Materials and Methods



Chemicals and instrumentations

Ferulic acid, cinnamoyl chloride, anthranilic acid, 3-aminobenzotrifluoride, 2,6-dimethylaniline, 4-bromo benzyl alcohol, thymol, eugenol, anhydrous dichloromethane (DCM), triethylamine, hydrochloric acid (HCl), sodium bicarbonate ($NaHCO_3$), magnesium sulphate (Mg_2SO_4), hexane, ethyl acetate and acetone were purchased from standard commercial suppliers such as Sigma-Aldrich, Merck, Acrós Organics, Fisher Scientific, HmbG® Chemicals and R & M Chemical. All chemicals and solvents used in this study were of reagent grade (AR) and were used without further purification. Column chromatography was performed using silica gel 60 (230-400 mesh, Merck). Analytical thin-layer chromatography (TLC) was done on precoated silica gel 60 (F254, Merck) plates and visualized under UV 254 nm without treatment.

^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were determined by Bruker Avance II 400 spectrometer in deuterated dimethyl sulfoxide (DMSO-d_6). The chemical shifts were reported in a ppm scale. The synthesized compounds were dissolved in dichloromethane (DCM) and analysed using Perkin Elmer GC-MS (Clarus 500 Chromatography/Mass Spectrometry).

Chemistry

The synthetic route of the synthesized compounds is described in Scheme 1.

Scheme 1. The synthetic work of cinnamic acid amide and ester derivatives

Synthesis of cinnamoyl amide derivatives (AC1-AC3)

Cinnamoyl chloride (0.40 g, 2.4 mmol) in anhydrous DCM (5 mL) was added dropwise at 0 ℃ to a stirred solution of 3.6 mmol of amine (anthranilic acid, 3-aminobenzotrifluoride and 2,6-dimethylaniline) in anhydrous DCM (10 mL). The mixture was stirred at 0℃ for 30 min and then at RT for 3 hours. After completion of the reaction, 10 mL of DCM was added. The solution was washed 3 times with 1 N HCl and 2 times with 1 N $NaHCO_3$. The separated organic layer was dried over Mg_2SO_4 and the solvent was evaporated completely to obtain a residue. The residue was purified by silica gel column chromatography to afford the desired products of **AC1-AC3** by using a solvent system of hexane and ethyl acetate.

2-cinnamamidobenzoic acid (AC1)

Colorless powder (0.34 g, 53 %), **AC1** was prepared from the reaction of cinnamoyl chloride (0.40 g, 2.4 mmol) with anthranilic acid (0.49 g, 3.6 mmol) in the same manner as described in Scheme 1, ^{1}H NMR (400MHz, DMSO-d_6): δ_H ppm, 11.38 (1H, s, NH) , 8.61 (1H, d, J = 7Hz, H-ar), 8.02 (1H, d, J = 6Hz, H-

ar), 7.74 (1H, t, *J* = 7Hz, H-ar), 7.66 (1H, d, *J* = 7Hz, CH), 7.62 (1H, t, *J* = 9Hz, H-ar), 7.44 (4H, m, H-ar), 7.19 (1H, t, *J* = 14Hz, H-ar), 6.89 (1H,d, *J* = 15Hz, CH); ^{13}C NMR (100MHz, DMSO-d_6): δ_C ppm, 117.5, 120.9, 123.4, 128.6, 129.4, 130.5, 131.6, 134.4, 134.8, 141.26 (CH-aromatic), 141.7 & 122.9 (C=C), 169.9 (C=O). HRESIMS (positive mode) m/z calculated for $[C_{16}H_{13}NO_3]^+$: 267, $[M+H]^+$; found: 268.2639.

N-(3-(trifluoromethyl)phenyl)cinnamamide (AC2)

Colorless powder (0.42 g, 61 %), **AC2** was prepared from the reaction of cinnamoyl chloride (0.40 g, 2.4 mmol) with 3-aminobenzotrifluoride (0.58 g, 3.6 mmol) in the same manner as described in Scheme 1, ^{1}H NMR (400MHz, DMSO-d_6): δ_H ppm, 10.57 (1H, s, NH) , 8.22 (1H, s, H-ar), 7.87 (1H, d, *J* = 8Hz, H-ar), 7.66 (2H, m, H-ar), 7.62 (1H, d, *J* = 4Hz, CH), 7.58 (1H, t, *J* = 8Hz, H-ar), 7.45 (4H, m, H-ar), 6.82 (1H, d, *J* = 16Hz, CH); ^{13}C NMR (100MHz, DMSO-d6): δ_C ppm, 115.7, 120.1, 123.2, 125.9, 128.3, 129.8, 1130.1, 130.5, 134.9, 140.4 (CH-aromatic), 141.4 & 122.1 (C=C), 164.5 (C=O). HRESIMS (positive mode) m/z calculated for $[C_{16}H_{12}NOF_3]^+$: 291, $[M+H]^+$; found: 292.0951.

N-(2,6-dimethylphenyl)cinnamamide (AC3)

Colorless powder (0.28 g, 46 %), **AC3** was prepared from the reaction of cinnamoyl chloride (0.40 g, 2.4 mmol) with 2,6-dimethylaniline (0.44 g, 3.6 mmol) in the same manner as described in Scheme 1, ^{1}H NMR (400MHz, DMSO-d_6): δ_H ppm, 9.52 (1H, s, NH) , 7.64 (2H, d, *J* = 7.0 Hz, H-aromatic), 7.57 (1H, d, *J* = 16.0 Hz, CH), 7.45 (3H, m, H-aromatic), 7.09 (3H, s, H-aromatic), 6.89 (1H, d, *J* = 16.0 Hz, CH), 2.00 (6H, s, CH_3); ^{13}C NMR (100MHz, DMSO-d_6): δ_C ppm, 18.6 (CH_3), 126.9, 128.1, 129.4, 130.1, 135.2, 135.5 (CH-aromatic), 163.9 (C=O), 140.1 & 122.2 (C=C). HRESIMS (positive mode) m/z calculated for $[C_{17}H_{17}NO]^+$: 251, $[M+H]^+$; found: 252.1391.

Synthesis of cinnamoyl ester derivatives (AC4-AC6)

Triethylamine (3 eq) was added into a stirred solution of 1 eq of alcohol (4-bromobenzyl alcohol, thymol, and eugenol) in anhydrous DCM (20 ml). The mixture was magnetically stirred for 0.5h at 0-5°C. Then, cinnamoyl chloride (1 eq) was slowly added to the mixture within a 15 min period. The reaction mixture was continued stirring for 0.5h at 0-5°C before being slowly removed to room temperature. Then, the stirring continued for another 24 h. The completion of the reaction was monitored by TLC. The solvent was evaporated by using a rotary evaporator and the compound was purified via column chromatography. Hexane/ethyl acetate was used as the eluent to afford the title ester products of **AC4**-**AC6**.

4-bromophenyl cinnamate (AC4)

Colorless powder (0.32 g, 43 %), **AC4** was prepared from the reaction of cinnamoyl chloride (0.40 g, 2.4 mmol) with 4-bromobenzyl alcohol (0.44 g, 2.4 mmol) in the same manner as described in Scheme 1, ^{1}H NMR (400MHz, DMSO-d_6): δ_H ppm, 7.69 (2H, m, H-aromatic) , 7.61 (1H, d, *J* = 16.0 Hz, H-aromatic), 7.52 (1H, d, *J* = 8.4 Hz, H-aromatic), 7.42 (3H, m, H-aromatic), 7.28 (1H, d, *J* = 8.4 Hz, CH), 6.55 (1H, d, *J* = 16.0 Hz, CH), 4.46 (1H, s, H-aromatic), 2.51 (1H, s, H-aromatic); ^{13}C NMR (100MHz, DMSO-d_6): δ_C ppm, 128.6, 129.0, 129.3, 130.7, 131.3, 134.7 (CH-aromatic). 142.4 &119.6 (C=C), 144.4 (C-O), 168.0 (C=O). HRESIMS (positive mode) m/z calculated for $[C_{15}H_{11}O_2Br]^+$: 303, $[M+H]^+$; found: 304.3010.

2-isopropyl-5-methylphenyl cinnamate (AC5)

Colorless powder (0.24 g, 35 %), **AC5** was prepared from the reaction of cinnamoyl chloride (0.40 g, 2.4 mmol) with thymol (0.36 g, 2.4 mmol) in the same manner as described in Scheme 1, ^{1}H NMR (400MHz, DMSO-d_6): δ_H ppm, 9.11 (1H, s, H-aromatic) , 7.92 (1H, d, *J* = 16.0 Hz, CH), 7.83 (3H, m, H-aromatic), 7.27-7.05 (2H, d, *J* = 8 Hz, H-aromatic), 6.97-6.61 (2H, m, H-aromatic), 6.56 (1H, d, *J* = 7.6 Hz, CH), 3.42 (3H, s, CH_3), 1.17 (6H, m, CH_3); ^{13}C NMR (100MHz, DMSO-d_6): δ_C ppm, 27.1-21.1 (CH_3), 123.2, 126.0, 126.8, 127.4, 129.1, 129.4, 135.7, 136.6, 137.2 (CH-aromatic), 146.8 & 116.0 (C=C), 148.1 (C-O), 165.6 (C=O). HRESIMS (positive mode) m/z calculated for $[C_{19}H_{20}O_2]^+$: 280, $[M+H]^+$; found: 281.1537.

4-allyl-2-methoxyphenyl cinnamate (AC6)

Colorless powder (0.33 g, 43 %), **AC6** was prepared from the reaction of cinnamoyl chloride (0.40 g, 2.4

mmol) with eugenol (0.39 g, 2.4 mmol) in the same manner as described in Scheme 1, ^{1}H NMR (400MHz, DMSO-d_6): δ_H ppm, 8.72 (1H, s, H-aromatic) , 7.54 (2H, m, H-aromatic), 7.48 (1H, d, J = 4.0 Hz, CH), 7.35 (3H, m, H-aromatic), 6.71 (2H, m, H-aromatic), 6.56 (1H, d, J = 4.0 Hz, CH), 3.74 (3H, s, CH_3) 3.25 (2H, d, J = 8.0 Hz, CH_2); ^{13}C NMR (100MHz, DMSO-d_6): δ_C ppm, 23.4 (CH_3), 115.9, 116.0, 123.3, 126.2, 148.3, 149.5 (CH-aromatic), 144.9 & 116.0 (C=C), 148.3 (C-O), 168.4 (C=O). HRESIMS (positive mode) m/z calculated for $[C_{18}H_{18}O_3]^+$: 282, $[M+H]^+$; found: 282.0887. Structures of synthesized cinnamic acid derivatives are shown in Figure 1.

Computational study

The synthesized derivatives (**AC1**-**AC6**) were simulated for molecular docking to investigate their binding affinity to the protein target of DENV type 2 (DENV-2) NS2B/NS3 protease, with Ser135, His51 and Asp75 as their catalytic triad amino acid residues. The virtual screening was carried out on the homology model of the DENV non-structural protein, NS2B/NS3pro developed by Wichapong et al. [16]. The DENV-2 NS2B/NS3pro model was built based on the DENV-2 complex cofactor-protease using the crystal structure of NS2B/NS3pro West Nile Virus (WNV) as the template. The protein structure was prepared as a macromolecule prior to docking using AutoDock version 1.5.6 package (www.autodock.scrips.edu). Briefly, the protein preparation was done by removing the native ligand, tetrapeptide inhibitor (Bz-Nle-Lys-Ar-H) and water molecules, the addition of polar hydrogen and Kollmann charges.

The 3D structures of all cinnamic acid derivatives were constructed and energetically optimized using ChemDraw Professional 16.0. The minimized structures were saved in sdf format before converted into pdb format using OpenBabel-3.1.1 software. The validation of the docking protocol was done by re-docking the inhibitor tetrapeptide (Bz-Nle-Lys-Ar-H) with the RMSD value not greater than 2.0 Å. The ligands were prepared by merging non-polar hydrogen and assigned a Gasteiger charge. The center of the grid box was employed around the protease active site at 23.038, 43.372, -0.316 in x, y, and z coordinates, respectively, with a box size of 60 × 60 × 60 dimensions and grid spacing 0.375 Å. The docking of ligands was run with the Lamarckian Genetics Algorithm (GA) search program applied to generate 100 runs. The binding modes of compounds were analyzed using Discovery Studio Client 2020 (www.accelrys.com). The identification of hit compound was identified based on the conformations with the ones of lowest free binding energy and of the most populated cluster.

Preparation of enzyme and ligand for docking

The structure of available DENV2, which is a complex of NS2B-NS3 protease (PDB code: 2FOM), is devoid of any ligand. Thus, to get an insight into the binding cavity we used coordinates of co-crystallized ligand from West Nile virus (PDB code: 2FP7) belonging to the same family as that of DENV and that shares the structural similarity of the catalytic triad. It is available in complex with the inhibitor tetrapeptide Bz-Nle-Lys-Arg-Arg-H. The structure of DENV2 complexed with the inhibitor tetrapeptide Bz-Nle- Lys-Arg-Arg-H was constructed by homology modelling method.

Results and Discussion

Chemistry

Six cinnamic acid derivatives (Figure 1) were successfully synthesized in moderate yield (35-61%) by modification of established methods [9]. The synthesis of the target compounds was straightforward, and the general synthetic pathway is illustrated in Scheme 1. Cinnamoyl chloride was reacted with various amines; anthranilic acid, 3-aminobenzotrifluoride and 2,6-dimethylaniline to produce the titled compounds of cinnamic acid amides (**AC1**, **AC2** and **AC3)**. For the synthesis of cinnamic acid ester derivatives, different alcohols; 4-bromobenzyl alcohol, thymol and eugenol were reacted with cinnamoyl chloride in DCM to afford the title compounds **AC4**, **AC5** and **AC6**. To optimize the reaction conditions, the polarity of the solvent medium from polar to non-polar was adjusted using DMSO, ethanol and tetrahydrofuran (THF) in the reaction of substituted cinnamoyl chloride with the corresponding alcohol and amine.

^{1}H and ^{13}C nuclear magnetic resonance (NMR) analysis confirmed the identity of all synthesized cinnamic acid derivatives. The presence of NH resonance peaks as observed in all three ^{1}H NMR spectra of **AC1**-**AC3** prove that the cinnamoyl amide derivatives were successfully synthesized. NH resonance which appears as singlet is found to be at the most downfield region (δ_H 11.38-9.52 ppm) for **AC1** to **AC3**. There is also a high-intensity singlet resonance in the upfield region at δ_H 2.17 ppm representing two methyl moieties presented in the **AC3** compound. For cinnamoyl ester derivatives, in the range of δ_H 7.41-7.70 ppm, multiple peaks can be observed in **AC4** indicating the presence of aromatic groups. Meanwhile, for **AC6** the peaks are in the range of δ_H 6.55-6.70 ppm. There are other high-intensity singlet resonances at δ_H 1.13-2.29 ppm and at δ_H 3.73 ppm respectively, representing methyl moieties presented in both compounds **AC5** and **AC6**. The alkene groups for all three compounds of **AC4**-**AC6** can be observed in the peak range of δ_H 6.51-6.57 ppm.

The resonance of the C=O group was clearly observed for all synthesized compounds at δ 169.9-163.8 ppm. The alkene group is also presented in all compounds which are in the range of δ 146.8-116.0 ppm. For the aromatic ring, the resonance carbon was found at the range between δ 129.8-123.3 ppm. Furthermore, the resonance for CH_3 moieties can also be observed for the compounds of **AC3**, **AC5** and **AC6** which are in the region δ 27.1-18.7 ppm.

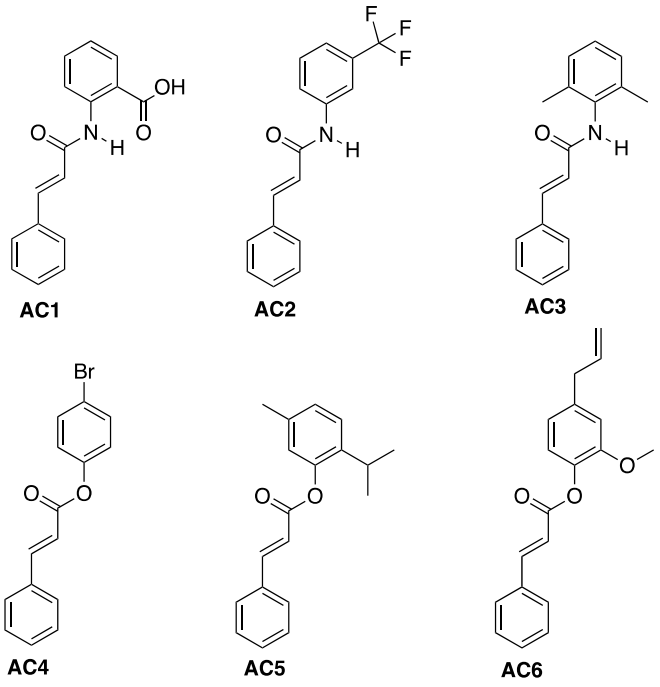


Figure 1. Structure of synthesized cinnamic acid derivatives

Molecular docking

The in-silico studies were conducted to investigate the binding interactions of the synthesized compounds **AC1**-**AC6** towards DENV-2 NS2B/NS3 protease and search for the best orientation of ligand-protease complex with the lowest free energy of binding (FEB). This step serves as a good tool to predict and match the desired binding site, understanding possible conformation of the compounds and further clarifies the binding interactions in the binding pocket [10].

DENV is a single-stranded RNA genome that encodes a single open reading frame (5-C-prM-E-NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5-3) with three structural and seven non-structural proteins [11]. The N-terminal of NS3 is a trypsin-like serine protease, which when combined with its co-factor can cleave the viral polyprotein [12]. Disruption of NS2B-NS3 protease inhibits viral replication [13]. This poses NS2B-NS3 protease of DENV-2 as a promising target for antiviral drug design [14].

The three catalytic triad amino acid residues were located in NS3 serine proteases namely His51, Asp75 and Ser135. The NS2B protease acted as an NS3 serine protease co-factor for an optimal catalytic activity [15]. The homology protein crystal structure generated by Wichapong et al., (2010) was used due to the lack of DENV-2 NS2B/NS3 serine protease inhibitor-bound 3D structures. Moreover, some of the protease database structures were found to have missing amino acid residues [16].

The Lamarckian genetic algorithm was employed in AutoDock version 1.5.6 to determine the binding modes and compounds conformation towards DENV-2 NS2B/NS3 protease homology protein crystal structure. In the preparation for docking simulation, only protease was retained as a part of the macromolecule file, while the Bz-Nle-Lys-Arg-Arg-H was extracted and saved as a positive control ligand. The ligand was extracted and re-docked into the binding site to evaluate the success of the docking method in reproducing the experimentally known complex.

The covalent map parameter was used during positive control docking simulation to constrain the molecular geometry of the peptide inhibitor. After that, all the synthesized compounds were docked with Wichapong et al., [16] homology crystal structure using the same parameter. The re-docked was carried out successfully with the root mean square deviation (RMSD) value of 1.23 Å. Henever et al. stated that the programs that able to poses the RMSD value in the range of 1.5-2 Å, depending on the ligand size, are considered to have performed successfully [17].

The synthesized compounds, **AC1**-**AC6** fit into the allosteric pocket of NS2B/NS3 serine protease. The free energy of binding (FEB) obtained was tabulated in Table 1. Figure 2 shows the overlay docked conformation of the cinnamic acid derivatives between the Wichapong et al. [16] homology model and Bz-Nle-Lys-Arg-Arg-H referenced ligand. The image was generated using Discovery Studio Visualizer 4.5.

The detailed ligand-binding site interaction in 2D structural views of all the compounds are shown in Figure 3 below. Compound **AC5** shows the lowest free energy of binding (-6.53 kcal mol^{-1}) indicating the highest binding affinity towards NS2B/NS3 protease of DENV-2 compared to the other five compounds [18]. Figure 3 also shows the poses and non-covalent interactions involved between the ligands and the protease-binding site. This compound showed a few van der Waals interaction, one C-H bonding interaction, one π-cation interaction, one π-lone pair interaction, one π-π T-shaped interaction, and two π-alkyl interactions with the amino acid residue in the DENV-2 NS2B/NS3 protease.

The presence of the aromatic group in the synthesized cinnamic acid derivatives enhances the possibilities of van der Waals interaction. Hence, we can see this interaction in all the synthesized compounds of **AC1**-**AC6**. Individually, van der Waals interaction was also observed in compound **AC5**, involving Ser135 (one of the catalytic triads) and other residues namely Asp129, Ser131, Gly151 and Thr134. Pi interactions such as π-π T-shaped interaction and π-lone pair interaction were also observed between the ester moiety of the synthesized compound with Tyr161 and Phe130, respectively. Meanwhile, another aromatic ring at cinnamic moiety of compound **AC5** appeared to have a π-cation interaction with the His51 (from the catalytic triad) and π-alkyl interactions with Val52. The π-cation interaction with the His51 suggested that the DENV-2 NS2B/NS3 replication was affected as His51 is one of the catalytic triads of NS2B required for replication activities [19].

Table 1. The free energy of binding (FEB) of compounds **AC1-AC6**

Compound	**FEB (kcal mol^{-1})**
Positive Control (peptide inhibitor)	-6.58
AC1	-6.11
AC2	-6.36
AC3	-6.45
AC4	-6.33
AC5	-6.53
AC6	-6.50

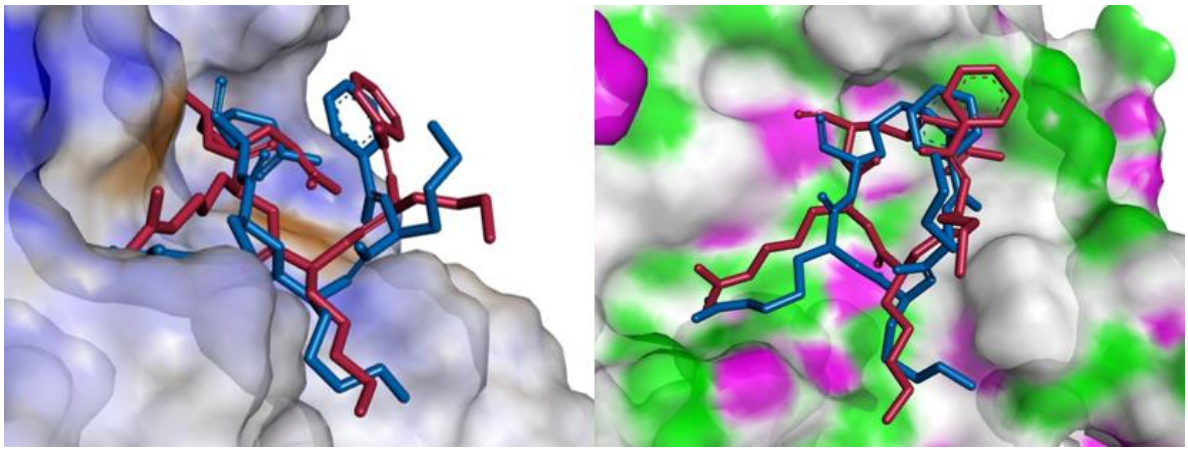

Figure 2. The overlay docked conformation of the cinnamic acid between the Wichapong et al. [16] homology model and Bz-Nle-Lys-Arg-Arg-H referenced ligand (red: original ligand conformation, blue: docked ligand conformation).

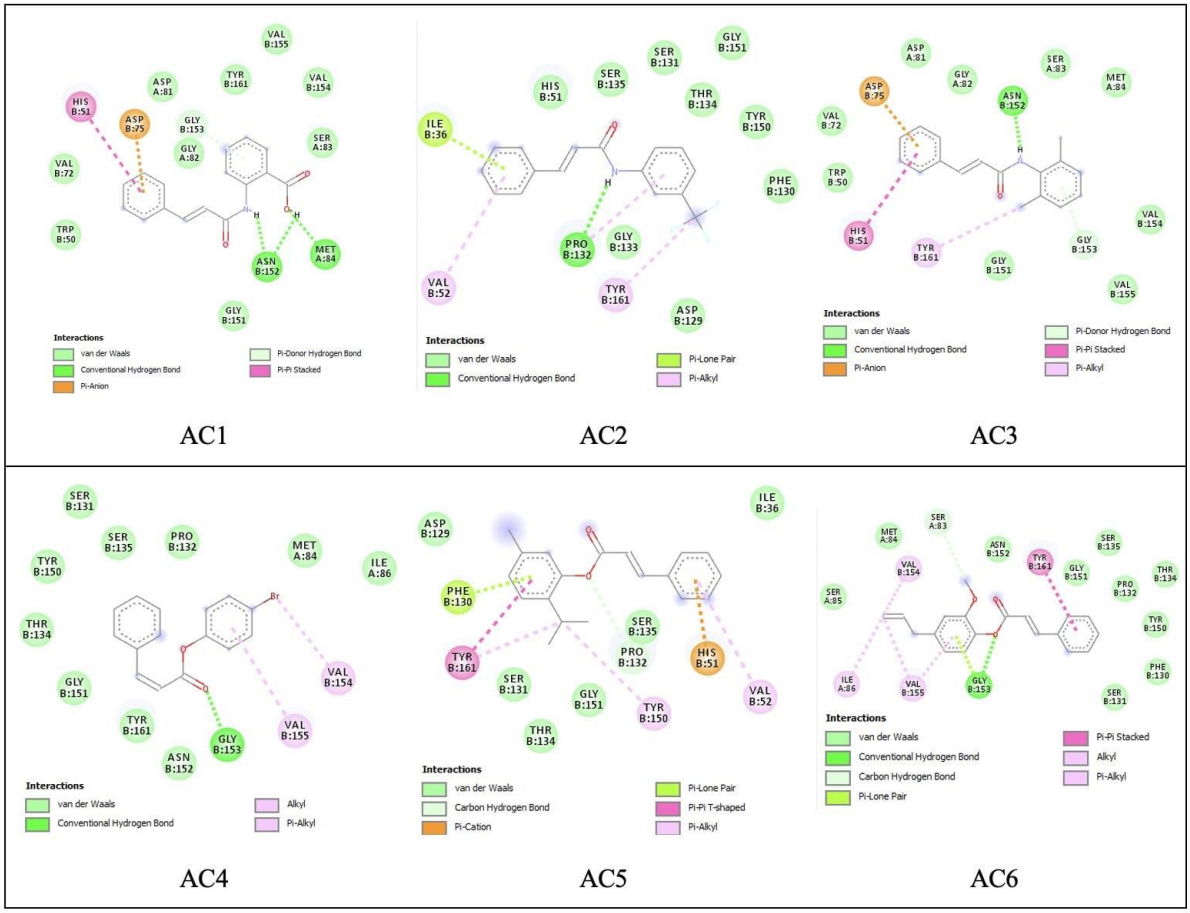

Figure 3. The 2D structural views of ligand-binding site interactions for synthesized compounds AC1-AC5

Conclusion

The present work has demonstrated that six cinnamic acid derivatives were successfully synthesized by the reaction of cinnamoyl chloride with various amines and alcohols. All synthesized compounds were characterized by ^{1}H and ^{13}C-NMR, and mass spectrometry. The significant molecular interaction between the synthesized compounds and DENV2 NS2B/NS3 protease were revealed by molecular studies indicating their potential activity as a protease inhibitor. The compound **AC5** is predicted to have a higher DENV-2 NS2B/NS3 protease inhibitor as it has the highest binding affinity, with a significant van der Waals force and pi interactions between the synthesized compound and the amino acid residues. Further verification studies such as *in-vitro*, toxicity analysis, and *in-vivo* analysis are required for identifying the possibilities of the cinnamic acid derivatives to be a lead molecule for anti-dengue drug development.

Abstract

Pectin has excellent potential as a main source of bioplastic due to its biodegradability. However, the neat pectin-based film has poor chemo-physical properties and low mechanical performance. In this study, the pectin-based film is successfully modified by adding eggshell and deep eutectic solvent (DES), comprising choline chloride and malonic acid, as a filler and plasticiser to enhance the performance of bioplastic. Five pectin-based bioplastics were prepared: pectin/eggshell (without DES) and pectin/eggshell with each 1%, 2%, 3%, and 4% of DES. The bioplastics were characterised by the Fourier-transform infrared (FTIR) spectroscopy and inverted camera analysis. The presence of filler and the effect of different DES concentrations were studied based on mechanical properties, biodegradability, and water uptake. The results showed that the addition of different percentages of DES had decreased the tensile strength and increased the flexibility of the bioplastic. Biodegradability testing using compost soil demonstrated an increased degradation rate when a high concentration of DES (4%) was added. The DES of choline chloride and malonic acid shows high potential as a plasticiser in pectin/eggshell bioplastic.

Keywords: pectin, plasticiser, deep eutectic solvent, eggshell filler, bioplastic

Abstrak

Pektin berpotensi sebagai sumber utama bioplastik kerana sifat biodegradasinya. Walau bagaimanapun, bioplastik yang hanya berasaskan pektin sahaja mempunyai sifat kimia-fizikal yang lemah dan prestasi mekanikal yang rendah. Dalam kajian ini, filem bioplastik berdasarkan pektin telah berjaya diubah suai dengan menambahkan cangkang telur dan pelarut eutektik (DES), yang mengandungi kolin klorida dan asid malonik, sebagai pengisi dan pemplastik yang bertujuan untuk meningkatkan prestasi bioplastik. Lima bioplastik berasaskan pektin disediakan: pektin/cangkang telur (tanpa DES) dan pektin/cangkang telur dengan masing-masing 1%, 2%, 3%, dan 4% DES. Bioplastik yand dihasilkan dicirikan secara fizik menggunakan spektroskopi Fourier-penukaran inframerah (FTIR) dan analisis kamera terbalik. Kehadiran pengisi dan kesan kepekatan DES yang berbeza dikaji berdasarkan sifat mekanik, kebolehbiodegradasian, dan pengambilan air. Hasilnya menunjukkan bahawa penambahan peratus DES yang berbeza telah menurunkan kekuatan dan meningkatkan fleksibiliti bioplastik. Ujian biodegradasi menggunakan tanah kompos menunjukkan peningkatan kadar degradasi apabila peratus DES yang tinggi (4%) digunakan. DES bagi kolin klorida dan asid malonik menunjukkan potensi yang tinggi sebagai pemplastik di dalam bioplastik pektin/cangkang telur.

Kata kunci: pektin, pemplastik, pelarut eutektik, pengisi cangkang telur, bioplastik

Introduction

Petrochemical plastic materials are important in our daily lives. However, the vast amounts of plastic waste materials generated contribute to worldwide environmental concerns [1]. About 34 million tons of plastic trash is produced each year, with 93% ending in landfills and the seas. Furthermore, the disposal of non-biodegradable plastic leads to significant global warming, ozone depletion, eco-toxicity, eutrophication, and long-lasting decomposition [2]. Improper management of plastic causes a severe effect on the ecosystem. Thus, biodegradable plastic is the best alternative to reduce plastic waste, save the environment and sustain green global issues. The use of natural sources, such as cellulose, pectin, starch, chitosan, and alginate as food packaging materials has slowly replaced petrochemical plastics [3, 4, 5]. Pectin is a polysaccharide found abundantly in fruits like apple, orange, lemon, mango, grapes, and peach [1, 6]. It is very compatible as a biodegradable and edible biopolymer for food packaging. However, due to its poor chemo-physical properties and low mechanical performance, the pectin biofilm must be improvised by adding a plasticiser and organic filler accordingly to meet the food packaging requirements [1]. Like most polysaccharides, pectin is glassy at room temperature, causing defects such as cracking or curling in a film due to its shrinking, followed by water evaporation or rapid drying [7]. Gennadios et al. [8] asserted that these films are often fragile and rigid due to extensive interactions between the polymer molecules. Therefore, a filler is commonly used to improve the rigidity and strength of the biofilm [9, 10]. A natural bio filler such as eggshell has grown popular since they are environmentally friendly, renewable, cheap, and abundantly available [11, 12].

However, a biofilm made of pectin with eggshells is mostly brittle. A plasticiser is a useful compound in minimising film brittleness by reducing intermolecular forces among polymer chains, increasing their mobility, and improving mechanical properties [13] by holding the polymer bonds together [14]. Deep eutectic solvent (DES) is a new category of plasticiser that has been competently tested for polysaccharide biofilms in various methods [15, 16, 17, 18]. The two most common plasticisers in the polymer industry are *o*-hydroxyphenyl (HBP) and di-2-ethylhexyl phthalate (DEHP), known for their ability to disrupt the endocrine system, with carcinogenic and mutagenic properties [19]. Phthalate is not bonded to plastic; therefore, it will easily leak out into the human body, causing major health effects [20]. According to Mekonnen et al. [21], an ideal plasticiser significantly reduces the glass transition temperature (T_g), biodegradable, non-volatile, non-toxic, and have minimal leaching or migration properties. DES, comprising two self-associating components, met the requirements as a plasticiser in bioplastic [22, 23]. The ability of DES to swell inside biopolymers has enabled bioplastic plasticisation [19], as well as improved thermal stability and decreased the glass transition temperature (T_g) of bioplastics [24]. Previously, Shafie et al. [17] have successfully used DES as a plasticiser in pectin extracted from *Momordica charantia* or known as *peria*. According to their findings, DES caused different degrees of plasticisation via hydrogen bonds and ionic bonds with the polymer chains, which improved thermal stability, tensile properties, percentage of moisture absorption, and water vapour transmission rate of bioplastic. However, the strength of biofilm is reduced without fillers. Hence, this study investigates the compatibility of pectin/DES with eggshells as a natural filler. The pectin/eggshell bioplastic was developed with different concentrations of DES (choline chloride: malonic acid) to analyse bioplastic performance based on tensile strength, biodegradability, and water uptake.

Materials and Methods

Material and reagents

The commercial pectin from citrus was purchased from Sigma Aldrich, Malaysia. The choline chloride (ChCl), malonic acid, and sodium hypochlorite were purchased from Acros, Belgium, with 99% purity. All chemicals used are of analytical grade. The DES was prepared as

suggested by Abbot et al. [15], with a 1:1 ratio of ChCl and malonic acid. The mixture was magnetically stirred at 80 °C until the colourless liquid was formed and maintained as a liquid after 24 hours at room temperature. The eggshell powdered filler was prepared according to Kasmuri et al. [14]. The eggshells were crushed using a mortar and pestle and placed in a beaker. Sodium hypochlorite was added until all the eggshells were soaked and stirred using a glass rod until heat and bubble were released. The beaker was covered using aluminium foil and left for 24 hours before filtering and washing using distilled water. The dried eggshell sample was then dried in the oven and left to cool at room temperature. The eggshell sample was then ground into powder to obtain the size of 58 μm.

Preparation of pectin-based bioplastic

The pectin-based bioplastic was prepared according to Cataldo et al. [25] and Almeida et al. [26]. A volume of 3% (w/v) aqueous pectin was stirred at 70 °C until completely dissolved. About 1% to 4% wt of DES was added to the pectin solution and stirred to homogenise and form film-forming solutions. Approximately 3% wt of eggshell filler was added until completely dissolved. The well-dispersed aqueous dispersions were poured into Petri dishes and dried in the oven at 50 °C for 24 hours. The control was prepared without DES, i.e., 3% of aqueous pectin with 3% wt of eggshell as the filler.

Characterisation of DES

The thickness of the bioplastic was measured using a Digimatic thickness gauge (Model 547-301, Mitutoyo). At least five measurements were performed at different positions for each bioplastic, and the average thickness was calculated. The mechanical properties, including tensile strength, Young's modulus, and elongation at break, were determined using the Instron Universal Testing Instrument (Instron 3365, Instron, USA) equipped with a 1 kN load cell. The sample was cut into a rectangular shape with the size of 7 cm × 1 cm. The initial grip separation was 50 mm, with a crosshead speed of 5 mm min^{-1}. At least five replicates were performed for each film formulation. The soil burial test was conducted according to the ASTM D6003-96 standard method to determine the ability of bioplastics to degrade in compost soil. The initial mass of each bioplastic was weighed and recorded. The bioplastic was buried in compost soil, and the mass was recorded daily until fully degraded. The W_o (g) is the average of the initial bioplastic weight before being buried in soil samples, and the W_t (g) is the average weight of bioplastic at the time of measurement.

The following equation was used to calculate the weight loss of the sample:

$$\text{Weight Loss}(\%) = \frac{W_o - W_t}{W_o} \times 100 \quad (1)$$

The synthetic seawater was prepared by dissolving 35 g of sodium chloride in a total mass of 1000 g distilled water in a beaker. The bioplastic with the size of 1.5 cm × 2 cm was weighed before being immersed in the synthetic seawater. The samples were dried and reweighed at three days intervals. The percentage weight loss of the bioplastic was calculated using the following formula, where M_0 is the average initial mass of the sample, and M_1 is the average residual mass of the bioplastic after the test.

$$\text{Weight Loss } (\%) = \frac{M_0 - M_1}{M_0} \times 100 \quad (2)$$

The water uptake method was conducted according to Zárate-Ramírez et al. [27]. A 1.5 cm × 2 cm sample was cut, dried in the oven at 50 °C for 24 hours, and weighed as W_o. The sample was then immersed in distilled water for 10 seconds at room temperature and reweighed as W_t. The experiment was conducted in triplicate. Water uptake was calculated using the following equation:

$$\text{Water Uptake } (\%) = \frac{W_t - W_o}{W_o} \times 100 \quad (3)$$

Results and Discussion

FTIR analysis was carried out to analyse the functional group present in pure pectin, eggshell, and pectin/eggshell (P-E) composites (Figure 1). The O-H stretching, C=O stretching, and C-O stretching at 3440 cm^{-1}, 1746 cm^{-1}, and 1018 cm^{-1} characterise the structure of pectin.

According to Bichara et al. [28], the main peaks observed at 3436 cm^{-1}, 1743-1640 cm^{-1}, and 1103-1146 cm^{-1} represented the O-H, C=O, and C-O glycosidic bonds in pectin. Meanwhile, the pure eggshell showed peaks at 712, 876, and 1425 cm^{-1}, as similarly reported by Li et al. [29], who characterised calcite by an in-plane bending, out-of-plane bending, and asymmetric CO_3^{2-} stretching at the peaks of 713, 875, and 1424 cm^{-1}. Similar findings were also reported by Siriprom et al. [30] and Pradhan et al. [31]. The combination of pectin with eggshell in the composite film shows all peaks in individual pectin and eggshell. However, a C-O peak from CO_3^{2-} at 1424 cm^{-1} disappeared in the composite as the formation of new bonding is expected between the calcite of eggshell with the glycosidic bond of pectin. The pectin/eggshell composite is enhanced with the addition of DES as a plasticiser. Figure 1(b) shows the FTIR analysis on the increasing concentration of DES from 1% to 4% on the pectin/eggshell composite. As observed, the intensity peaks at 3350 cm^{-1} and 1000 cm^{-1} are slightly decreased when the concentration of DES increases. The IR spectra of all films are dominated by vibration, related to the presence of the pectin compound. A similar result was also reported by Gouveia et al. [32], indicating the interaction between pectin and the additives.

The images of bioplastic sample surfaces were analysed using an Olympus CKX53 inverted microscope (Figure 2). The bubbles trapped in the pectin/eggshell biofilm surfaces are due to the agitation process and the addition of the eggshell powder with pectin solution during sample preparation. The number of bubbles is reduced with the addition of a high percentage of DES, as shown in Figures 2(b) to 2(e). In general, it is also observed that the solubility of eggshell powder increases with the concentration of DES, especially at 3% to 4% of DES (Figure 2(d) and 2(e)). Kong et al. [33] stated that the addition of plasticiser might modify polymer chain intermolecular forces and reduce viscosity in the system. Thus, the DES enhances the dispersion of the added eggshells within the polymer matrices, which is expected to affect the mechanical performance of the bioplastics.

The thickness of the biofilms is an important characteristic that determines its purpose and function. A thin biofilm can lead to fragility and easily be torn, while a very thick biofilm has less flexibility. Table 1 shows the thickness of the pectin/eggshell biofilms. According to ASTM D885, the standard maximum thickness for plastic is 1 mm. Meanwhile, the pectin/eggshell bioplastic is the thinnest bioplastic with 0.0985 ± 0.01 mm. The thickness of bioplastic increases as the plasticiser is added from 1% to 4%, i.e., 0.0991 ± 0.01mm to 0.2687 ± 0.06 mm. The film tends to be thicker as the amount of DES increases. The result is congruent with Esposito et al. [34], which showed that the pectin film thickness increased as polyamines were added as a new cationic plasticiser for pectin-based edible (PEC) films. In this work, the thickness of the PEC films is doubled in the absence of glycerol.

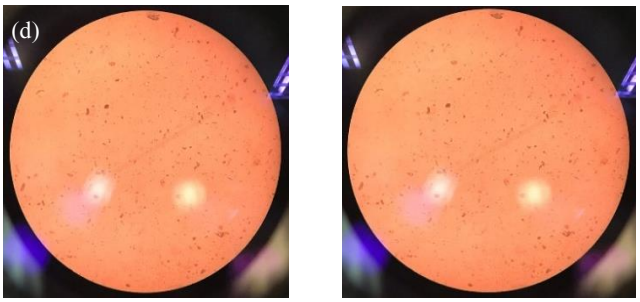

Figure 2. Bioplastic surface images in 4× magnification of (a) Pectin/Eggshell; (b) Pectin/Eggshell in DES 1%; (c) Pectin/Eggshell DES 2%; (d) Pectin/Eggshell DES 3%; and (e) Pectin/Eggshell DES 4%

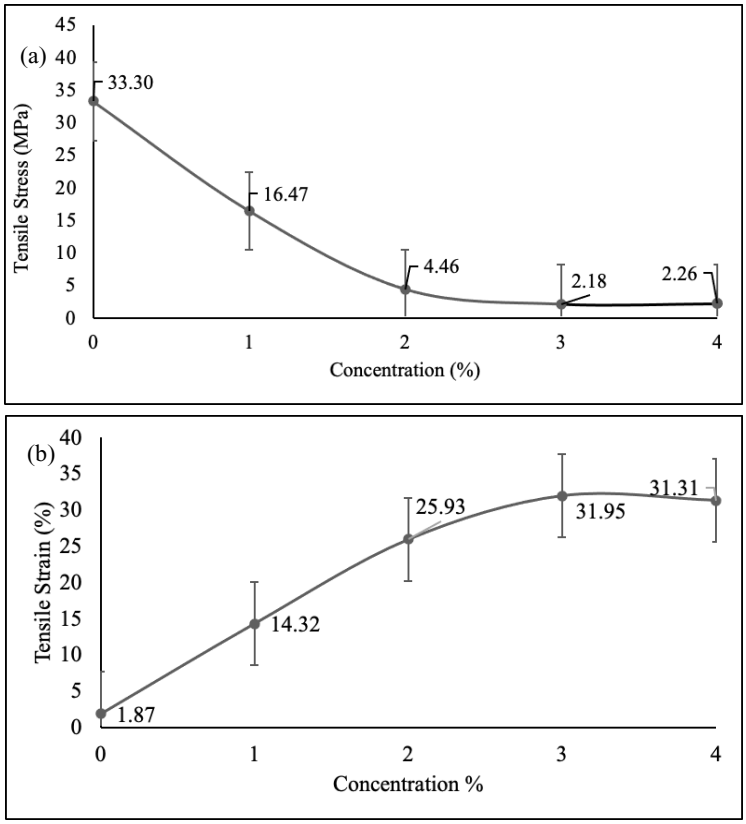
Table 1. Thickness of pectin-based bioplastic



Sample Bioplastic	Thickness (mm)
Pectin/Eggshell (P-E)	0.0985 ± 0.01
P-E + DES 1%	0.0991 ± 0.01
P-E + DES 2%	0.1448 ± 0.02
P-E + DES 3%	0.2146 ± 0.02
P-E + DES 4%	0.2687 ± 0.06

The mechanical properties of the prepared bioplastic in 1% to 4% DES concentration were determined via tensile testing analysis. Figures 3(a-c) show the trend of tensile stress, strain, and modulus of the bioplastic at different DES concentrations. The results indicated that the pectin/eggshell bioplastic is the most rigid with high tensile stress at 33.30 MPa. As a filler, eggshells fill the space in the pectin polymer and increase the stiffness of bioplastic. The tensile strain of pectin/eggshell bioplastic is observed at 1.87%, with the modulus reaching 2754.00 MPa. A study by Kong et al. [33] stated that the addition of eggshell powder to polylactic acid (PLA) yielded a more rigid plastic than PLA only. The PLA/eggshell had superior tensile stress with 200% strain at break and a high modulus. Hence, a similar effect is observed in this study, where the addition of eggshells resulted in substantial improvement in the tensile strength and modulus of the pectin/eggshell bioplastic.

The DES was later added to pectin/eggshell as a plasticiser. The tensile stress and modulus are reduced from 33.30 to 16.47 MPa and 2754.00 to 774.00 MPa, with the addition of 1% DES to the pectin/eggshell. However, the addition of 1% DES caused the tensile strain to increase from 1.87% to 14.32%. The continual addition of DES from 1% to 3% has decreased the tensile stress from 16.47 to 2.18 MPa. A similar effect was observed on the modulus, which is reduced from 774.00 to 14.00 MPa with 1% to 3% DES. The opposite happened to tensile strain, which increased from 14.32% to 31.95% DES. The addition of plasticiser creates substantial intermolecular interaction between the polymer chains, preventing them from gathering close to each other, restricting the molecular chains to compact and cohesive strength in the sample. Thus, it can be concluded that DES has reduced the tensile stress of pectin/eggshell by subsequently weakening the hydrogen bonds between the pectin chains. Eggshells that caused the films to break after a certain force is applied. Muscat et al. [35], who previously used starch to make a film, stated that plasticisers diminish the strong intramolecular attraction between the starch chains. A similar

observation by Sanyang et al. [36] found that the tensile strength decreases with an increasing percentage of mixture glycerol/sorbitol/glycerol-sorbitol as the plasticiser increased from 15% to 45% on sugar palm starch films. However, the tensile strain value remains at the same range with 4% DES, which is 2.26 MPa. Similar results are observed for tensile strain and tensile modulus, i.e., constant at the addition of 4% DES. The addition of plasticiser did not significantly change the properties of bioplastic after 3%, indicating that at 3%, the liquid has swelled and filled up the free volume within polymer chains to prevent intermolecular interaction. Hence, the study only conducted only up to 4% of DES.

The biodegradability test was carried out to determine the weight loss of the pectin/eggshell after ten days in soil. The biodegradation process mainly depends on the moisture content and the presence of microorganisms in the ground. Figure 4 indicates the biodegradability behaviour in the weight loss of the bioplastic at a different DES percentage. All bioplastics show a continuous weight loss increase, with the bioplastic with 4% DES fully degraded (100%) on the third day and bioplastic with 1%, 2%, and 3% DES fully degraded on the fifth day. The pectin/eggshell composite without DES showed the highest percentage loss on the first day, but only 93% degraded on the fifth day and remained around 97% on the tenth day of the test. The higher percentage of DES concentration in bioplastic, led to a higher weight loss of the bioplastic. The bioplastic at 4% DES degrades faster than lower DES concentration. Kasmuri et al. [14] stated that the presence of the eggshell filler reduced the biodegradability rate since 95% of the eggshell is made up of calcium carbonate compounds, which mostly remained in the soil after the bioplastic had degraded. However, as proven by the tests, DES enhanced the biodegradability properties of bioplastic.

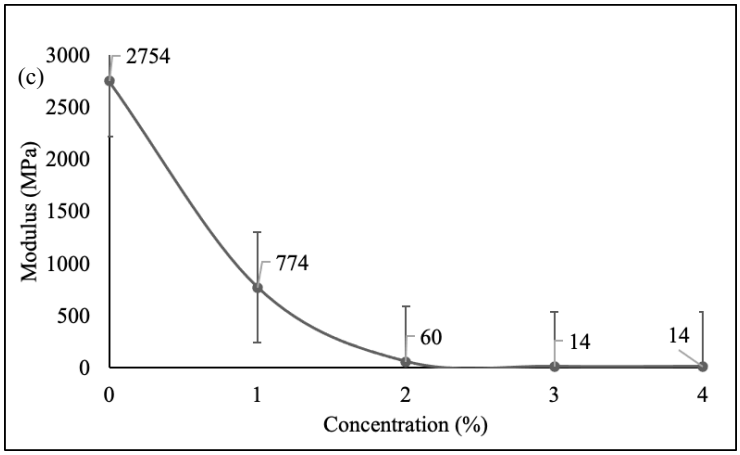


Figure 3. The properties of bioplastic in (a) tensile stress; (b) tensile strain and (c) modulus

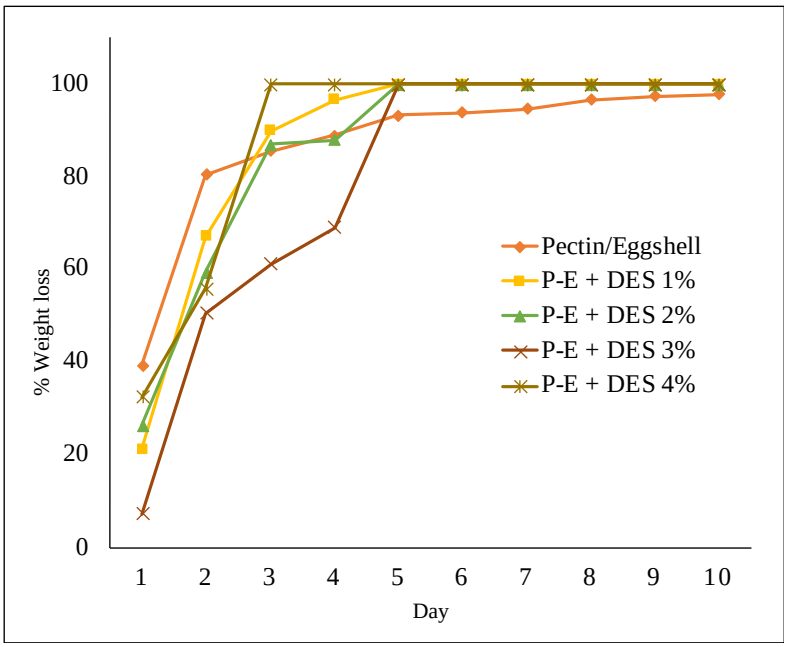

Figure 4. The percentage of weight loss of bioplastic in 10 days of biodegradability test in soil

Another biodegradability test was conducted in synthetic seawater. All bioplastics immediately swelled and curved when immersed in seawater. After one day in seawater, the pectin/eggshell bioplastic was fully degraded, but not the pectin/eggshell/DES bioplastics. Figure 5 shows the degradation of bioplastics in seawater. The result is contrary to the biodegradability test conducted in soil. In seawater, the bioplastic with a high DES concentration takes longer to degrade than those without DES. The inclusion of electrolytes from NaCl in synthetic seawater influenced bioplastic breakdown. According to Trindade et al. [37], ionic liquid shows the effect of salting out in salt solution. The same effect might be seen in the biofilm

containing DES. The added salt (NaCl) might compete with the ions in DES, causing the migration of NaCl molecules from the DES ions, decreasing the hydration and solubility of bioplastic-containing DES.

The analysis of water uptake was performed to measure the ability of bioplastic to absorb water with the addition of different concentrations (%) of DES. Figure 6 shows that the highest percentage of water uptake is at 1% concentration of DES, with 85% of water uptake. According to Suppakul et al. [38], the presence of hydroxyl group in plasticiser is strongly interacted with water molecules by forming hydrogen bonds. DES (choline chloride: malonic acid) consists of O-H bonds that interact directly with water, increasing the volume of the water uptake. However, when the percentage concentration of DES is more than 1%, the water absorption is reduced since the holding ability is weakened.

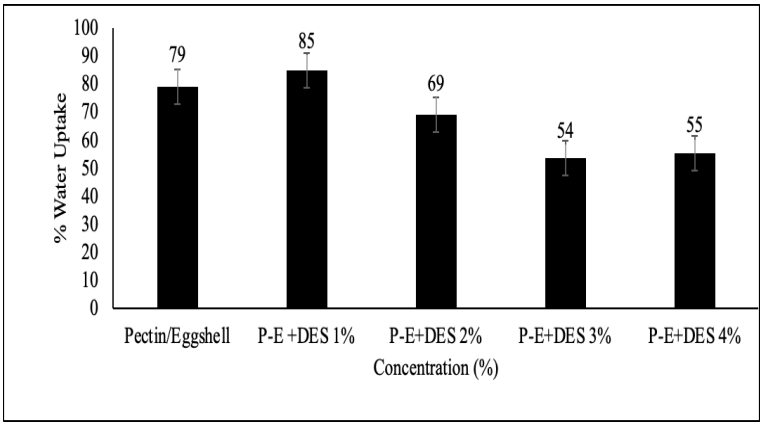

Figure 6. Percentage water uptake of bioplastics test in different concentration (%) of DES

Conclusion

The pectin/eggshell bioplastics with different concentrations of DES were successfully prepared. The eggshell and choline chloride: malonic acid are compatible with pectin, and no crystallisation occurred during the formation of biofilm. DES allowed the bioplastic to become more flexible by disrupting the polymer chains, causing an increase in elongation and a decrease in tensile strength of pectin/eggshell/DES. The higher concentration of DES leads to more flexibility and higher biodegradation in soil but with lower water uptake. These results indicated that

Choline chloride:malonic acid could be used as a potential plasticiser for pectin/eggshell bioplastic.

Abstract

Supramolecular interactions such as hydrogen bonding, π-π stacking, Van der Waals interactions, and metal-ligand are important in stabilising the structure of molecules. In order to determine the presence of supramolecular interactions in two novel compounds, 1,2-disubstituted cyclohexane amide ligands, namely 1,2-bis[*N,N'*-6-(3-pyridylmethylamido)pyridyl-2-carboxyamido]cyclohexane (L1) and 1,2-bis[*N,N'*-6-(4-pyridylmethylamido)pyridyl-2-carboxyamido]cyclohexane (L2) were successfully synthesised and fully characterised by FTIR, ^{1}H and ^{13}C NMR and mass spectrometry, while the molecular formula was determined by elemental analysis. X-ray crystallography revealed that the folded conformations of both ligands were stabilised by intramolecular N-H···O=C and N-H···N hydrogen bonds at the pre-organised amide moieties. The crystal's structure was stabilised by weak face-to-face π-stacking interaction or centroid-centroid π-stacking interaction involving the two pendant pyridine rings. In the crystal structure of one-dimensional coordination polymer, there are two intermolecular hydrogen bonding interactions (N-H···O=C, d = 2.094 Å, D = 2.946 Å and d = 2.090 Å, D = 2.938 Å, N-H···O angle = 161.52°) formed between the pre-organised NH amide donors of a molecule of L1 in one coordination polymer and the amide carbonyl group of a molecule of L1 in an adjacent polymer that leads to the formation of 2-D hydrogen-bonded sheets extend in the *ac* diagonal.

Abstrak

Interaksi supramolekul seperti ikatan hidrogen, susunan π-π, interaksi Van der Waals dan logam-ligan adalah penting dalam menstabilkan struktur molekul. Dalam usaha mengenalpasti kehadiran interaksi supramolekul dalam dua sebatian baharu, ligan amida sikloheksana 1,2-tertukar ganti, iaitu 1,2-bis[*N,N'*-6-(3-piridilmetilamido)piridil-2-karboksiamido]sikloheksana (L1) dan 1,2-bis[*N,N'*-6-(4-piridilmetilamido)piridil-2-karboksiamido]sikloheksana (L2) telah disintesis dan dicirikan sepenuhnya dengan FTIR, ^{1}H dan ^{13}C NMR serta spektrometri jisim, manakala formula molekul ditentukan melalui analisis unsur. Kristalografi

sinar-X menunjukkan bahawa konformasi bagi kedua-dua ligan distabilkan oleh ikatan hidrogen intramolekul N-H···O=C dan N-H···N pada kawasan amida separa tersusun. Struktur hablur juga distabilkan oleh interaksi lemah susunan muka ke muka atau titik pusat ke titik pusat di antara gelang aromatik piridina. Dalam struktur hablur polimer koordinatan satu dimensi, terdapat dua ikatan hidrogen intermolekul (N-H···O=C, d = 2.094 Å, D = 2.946 Å dan d = 2.090 Å, D = 2.938 Å, N-H···O sudut = 161.52°) yang terbentuk di antara NH amida dari molekul L1 dalam polimer koordinatan dan karbonil amida dari molekul L1 dalam polimer bersebelahannya dan menghasilkan lapisan 2-D ikatan hidrogen yang bersambung ke diagonal *ac*.

Introduction

Supramolecular chemistry is often defined as 'the chemistry beyond the molecule' [1]. This term was introduced by Jean-Marie Lehn who won the Nobel Prize in Chemistry in 1987 together with Donald J. Cram and Charles J. Pedersen. They received the prize for their contributions to the synthesis of shape-selective and ion-selective receptors, in particular, the development of selective 'host-guest' complexes. In broader terms, supramolecular chemistry is defined as the self-assembly of small molecular subunits into large aggregates *via* weak intermolecular forces or reversible covalent bonding. The interactions commonly involved in the self-assembly process are hydrogen bonds, π-π interactions (stacking of aromatic rings), Van der Waals forces, cation-interactions, and metal-ligand (M-L) interactions [2]. The order of strength for the intermolecular interactions from very weak to very strong is broadly as follows: hydrophobic/hydrophilic interactions, Van der Waals forces, H-bonding interactions, electrostatic forces and metal coordination [3].

In general, the intermolecular interactions are individually weak, but by using multiple weak intermolecular forces within the assemblies, robust structures can be generated. Besides, the dynamic nature of noncovalent interactions endows supramolecular polymeric systems with many fascinating properties and functions, such as reversibility, adaptability, self-healing, and stimuli-responsiveness [4]. Hydrogen bonding interactions are commonly employed in supramolecular chemistry [5]. Hydrogen bonding occurs between a proton donor attached to an electronegative atom such as O, N, S, F or C (D-H) and an acceptor (A). The donor is partially positive hydrogen while the acceptor is a partially negative atom with unshared valence electrons or polarisable π electrons. The strength of hydrogen bonds is typically around 20 kJmol^{-1}, but can even be as strong as 163 kJmol^{-1} as has been reported for the F···HF interaction [6,7]. Weak interactions involving π-systems such as π-stacking interactions (π···π) are observed in many supramolecular systems [8]. Other weak interactions involving π-systems are C-H···π, cation···π and anion···π interactions. The C-H···π interaction is classified as weak H-bonding and have similar properties to the weak hydrogen bonds. Cation···π interactions occur between metallic or organic cations and π-bonded systems of the molecule.

Open chain molecules such as amide, thiourea, and urea are of interest because intermolecular amide-amide hydrogen bonding can promote the fabrication of well-defined assemblies of supramolecular chemistry [9]. Furthermore, amide ligands with the presence of pyridyl as one of the outstanding N or O-donor organic linkers have been effectively selected because they can connect metal centres through their pyridyl groups or the amide groups [10]. Thus, in this research, two novel amide compounds containing 1,2-disubstituted cyclohexane spacer were prepared (Figure 1). Compounds 1,2-bis[*N,N'*-6-(3-pyridylmethyl amido)pyridyl-2-carboxyamido]cyclohexane (L1) and 1,2-bis[*N,N'*-6-(4-pyridylmethylamido)pyridyl-2-carboxyamido]cyclohexane (L2) were synthesised from a racemic mixture of *trans*-1,2-diamino cyclohexane in two steps. The incorporation of a cyclohexyl spacer was anticipated to limit the relative arrangements of the two 2,6-pyridine dicarboxamide moieties as compared to common approaches of using aliphatic alkyl chains spacer [11].

The advantages of the pyridyl-amide ligands are the amide groups with both N-H hydrogen donor and C=O hydrogen acceptor can enhance the formation of hydrogen bonds and supramolecular structures. The isomerism and flexibility of ligands play important roles in permitting guest molecules such as anions to interact with the host molecules by using weak hydrogen bonding. The presence of aromatic rings from 1,2-disubstituted cyclohexane amide moieties and pyridine pendant groups is important to achieve well-defined frameworks with higher stability contributed by the supramolecular interactions of π-π stackings. In a work by Yusof et al. [12] the conformation of cyclohexane derived compound was stabilised by intramolecular hydrogen bonds and intermolecular N-H···O and C-H···O hydrogen bonds, which led to centrosymmetric dimers arrangement [12].

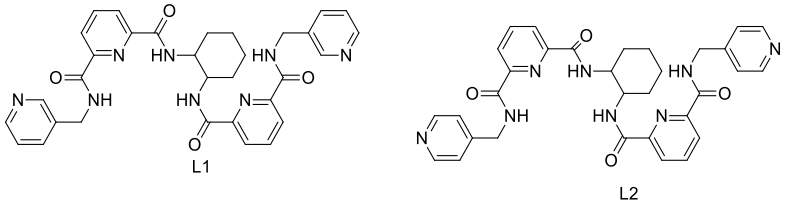

Figure 1. The structure of 1,2-bis[*N,N'*-6-(3-pyridylmethylamido)pyridyl-2-carboxyamido]cyclohexane (L1) and 1,2-bis[*N,N'*-6-(4-pyridylmethylamido)pyridyl-2-carboxyamido]cyclohexane (L2)

Materials and Methods

Synthesis of 1,2-bis[*N,N'*-6-(3-pyridylmethyl amido)pyridyl-2-carboxyamido]cyclohexane (L1)

1,2-bis[6-methoxycarbonyl)pyridyl-2-carboxyamido] cyclohexane (0.50 g, 1.1 mmol) and 3-aminomethylpyridine (0.22 mL, 2.3 mmol) were suspended in toluene (20 mL). The reaction mixture was heated at reflux for 72 hours, during which time a white solid precipitated. After cooling to room temperature, the solvent was removed in vacuo, the residue re-dissolved in dichloromethane (40 mL), washed with saturated aqueous sodium bicarbonate solution (2 × 100 mL), and the chlorinated extract was dried over magnesium sulphate. The solvent was removed in vacuum to give a sticky off-white solid. The solid was washed with diethyl ether, dried, and recrystallised from ethanol to give L1 as a white solid (0.55 g, 82%). Mp 250-252 °C. Anal. found: C, 64.19; H, 5.52; N 18.70. ($C_{32}H_{32}N_8O_4$) requires C, 64.84; H, 5.45; N 18.90%. ^{1}H (300 MHz; $CDCl_3$; Me_4Si) δ = 1.32 (2H, m, CH_2), 1.65 (1H, m, CH_2), 2.17 (1H, m, CH_2), 3.87 (1H, s, CH), 4.15 (2H, d, J = 11.43 Hz, CH_2), 7.23 (1H, m, pyH5), 7.82 (2H, m, pyH3, pyH4', pyH4), 8.28 (2H, m, pyH5'), 8.54 (2H, d, J = 4.81 Hz, pyH6'), 8.65 (2H, m, NH, pyH2') and 9.07 (1H, d, J = 8.38 Hz, NH). ^{13}C (75.1 MHz; $CDCl_3$; Me_4Si) δ = 23.1, 28.3, 45.1, 54.6, 123.9, 125.7, 125.9, 134.8, 136.7, 139.2, 148.1, 149.5, 149.9, 150.8, 161.1, 162.4. m/z (ES-MS) 592.2 (MH^+, 100), 593.6 (MH^+, 50%), 614.5 (MNa^+, 65%), 1204.2 ($M.H_2O+H)^+$, 30%). Selected IR bands (KBr disk, cm^{-1}): 3368 (m), 3267 (m), 2916 (s) 1627 (m), 1650 (s), 1527 (s), 1424 (m), 1306 (s). Crystals were obtained by slow evaporation of a methanol solution of L1 and copper nitrate.

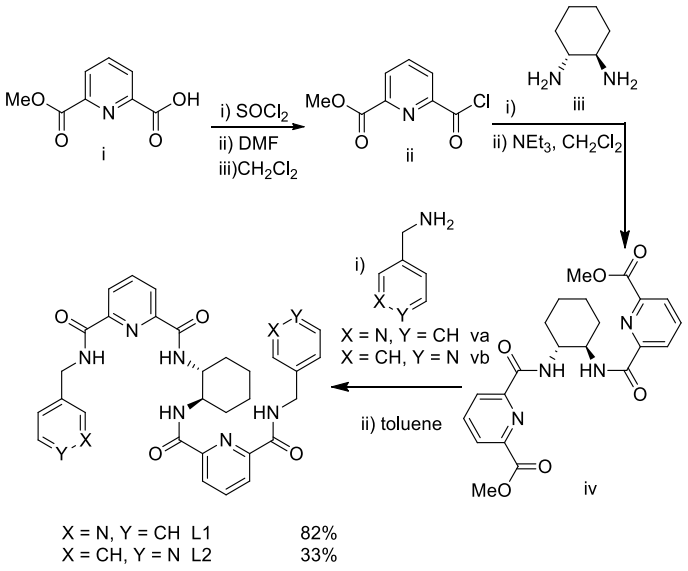
Synthesis of 1,2-bis[*N,N'*-6-(4-pyridylmethyl amido)pyridyl-2-carboxyamido]cyclohexane hydrate L2·H_2O (L2)

1,2-bis[6-methoxycarbonyl)pyridyl-2-carboxyamido]cyclohexane (0.52 g, 1.2 mmol) and 4-aminomethylpyridine (0.24 mL, 2.4 mmol) were dissolved in hot toluene (20 mL) and heated at reflux for 72 hours. During the course of the reaction, a yellow solid precipitated. The solvent was removed in vacuum to give a yellow solid. The solid was re-dissolved in dichloromethane (40 mL), washed with saturated sodium bicarbonate solution (2 × 100 mL), and the chlorinated layer was dried over magnesium sulphate. The solvent was removed in vacuum to give a yellow oil which was triturated with hot ethyl acetate (5 mL) to give a brown solid. This solid was purified by column chromatography, eluting with 1:9 methanol–CH_2Cl_2 to give L2·H_2O as a brown solid (0.24 g, 33%). Mp 220 – 225 °C. Anal. found: C,

64.67; H, 5.89; N, 18.90. ($C_{32}H_{34}N_8O_5$) requires C, 64.84; H 5.45; N, 18.91%. ^{1}H (300 MHz; $CDCl_3$; Me_4Si) δ = 1.43 (2H, m, CH_2), 1.93 (2H, d, *J* = 6.73 Hz, CH_2), 2.14 (2H, d, *J* = 13.29 Hz, CH_2), 3.77 (1H, s, CH), 4.72 (2H, m, CH_2), 7.25 (2H, m, pyH3', pyH5'), 7.74 (2H, m, pyH3, pyH5), 8.32 (1H, m, pyH4), 8.54 (2H, d, *J* =5.70 Hz, pyH2', pyH6'), 9.15 (1H, d, *J* = 6.25 Hz, NH) and 9.75 (1H, t, *J* = 6.40 Hz, NH). ^{13}C (75.1 MHz; $CDCl_3$; Me_4Si) δ = 22.5, 28.9, 45.6, 54.0, 124.3, 125.6, 125.9, 139.8, 147.3, 148.9, 149.2, 149.9, 160.5, 161.8. *m/z* ES-MS) 592.3 (MH^+, 100%), 593.1 (MH^+, 75%). Selected IR bands (KBR disk, cm^{-1}): 3282 (m), 2923 (s), 1652 (s), 1671 (s), 1529 (s), 1444 (m), 672 (s). Crystals were obtained by slow evaporation of a methanol solution of L2 and copper perchlorate.

Synthesis of $\{[CdBr_2(L1)_4]\cdot 4H_2O\}_n$

$CdBr_2$ (0.0026 g, 0.010 mmol) was dissolved in water (5 mL), heated for 5 minutes, before being added dropwise to a solution of L1 (0.0120 g, 0.020 mmol) dissolved in methanol (15 mL). The resulting slightly cloudy solution was heated for 45 minutes to re-dissolve the precipitate and was left to evaporate at room temperature. The solution afforded $\{[CdBr_2(L1)_4]\cdot 4H_2O\}_n$ as colourless crystals in low yields (0.009 g, 24%). Mp 230-235ºC.



Results and Discussion

Compounds 1,2-bis[*N,N'*-6-(3-pyridylmethyl amido)pyridyl-2-carboxyamido]cyclohexane (L1) and 1,2-bis[*N,N'*-6-(4-pyridylmethylamido)pyridyl-2-carboxyamido]cyclohexane (L2) were synthesised from a racemic mixture of *trans*-1,2-diaminocyclohexane in two steps (Scheme 1). To synthesise the ligand, firstly, pyridine-2,6-dicarboxylic acid monomethyl ester (i) was reacted with thionyl chloride to produce 6-(methoxycarbonyl)pyridine-2-carboxylic acyl chloride (ii). Then, compound (ii) was reacted with 1,2-diaminocyclohexane (iii) with a 2:1 mol ratio to provide 1,2-bis[6-methoxy carbonyl)pyridyl-2-carboxyamido]cyclohexane (iv). At the second step, precursor (iv) and 3-aminomethylpyridine were suspended in toluene and heated at reflux for approximately 72 hours to give 1,2-bis[*N,N'*-6-(3-pyridylmethylamido)pyridyl-2-carboxy amido]cyclohexane (L1) (Scheme 1). The crude product of L1 was obtained as an off-white solid after being isolated after re-dissolved in hot ethanol. The insoluble solids were removed by filtration, and the filtrate was left to evaporate to afford L1 as a colourless powder in an 82% yield.

Ligand L2 was prepared with a similar procedure, but the 3-aminomethylpyridine was replaced with 4-aminomethylpyridine. The coordination chemistry of these ligands was investigated with a range of late transition metals, including cadmium(II), copper(II), cobalt(II), silver(I), and zinc(II). The focus of this synthesis was to produce coordination polymers that display anion coordinating pockets (Figure 2). Compounds L1 and $L2\cdot H_2O$ were found to preferentially crystallise from solutions containing metal salts. It showed that the ligands were insoluble in the metal salts solution and caused limitations to obtain metal complexes. Rectangular block-shaped colourless crystals of both compounds were obtained from several different reactions and were suitable for X-ray crystallography.

The FTIR spectra for the three compounds showed distinctive peaks for *ν*(N-H), *ν*(O-H), *ν*(C=N), *ν*(C=O), *ν*(Cd-N), and *ν*(N-O). As for compound L1, the *ν*(N-H) stretching displayed a broad peak due to the water molecule and the weak hydrogen bond interactions interrupted the chemical changes. The low frequency (N-H) stretching appeared at 3267 cm^{-1} showing that the steric effect occurred with the presence of methyl located near the amino group [13]. Meanwhile, the *ν*(N-H) bending was interpreted at 1527 cm^{-1} because of the hydrogen bond donor. The strong frequency band at 2916 cm^{-1} referred to *ν*(C-H) aromatics vibration respective to the formation of sp^3 hybridisation. The carbonyl *ν*(C=O) band shifted to the low frequency at 1650 cm^{-1} suggested the involvement of hydrogen bonds formed between the amide moieties and pendant pyridyl group [14]. In the IR spectrum, the high frequency above 3000 cm^{-1} regions is a signature area for recognition phenyl C-H stretching vibrations. The region below 2000 cm^{-1} showed very sharp and strong peaks [15]. The spectrum of L2 showed a close resemblance of the absorbance pattern

compared with L1. Compound L2 observed the appearance of amide stretching, ν_{str}(N-H) at 3282 cm^{-1}. A significant stretching vibration of ν_{str}(C-H) aromatics band attributed at 2923 cm^{-1}. Nevertheless, the wavenumbers captured in both compounds for *ν*(C=O) amide revealed a significant difference. Compound L2 recorded the appearance of the carbonyl stretching at wavenumbers 1647 cm^{-1}. The compounds showed bands at 1529 cm^{-1} which was ascribed to the N-H bending.

Scheme 1. The synthesis of L1 and L2

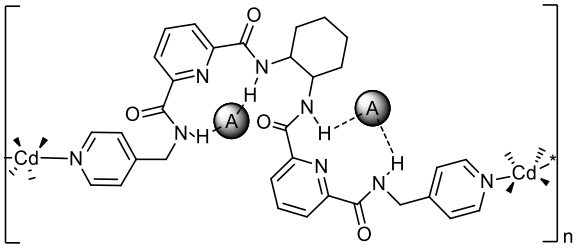


Figure 2. Coordination polymers that display anion coordinating pockets, where A in the circle represents anion

The ^{1}H NMR spectra of L1 were recorded in deuterated chloroform (Table 1). A signal that appears as a triplet at 9.09 ppm corresponding to the N-H protons of the pyridine core amide [16,17]. The signals for the cyclohexyl amide and the pendant pyridyl H2' are overlapped to give a broad singlet at 8.65 ppm. Another two signals (H6' at 8.54 and H5'at 8.28 ppm) were assigned to the pendant pyridine protons H6' and H5', while the multiplet near 7.82 ppm corresponded to the overlap between one triplet and doublets from the pyridine carboxamide H4 proton and the H4' of the pendant pyridine ring. The nearby doublet was assigned as the H3 and H5 hydrogen atoms from the pyridine core. The multiplets at 4.15 ppm arise from the CH_2 protons from the methylene linker adjacent to the pyridine rings. The cyclohexane protons are doublets that appear upfield at 3.87, 2.17, 1.65 and 1.32 ppm. The ESI-MS obtained on a methanol solution of

L1 revealed peaks for the parent ion $[L1+H]^+$ at m/z 591.2. Meanwhile, a peak at m/z 1204.2 corresponded to the hydrated dimeric species, $[(L1)_2 \cdot H_2O+H]^+$, while a hydrated trimeric species $[(L1)_3 \cdot H_2O+H]^+$ was observed at m/z 1793.2 in low relative abundance. There is also a peak observed for a sodium-containing ion, $[L1+Na]^+$, at m/z 614.5 (25%).

Based on the conditions employed for the synthesis of L1, the reaction of 6-(methoxycarbonyl)pyridine-2-carboxylic acyl chloride with a greater than two-fold excess of 4-aminomethylpyridine gave L2. Similar to the synthesis of L1, the reaction was heated at reflux for approximately 72 hours, and the formation of the product was monitored by TLC and NMR spectroscopy. Compound L2 was isolated by flash column chromatography techniques using the mixture of dichloromethane-methanol (9:1) as the eluting solvent system. Unfortunately, L2 was isolated in a much lower yield (33%) compared to L1. This is a consequence of the reduced nucleophilicity of the amine nitrogen compared to the 3-substituted precursor, as reported by Ikawa et al., 2011 [18]. Elemental analysis of the product obtained supports the isolation of the hydrate, $L2 \cdot H_2O$. In the ^1H NMR spectrum of $L2 \cdot H_2O$, the amide protons were observed downfield compared to L1, with a doublet at 9.75 ppm and a doublet at 9.15 ppm. The remaining signals between 7.25-8.54 ppm corresponded to the protons from the pyridine ring and the pyridine core. The methylene linker had a resonance at 4.72 ppm, while the cyclohexane protons showed signals at 3.77, 2.14, 1.93, and 1.43 ppm. The mass spectrometry indicated the presence of a dominant molecular ion corresponding to $[L2+H]^+$ at m/z 592.3 (100%).

X-ray crystallography

Crystal structure of L1

The particular crystals of L1 studied here were readily obtained from a methanol solution of copper nitrate and L1, consistent with the poor solubility of these compounds. Compound L1 crystallises in the triclinic space group *P*-1 with one molecule of L1 in the asymmetric unit. The structure reveals that this compound retained the two pre-organised amide hydrogen bond donor regions in the anticipated conformation (Figure 3), but as observed in molecule L1, these were arranged to form two separate pockets rather than one larger pocket. This arrangement is attributed to the planar arrangement of the substituents on the cyclohexane ring at the 1 and 2 positions.

In the conformation of L1 observed in the crystal structure, it appears there were intramolecular N-

H···O=C and N-H···N hydrogen bonds that stabilised the folded conformation. Figure 3 shows these hydrogen bonds have the following distances, N15-H15···O14 (*d* = 2.201 Å, *D* = 2.953 Å), N49-H49···O14 (*d* = 2.333 Å, *D* = 3.157 Å), N49-H49···N41 (*d* =2.308 Å, *D* = 2.697 Å), and N15-H15···N41 (*d* = 2.251 Å, *D* = 2.663 Å). The N-H···N angles are 106.78° and 108.41°, respectively.

Figure 4 shows that several intermolecular interactions were responsible for the formation of a dimeric arrangement of L1 in the solid state. The dimer was stabilised by four N-H···O=C hydrogen bonds between each molecule of L1 (N12-H12···O17, *d* = 2.158 Å, *D* = 3.000 Å; and N29-H29···O17 *d*= 2.111 Å; *D* = 2.951 Å).

The structure was further stabilised by π-π stacking interactions between the pyridine rings [19]. In the dimer, the pendant pyridyl group and the central pyridine core interact in an edge-to-face interaction, in which the C-H···π(centroid) distance is 2.912 Å. Adjacent dimers were then further involved in the π-stacking interactions involving one 2,6-pyridine dicarboxamide core of each molecule of L1 (Figure 5). The two pyridine cores formed a weak face-to-face π-stacking interaction (centroid-centroid distance 4.20 Å; angle 47.46°; centroid offset 1.32 Å). This ultimately resulted in a 1-D chain-like arrangement of the dimers.

Crystals of L2 were obtained from a methanol solution of copper perchlorate and compound L2. Like compound L1, compound L2 also crystallised in the triclinic space group *P*-1 but with two molecules of compound L2 in the asymmetric unit. The two molecules of L2 have similar conformations, with the major distinction between the two molecules being differences in bond lengths and angles. As observed in compound L1, intramolecular hydrogen bonding (*d* = 2.249-2.445 Å; N-H···N angles = 107.7 and 105.60°) pre-organised the NH functionalities of the compound to provide two anion pockets (Figure 6).

Like L1, one of these pockets was occupied by carbonyl oxygen of the other 2,6-pyridine dicarboxamide moiety (N-H···O, *d* = 2.380 Å ; *D* = 3.234 Å). Once again, intermolecular hydrogen bonding between the carbonyl oxygen (N-H···O) (*d* = 2.107 Å and *D* = 2.135 Å) and the pre-organised amide led to the formation of a dimer in the solid-state (Figure 7). Both molecules in the asymmetric unit demonstrated the same hydrogen bonding motifs with slightly different hydrogen bond distances (Table 2). One of the dimers had N-H···O hydrogen bond lengths of *d* = 2.109 - 2.137 Å, while the second dimer had hydrogen bond lengths of 2.106-2.153 Å. As observed in compound L1, the structures were also stabilised by intermolecular π-π stacking interactions. In the crystal packing, compound L2 was stabilised a centroid-centroid π-stacking interaction involving the two pendant pyridine rings (centroid-centroid distance 3.731 Å). The presence of excessive hydrogen-bonds networks in the compounds explains the huge range in the melting points for both compounds L1 and L2.

Crystal structure of CP-L1

Crystals of $\{[CdBr_2(L1)_2]\cdot 4H_2O\}_n$ were obtained from a methanol-water solution of L1 and cadmium bromide upon slow evaporation in 24% yield. Complex $\{[CdBr_2(L1)_2]\cdot 4H_2O\}_n$ was crystallised in the triclinic space group *P*-1 with one ligand L1, one cadmium atom (on a centre of inversion), two water molecules, and one bromide in the asymmetric unit (Figure 8). The cadmium atom adopts an octahedral coordination environment, with two bromide atoms in the axial positions and the equatorial positions occupied by four pyridyl donors from four separate molecules of L1. The Cd-N bond length is 2.453(4) Å and the Cd-Br bond length is 2.6805(5) Å, which is typically observed [20]. The Cd-Br bond distance was approximately 0.08-0.1 Å longer than the Cd-Br distance in compound 4.27, while the Cd-Cd distance in this compound is 16.765 Å.

The extended structure of compound CP-L1 is shown in Figure 9. Within the ligand, the pendant 4-pyridyl rings twisted backwards and forward relative to the 1,2-cyclohexane core with an -N-CH_2-CH_2-N- torsion angle of 56.3(2)° (Figure 9). This enabled the ligand to coordinate with two different cadmium centres which are also linked by a second molecule of L1.

Each cadmium is coordinated by four molecules of the ligand to generate a necklace-type 1-D coordination polymer. This coordination polymer was also

constructed from a dinuclear metallo-macrocylic repeating unit (Figure 9). Two types of ligand derived hydrogen bonding interactions are responsible for the internal conformation of the coordination polymers and the packing of adjacent 1-D coordination polymers in the solid-state. In the inter-polymer packing there are two intermolecular hydrogen bonding interactions in (N-H···O=C, d = 2.094 Å, D = 2.946 Å and d = 2.090 Å, D = 2.938 Å, N-H···O angle = 161.52°) formed between the pre-organized NH amide donors of a molecule of L1 in one coordination polymer and the amide carbonyl group of a molecule of L1 in an adjacent polymer (Figure 10(a)). The intermolecular hydrogen bonding led to the formation of 2-D hydrogen bonded sheets of the 1-D coordination polymers that extended in the *ac* diagonal (Figure 10(b)). Internally, each ligand within the coordination polymer adopts a conformation whereby the amide C=O forms a moderately strong N-H···O=C intramolecular hydrogen bonding interaction (d = 1.862 Å, D= 2.911 Å). This blocked one of the anion binding pockets of the ligand (Figure 10 (a)). In the 2-D crystal packing, the 1-D coordination polymers in each 2-D layer form C-H···π stacking interactions with 1-D coordination polymers in adjacent layers. These interactions occur between the pendant pyridyl rings of molecules of L1 in the adjacent layers (C-H-centroid distance 2.73 Å; angle 95.30°, centroid offset 1.39 Å Figure 10 (c). Weak intramolecular hydrogen bonding interactions of CP-L1 is shown in Table 3 while crystal data for CP-L1 is shown in Table 4.

Conclusion

In conclusion, two new 1,2-disubstituted cyclohexane amide ligands and one-dimensional coordination polymer were successfully prepared. L1 and L2 still maintained the pre-organisation of the 2,6-pyridine dicarboxamide in the solid states. X-ray crystallography also revealed that these three compounds crystallised in a triclinic crystal system with space group *P*-1. Several supramolecular interactions such as intramolecular and intermolecular hydrogen bonding interactions, π-π stacking interactions, C-H···π stacking interactions, and metal to ligand interactions were observed in the crystal structure in order to form a stable molecular architecture.

Abstract

Pesticide detection for organic produce authentication requires laboratory work involving sample testing, which is generally arduous and time-consuming. In this study, a simple and reliable technique to produce an instant result for the pesticide screening of organic chili was developed, using attenuated total reflection-Fourier transform infrared (ATR-FTIR) spectroscopy. The resultant spectra observed in the region between 600-1800 cm^{-1} were further analyzed using principal component analysis (PCA) and orthogonal partial least square-discriminant analysis (OPLS-DA). Accordingly, the outcomes underline the potential for distinguishing chili samples sprayed with pesticides, such as cypermethrin, fenobucarb, and malathion, versus their organic counterparts. Furthermore, the models constructed by OPLS-DA were capable of classifying chili samples, yielding high-classification rates ranging between 91.67-100%. Thus, ATR-FTIR combined with chemometrics may be utilized as a potentially reliable screening tool for 'front-line' organic produce screening, where only flagged samples need to undergo further confirmation testing.

Abstrak

Pengesanan racun perosak untuk tujuan pengesahan hasil organik memerlukan kerja makmal yang melibatkan ujian sampel, yang biasanya sukar dan memakan banyak masa. Dalam kajian ini, satu teknik yang mudah dan berkesan dijalankan dengan menggunakan kaedah spektroskopi inframerah transformasi Fourier-pantulan keseluruhan dikecilkan (ATR-FTIR) bagi tujuan saringan racun perosak untuk sayuran cili organik. Spektrum yang dihasilkan dalam lingkungan antara 600-1800 cm^{-1} dianalisis dengan lebih lanjut dengan analisis komponen prinsipal (PCA) dan analisis ortagonal kuasa dua terkecil separa-diskriminan (OPLS-DA). Hasil kajian menunjukkan potensi yang baik dalam membezakan sampel cili yang disembur dengan racun perosak seperti cypermethrin, fenobucarb, dan malathion daripada sampel organik. Model yang dibina oleh OPLS-DA dapat

mengklasifikasikan sampel cili dengan kadar klasifikasi yang tinggi dalam lingkungan antara 91.67-100%. Oleh itu, penggabungan spektroskopi ATR-FTIR bersama aplikasi kimometrik dapat digunakan sebagai alat saringan yang berpotensi tinggi untuk pengesahan hasil organik, di mana hanya sampel yang dikenal pasti sahaja perlu menjalani ujian pengesahan dengan lebih lanjut.

Introduction

The demand for organic fruits and vegetables is growing in domestic and global markets alike, following consumers perceiving them as a healthier, safer, and more environmentally friendly option than non-organic types. Subsequently, there people have become increasingly apprehensive about the safety of the food that they consume on a daily basis. Accordingly, pesticide-free production is one of the most important factors influencing consumer preference for organic food options. Contrary to popular belief, however, some pesticides are permitted in organic farming as long as they have natural substances, such as hydrogen peroxide, lime sulfur, and copper sulfate, as ingredients [1]. Besides this, certain fairly low-risk synthetic pesticides are allowed in limited circumstances to manage pests and weeds, whereby their use markedly differs from the approach employed in non-organic farming.

It should be noted that organic fruits and vegetables may contain residues of synthetic pesticides, due to drift from neighboring non-organic farms or to irrigation contamination, originating at streams and groundwater polluted by synthetic fertilizers and pesticide runoff. According to the U.S. National Organic Program, the U.S. Environmental Protection Agency defines a level of tolerance in which organic claims are allowed for products containing synthetic pesticide residues as no more than 5% of said specified tolerance level [1]. In general, major manufactured pesticides are classified based on their chemical composition; examples include carbamates and dithiocarbamates, organophosphorus, and pyrethroids [2]. Malathion, an organophosphate insecticide, is especially prevalent as one of the oldest and widely-used active ingredients for pest control in fruits and vegetables [3]. Cypermethrin belongs to the class of pyrethroid insecticides, which are more effective and less toxic compared to organophosphates. Fenobucarb is a carbamate insecticide extensively implemented in controlling plant hopper, thrips, aphids, and whiteflies.

The increased utilization of pesticides has been associated with various health and environmental effects. Hence, maximum residue limits (MRLs) are defined by respective countries to monitor the level of pesticide chemical residues allowable in their food crops. The MRL represents the highest level of pesticide residue legally permitted in food crops [4]. In particular, the Malaysia Food Regulation 1985 in the 16th Schedule (Regulation 41) provides the MRLs for selected pesticides, as shown in Table 1. Standard techniques used for pesticide detection in fruits and vegetables, such as gas chromatography and high-performance liquid chromatography (HPLC), are often time-consuming and laborious. These methods necessitate sample destruction, lengthy test duration, controlled test conditions and expert lab skills, rendering them unsuitable for on-site analysis [5].

Therefore, a robust and quick technique capable of providing immediate results during organic produce screening for pesticides is currently necessary in the commercial world, particularly for the fast-moving consumer goods (FMCG) industry. As an alternative technique, attenuated total reflection-Fourier transform infrared (ATR-FTIR) spectroscopy represents an attractive option for pesticide detection in organic produce authentication, due to its non-destructive capability and portability, as well as its reliability in producing accurate results in a matter of minutes when combined with chemometrics [6]. Previous studies have shown that ATR-FTIR could be used to confirm the presence of organophosphate insecticides in vegetables [7]. Furthermore, data from several works also demonstrate the potential of ATR-FTIR, combined

with chemometrics, to solve adulteration and authentication issues for various food products, such as green tea, rice, and fruits [8, 9, 10].

Principal component analysis (PCA) is the most widely-used statistical procedure for interpreting large spectral data. As an unsupervised technique, it provides an overview of any patterns and groupings observable in studied samples, via a graphical representation in the form of 2D or 3D scatter plots [10]. However, it is not always possible to obtain differentiating features and adequate information directly from PCA models. On the other hand, supervised techniques such as orthogonal partial least squares-discriminant analysis (OPLS-DA) are often utilized to build classification models for further exploration of the data generated [11]. The combination of PCA and OPLS-DA may offer remarkable information for the classification and discrimination of the considered samples.

Chili (*Capsicum annuum L. var Kulai*) is one of the most widely cultivated and consumed vegetables in Malaysia [12]. The chili plant is highly susceptible to many diseases caused by insects, such as mites and thrips, resulting in the routine use of chemical insecticides to combat the problem. Therefore, this study aims to develop a screening method for the detection of pesticide presence in chili samples by using ATR-FTIR combined with chemometrics (PCA and OPLS-DA). The developed procedure can, thus, be utilized as a 'front-line' detection tool by food regulators prior to advanced laboratory testing, reserved only for flagged samples, resulting in cost and time-saving opportunities.

Table 1. The maximum residue limit for selected pesticides used in chili plant

Pesticide	**Molecular Formula**	**Classification**	**Maximum Residue Limit (mg/kg)**
Malathion	$C_{10}H_{19}O_6PS_2$	Organophosphate (OP)	2
Cypermethrin	$C_{22}H_{19}Cl_2NO_3$	Synthetic Pyrethroid (SP)	2
Fenobucarb	$C_{12}H_{17}NO_2$	Carbamate	0.5

Materials and Methods

Sample preparation

Three types of pesticides that were selected contained different concentrations and were in liquid form. The commercial pesticides, namely Wesco Malathion 57 (malathion, 57% w/w), Wesco Cyperin 550 (cypermethrin, 5.5% w/w), and Hoppergone (Fenobucarb, 50% w/w), were purchased from Volcano Agribusiness Sdn. Bhd. These pesticides were selected as they are frequently quantified in fruit and vegetable samples, and can be easily obtained from pesticide distributors [13]. The pesticides were diluted using distilled water, according to commercial formulations under Pesticides Act 1974, to replicate actual field conditions (Table 2). The prepared solutions were kept at room temperature and used within one week.

A total of 120 samples of organic chili (*Capsicum annuum L. var Kulai*) were purchased directly from a local certified farmer in Pulau Pinang. The farmer was aware of the aim of this study; hence the chance of including any fraudulent or inauthentic organic products in the dataset is minimized. The chili samples were left unwashed and randomly divided into four groups. In the first group, the chili samples were not treated and marked as group O (Organic). In the second, third and fourth groups, the chili samples were evenly sprayed with different pesticide solutions and marked as group M (Malathion), C (Cypermethrin), and F (Fenobucarb), respectively. All samples were left to dry for 2 hours so that the pesticide solution was evenly distributed over the surface of the chili prior to analysis.

Infrared spectroscopy measurements

The chili samples were scanned using a Perkin-Elmer Spectrum ATR-FTIR spectrophotometer. The equipment was connected to computer software

(Spectrum for Windows, Perkin-Elmer), and mid-infrared spectra were recorded in the wavenumber range of 4000-600 cm^{-1}, with a spectral resolution of 4 cm^{-1} at 16 scans. To simulate the on-site pesticide screening analysis, the whole chili was placed on the sample stage for direct measurement with no sample preparation. As a reference, the background spectrum of air was collected. Prior to each analysis, the ATR crystal surface was thoroughly cleaned with ethanol and wiped with clean tissue paper. The spectra for each of the three pesticide samples (cypermethrin, fenobucarb, and malathion) were also measured in ATR mode. Spectrum acquisition of each sample was repeated in triplicate under the same conditions, and an average spectrum was obtained.

Data pre-processing and chemometrics

Experimental data were subjected to chemometrics using SIMCA software (version 14.1, Umetrics, Sweden), wherein both unsupervised PCA and supervised OPLS-DA were performed for sample classification. The usual spectral region for mid-IR (4000-600 cm^{-1}) was observed and taken into account for the analysis; however, the fingerprint region between 1800-600 cm^{-1} was scrutinized further, due to this being the primary region where biomolecules absorb IR radiation [14]. Spectral pre-processing, such as first derivative transformation with third-degree polynomial, and standard normal variate (SNV) was applied to the IR data matrices to increase the predictive ability and accentuate any subtle features [15]. All variables were scaled and normalized using UV-scaling (unit variance) and log-10, respectively. The assessment of PCA's ability to detect and discriminate organic from pesticide-contaminated chili samples was made based on score plots observations, in which the principal component (PC) score plots were constructed using the first two resultant principal components. The OPLS-DA models were presented with several components based on the predictive performance from the internal sevenfold cross-validation by default, as suggested by the SIMCA software.

Table 2. Pesticide preparation according to commercial formulations

Pesticide	Amount Taken (mL)	Total Volume (solvent, mL)
Wesco Cyperin 550 (cypermethrin 5.5% w/w)	5	1000
Hoppergone (fenobucarb 50% w/w)	1.5	1000
Wesco Malathion 57 (malathion 57% w/w)	1.5	1000

Results and Discussion

ATR-FTIR spectral analysis of organic chili

The mid-FTIR spectrum of organic chili in the range of 4000-600 cm^{-1} is shown in Figure 1. As expected, the spectrum showed absorption bands corresponding to the vibrations of functional groups belonging to carotenoids, phenolic compounds and ascorbic acid, which corresponded to previously reported studies [16, 17]. A strong absorption band was observed at 3342.05 cm^{-1}, corresponding to characteristic stretching vibrations of O-H from amino acids. The small sharp cluster of peaks at 2900-2800 cm^{-1} was assigned to the C-H stretching band of methyl and methylene groups from the carboxylic acid structure. The medium-intensity peak at 1635 cm^{-1} corresponded to the C=O stretching, indicating the characteristic amide I band, while a low-intensity band at 1454 cm^{-1} was observed for the characteristic bending vibrations of C-H. The presence of polyphenols could be identified by the intense bands in the region of 1260-1180 cm^{-1}, caused by the stretching vibration of C-C-O and low-intensity C-H bending [16]. The functional groups associated with the absorption peaks identified from the spectra of the organic chili samples are summarized in Table 3.

ATR-FTIR spectral analysis of pesticides

The IR spectra of the three pesticides were also recorded to identify functional groups with unique absorption bands. As depicted in Figure 2, the green spectrum represents cypermethrin, the blue spectrum represents fenobucarb, and the red spectrum represents malathion. Each peak was contributed by a particular functional group present in the compound. In general, the pesticides revealed similar spectral patterns with a minimal shift of absorption band positions and intensity across the samples.

The C-H stretching in the two benzene rings of cypermethrin contributed to the stronger peaks within the wavenumber range of 3080–2820 cm^{-1}; thus, distinguishing this from the other two pesticides. The other, stronger peak which was more obvious for cypermethrin is the peak at 806 cm^{-1}, which is contributed by the C-Cl functional group, present in cypermethrin but not in fenobucarb or malathion. The peaks contributing to the fenobucarb cluster were mainly the N-H stretching at 3346 cm^{-1}, C=O stretching at 1718 cm^{-1}, C-O-C stretching at 1216 cm^{-1}, and C-N stretching at 1183 cm^{-1}. Malathion has a strong peak at 1013 cm^{-1}, mainly due to the presence of two P-O-C stretches. The P-O-C stretching was only observed in malathion as compared to cypermethrin and fenobucarb. Another prominent strong peak present only in malathion was observed at 654 cm^{-1}, mainly due to S=P-S-C stretching.

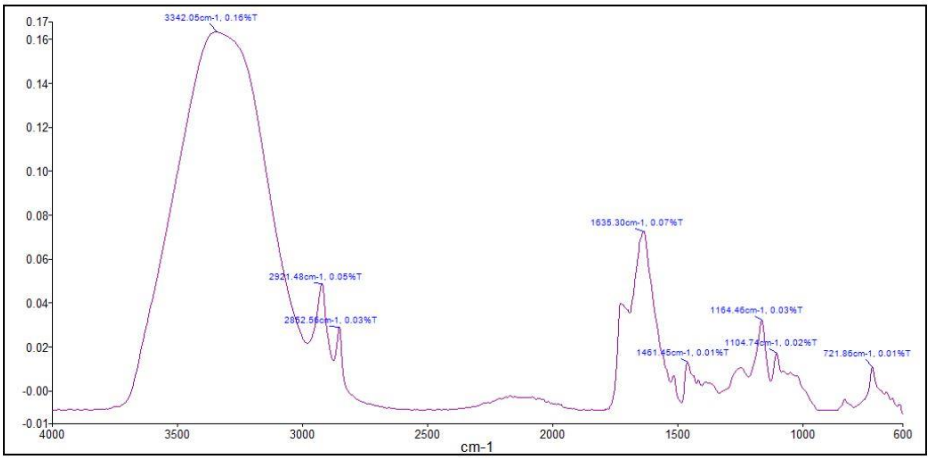

Figure 1. The FTIR spectrum of chili at wavenumber 4000-600 cm^{-1}

Table 3. The functional groups associated with absorption peaks identified in organic chili

Absorption Peak (cm^{-1})	**Possible Functional Group**
3342.05	O-H stretching from amino acids
2921.48 and 2852.56	C-H stretching (from CH_3 and CH_2 groups)
1635.3	C=O stretching of amide I band
1461.45	C-H bending
1164.46	C-C-O stretching
1104.74	C-H bending

Principal component analysis

Prior to analysis, the IR spectra of the chili samples were pre-processed to minimize data variation and overcome the dominating effect of strong peak absorbance over weaker absorbance intensity [18]. Selecting a proper spectral range may be beneficial in reducing the computational burden of the software in terms of variables. Hence, the spectral region 1800–600 cm^{-1} was selected for further analysis, due to the high positive correlations between changes in the composition and spectral response observed, which may be due to biomolecules' absorption of IR radiation occurring primarily in this region [14, 17].

As an unsupervised method, PCA was adopted for the initial exploratory data analysis, whereby the score plot reflected separation among the samples. PCA was applied to the dataset of 120 chili samples to detect outliers, as well as to predict possible patterns and trends of clustering. For a visual illustration and understanding, different classes of organic and pesticide samples were mapped and labeled with representative symbols. Figure 3(a) shows the score scatter plot for PCA overview using the first two principal components, PC1 (as in t1) and PC2 (as in t2). Most samples fell within Hotelling's T2 ellipse at

95% confidence intervals, with a few outliers. The combination of PC1 and PC2 explained 43.6% of the variation in the dataset. However, the organic and pesticide-contaminated samples could not be distinctly classified into two clusters, as some samples overlapped with each other. The presence of outliers may indicate experimental error due to sample preparation. Direct measurement of the samples without additional preparation may cause possible background noise, leading to inconsistencies.

PCA was performed further by plotting the individual score plots of each pesticide and organic sample, to allow better qualitative discrimination between sample groups. Results showed that a distinct separation into two clusters was observed in each of the scatter plots, meaning that PCA adequately captured relevant information within the dataset. As illustrated in Figure 3(b), the organic samples were well-segregated from cypermethrin-containing samples, with clearly defined clusters along PC2. When both PC1 and PC2 were combined, they contributed about 56.7% of the total variance, with some samples overlapping with each other. As for the outcome of PCA on organic samples and fenobucarb-containing samples (Figure 3(c), the result shows that the samples were well-distinguished, also mostly based on PC2. When both PC1 and PC2 were combined, these accounted for 57.5% of the total variance. Likewise, as shown in Figure 3(d), partially overlapping samples were observed in the score plot of organic and pesticide malathion-sprayed samples, with a total variance of 56.7%. This may be due to a low concentration of spiked malathion, making it difficult to differentiate between the IR spectra of both organic and pesticide-containing samples.

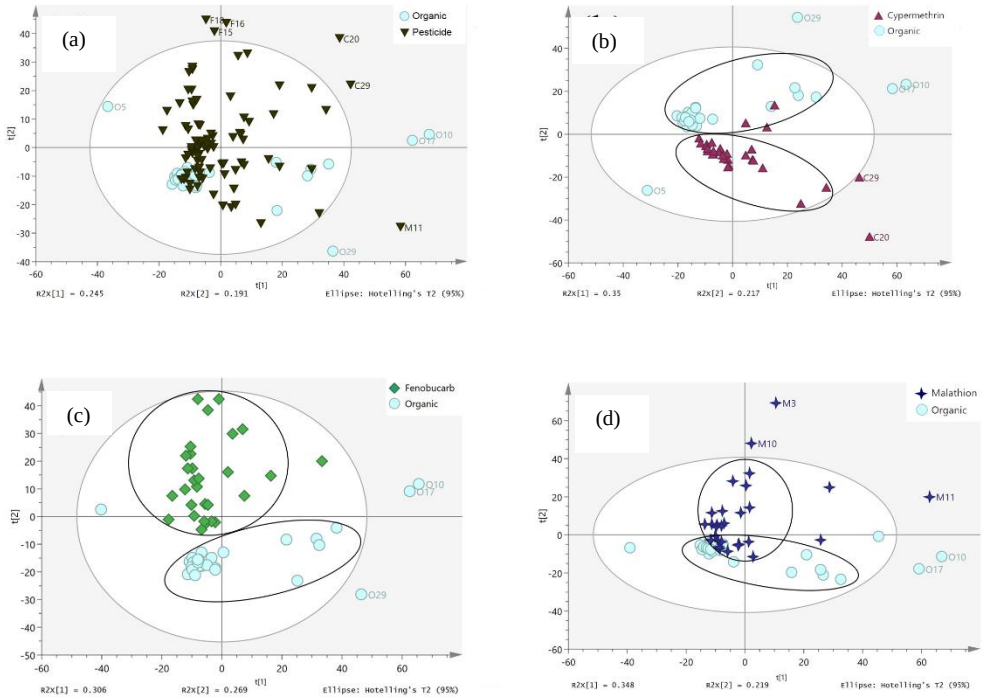

Figure 3. PCA score scatter plot based on PC1 and PC2 (a) organic and pesticide-contaminated samples, (b) organic and cypermethrin-contaminated samples, (c) organic and fenobucarb-contaminated samples, and (d) organic and malathion-contaminated samples

PCA was also performed on the IR spectra of neat cypermethrin, fenobucarb and malathion samples, to investigate the main variance among the three pesticides used in this study (Figure 4). The first two principal components explained 90.6% of data variation and showed observable clustering of the samples, according to the main active compound for the three pesticides.

Predictive models

As PCA had successfully distinguished the dataset into the observable cluster, a supervised OPLS-DA method was later performed using each dataset separately: organic with cypermethrin, organic with fenobucarb, and organic with malathion. The original dataset was divided into a training set and testing set, using an 80:20 ratio. Initially, 80% of the samples from the original dataset (24 samples from each class) were randomly selected as a training dataset, to build the predictive models aimed at differentiating organic and pesticide-contaminated chili samples. Classification rates were obtained from the internal sevenfold cross-validation by default in the SIMCA software. The remaining 20% of the samples (6 samples from each class) were set aside as an external validation test set, to evaluate the robustness of the predictive models. The overall efficiency of the models was assessed by observing the numbers of correctly and incorrectly assigned members of different classes for training and test datasets.

The score scatter plots displayed the samples by specific color-coded classes are shown in Figure 5. The four classes in the training set were organic chili (denoted as Organic Training Set), and organic chili that had been sprayed with pesticides: cypermethrin (denoted as Cypermethrine Training Set), fenobucarb (denoted as Fenobucarb Training Set), and malathion (denoted as Malathion Training Set). The scatter plots in OPLS-DA showed better separation between classes compared to PCA. As depicted in Figure 5, the samples in each cluster were more tightly grouped in OPLS-DA than in PCA.

The predictive model for organic and cypermethrin has a fitness of data (R^2) of 64.6%. The predictive ability (Q^2) was above moderate at 79.6%, with a total sum of variation ($R^2(Y)$) of 84.2%. The model for organic and fenobucarb has an R^2 of 62%, high predictive ability (Q^2) of 80.3%, and $R^2(Y)$ of 85.8%. For organic and malathion-contaminated samples, the predictive model has an R^2 of 78.1%, moderate Q^2 of 70.6%, and $R^2(Y)$ of 88.9%. The cross-validated analysis of variation (CV-ANOVA) for cypermethrin, fenobucarb, and malathion models reported *P*-values of 1.10×10^{-12}, 5.70×10^{-13}, and 3.15×10^{-7}, respectively. The results showed that the discrimination between organic and pesticide-contaminated chili samples was significant ($p < 0.05$).

The classification of the samples has been accurately performed (100% accuracy) for organic and cypermethrin models (Table 4), as well as organic and fenobucarb models (Table 5). In the case of organic and malathion models (Table 6), a single sample was misclassified into the organic class (91.67% accuracy), while all six organic chili samples fell accurately into their right cluster (100% accuracy). These results demonstrate the reliability of the models as a primary screening tool to detect the presence of pesticides in organic produce. It may help food regulators to ascertain whether the fruits or vegetables require further testing using more sophisticated instrumentation.

Conclusion

The combination of ATR-FTIR and chemometrics can be utilized for preliminary screening of pesticides in organic produce, yielding benefits such as high speed, non-invasiveness, and simplicity of sample preparation. In general, distinguishing each pesticide was possible according to its functional groups, as analyzed by ATR-FTIR. Cypermethrin, for example, revealed stronger peaks contributed by C-H (from benzene rings) and C-Cl functional groups, whereas fenobucarb was identifiable by N-H stretching, C-O-C stretching, and C-N stretching. Malathion had strong peaks contributed by two P-O-C stretches and S=P-S-C stretching. The results also showed clear discrimination and classification between organic and pesticide-contaminated chili samples through PCA, and can be considered as a successful attempt, despite a few outliers observed in the process. With the use of OPLS-DA, it is possible to classify samples according to organic and pesticide-contaminated classes and predict

the residues of unknown pesticides. This study serves as an approach for pesticide screening of organic produce, thereby suggesting further investigation, based on the detection limit of pesticide residues for various fruit and vegetables, in ensuring more robust classification models.

Abstract

Endophytes including bacteria and fungi produce an array of biologically active secondary metabolites. Different approaches have been applied in order to increase the probability production of new metabolites including mimicking the environment, media and the microbes. However, the use of single culture usually re-produces known compounds with known bioactivities. Therefore, co-culturing between *Streptomyces* sp. strain SUK10 and *Fusarium* sp. in the same media at different growth stages leads to direct interaction which may trigger the expression of "silent" biosynthetic pathway to produce novel secondary metabolites. In this study, we elicited the production of the unknown secondary metabolites from co-culture extracts by using high resolution liquid chromatography-mass spectrometry, while data was processed by utilizing the quantitative expression analysis software MZmine 2.40.1 and SIMCA P+ 15.0 coupled with macro analysis and supported with DNP database for dereplication studies. The results showed that only the extract from co-culture of F7S15 showed enhances antibacterial activity on the Gram-positive bacteria with minimum inhibition concentration (MIC) values of 5 mg/mL and 10 mg/mL against *Micrococcus* sp. and *Staphylococcus aureus*, respectively, compared with their independent and other co-culture extracts were non-active. However, all extracts were non-active on the Gram-negative bacteria. Our preliminary results showed that the potential of co-culture method leading the production of novel metabolites which could be explored for future antibacterial agents.

Abstrak

Endofit termasuk bakteria dan fungus menghasilkan satu tatasusunan metabolit sekunder yang mempunyai keaktifan biologi. Pelbagai pendekatan telah digunakan bagi tujuan meningkatkan kebarangkalian penghasilan metabolit baru termasuk mengajuk persekitaran, media dan mikrob. Walaubagaimanapun, penggunaan kultur tunggal selalumya menghasilkan semula sebatian dengan bioaktiviti yang telah diketahui. Oleh itu, satu pengkulturan bersama di antara *Streptomyces* sp. strain SUK10 dan *Fusarium* sp. di dalam media yang sama di peringkat pertumbuhan yang berbeza, memacu kepada interaksi yang mungkin pencetus kepada ungkapan laluan biosintetik senyap untuk menghasilkan metabolit sekunder baru. Dalam kajian ini, kami telah memperolehi penghasilan metabolit sekunder yang belum diketahui daripada ekstrak kultur bersama dengan menggunakan kromatografi cecair-spektrometri jisim resolusi tinggi, sementara itu data telah dianalisis menggunakan perisian analisis ungkapan kuantitatif MZmine 2.40.1 dan SIMCA P+ 15.0 beserta analisis makro dan disokong oleh pengkalan data DNP bagi kajian dereplikasi. Keputusan telah menunjukkan bahawa hanya ekstrak daripada kultur bersama F7S15 telah menunjukkan peningkatan aktiviti antibakteria ke atas bakteria Gram-positif dengan nilai minimum kepekatan perencatan (MIC) 5 mg/mL dan 10 mg/mL melawan *Micrococcus* sp. dan *Staphylococcus aureus*, masing-masing, berbanding ekstrak kutur bebas dan kultur bersama yang lain adalah tidak aktif. Walaubagaimanapun, semua ekstrak tidak aktif ke atas bakteria Gram-negatif. Keputusan awal kajian kami telah menunjukkan potensi kaedah kultur bersama memacu penghasilan metabolit baru yang boleh diterokai bagi agen antibakteria masa hadapan.

Introduction

Natural products have been rich sources of therapeutic agents as they inspire the advancement of synthetic methodologies to allow the possibility of making analogues of original lead compounds with improved pharmaceutical properties. For example, the secondary metabolites obtained from endophytic microbes are found to have antimicrobial, antiviral, anticancer, antioxidants, antidiabetic and immunosuppressant properties. The endophytic fungi and bacteria are known to produce these types of natural products that are potent for antibiotics [1]. They live inside the living plant tissues for at least a part of their life without causing any apparent disease symptoms in the host. Various bioactive metabolites are produced by endophytes that are proven to have potential to be anticancer, antioxidant, antifungal, antibacterial, antiviral and anti-insecticidal [2]. The induction of secondary metabolites is triggered by the interaction between the microorganisms, simulating the microbial competition for nutrition and space. Besides, the cultivation of the microbes is sustainable and reproducible in laboratory conditions. A well-known drugs-producer *Streptomyces* sp. belonging to actinobacteria varies in structures and has a great potential to be developed as therapeutic drugs for human use [3]. *Streptomyces* sp. is an aerobic, Gram-positive mycelial bacteria that disperse sporse as a method of reproduction and can develop branching vegetative hyphae in which the mycelium helps in scavenging nutrients from the surroundings [4]. *Streptomyces* sp. is able to synthesise potent secondary metabolites for medical applications such as antibiotics, herbicidal, antiparasitic, antitumor, antifungal and enzyme inhibiting agents as well as having the ability to inhibit various human pathogens including gancidin W [5], divergolides A-D [6], polycyclic anthraquinones [7], cyclic dipeptide [8-10] and xiamycin [11]. Meanwhile, a pathogenic fungus *Fusarium* sp. produces metabolites including naphthoquinones [12, 13], pyrones [14-16] and indole-acetic acids [17], naphthalenone derivatives [18] and aminobenzamide [19].

However, the discovery of new potential bioactive metabolites from independent cultures is challenging due to re-isolation of the known compounds with the same reported bioactivity. The re-occurrence of the known metabolites from an independent culture either of *Streptomyces* sp. SUK10 or *Fusarium* sp. may lead to similar bioactivities. Therefore, a co-culture method is introduced to challenge different strains instead of

individual strains. A co-culture is a process of culturing of two or more different microorganisms that mimic the complex microbial habitat in nature where they co-exist, leading to competition among them due to limited source and antagonism. Microbial community is a complex and dynamically changing consortium in which metabolic interactions between microbial species take place. The interaction between microbial communities often involves exchange of molecules for nutritional purposes that may benefit one or both species, which is known as symbiosis [20]. The co-cultures of different microbes in comparison to mono-cultures are increasingly being used in microbial natural product research as the interaction of two different microbes can increase the availability of existing natural products or may induce the expression of silent biosynthetic pathways resulting in new metabolites that are useful in the medical field [21].

A co-cultivation between *Streptomyces* sp. SUK10 and *Fusarium* sp. at different growth stages was carried out. Present study, the metabolomics approach was used to predict and identify potential novel bioactive components from the crude extracts, leading to the rapid and high-throughput assessment of metabolites. Metabolite profiling of the active metabolites in crude extracts of natural sources was supported by dereplication in which the novel compounds from the active groups were differentiated from known compounds that have been studied previously [22]. The dereplication method is a process for screening the known metabolites from the crude extracts before further scale-up or isolation work is undertaken, in order to avoid repetitive work.

High-resolution electrospray ionisation-liquid chromatography-mass spectrometry (HRESI-LCMS) data from both positive and negative ionisation modes were subjected to multivariate statistical analysis including unsupervised principal component analysis (PCA) and orthogonal partial least squares-discriminant analysis (OPLS-DA) to establish the optimal position of the discriminating plane, which would best separate classes. The high-resolution mass spectral data generated predicted molecular formulas used for dereplication of the secondary metabolites found in the crude extracts. Later in the final step of the metabolomics approach, the selected unique biomarkers were interpreted to putatively identify the novel metabolite using databases like Dictionary of Natural Products (DNP). The ultimate aim of this study was to fast track the identification of the metabolites from the co-culture extracts, which can lead to the decision-making of the optimum parameter for up-scaling of targeted metabolites responsible for biological activities. In future, the targeted metabolites will be isolated and absolute elucidation and identification of the molecule structures will be achieved using one and two dimensional-nuclear magnetic resonance (NMR) and high-resolution mass spectrometry (MS).

Materials and Methods

Preparation of microbial samples

A stock culture of *Streptomyces* sp. strain SUK10 was obtained from the Novel Antibiotics Laboratory, Programme of Biomedical Sciences, Faculty of Health Sciences, Universiti Kebangsaan Malaysia (UKM), Kuala Lumpur, while *Fusarium* sp. was obtained from the culture collection of Fungus Laboratory, Central Laboratory, Universiti Malaysia Terengganu (UMT). *Streptomyces* sp. SUK10 was originally isolated from the barks of *Shorea ovalis* [5] and *Fusarium* sp. was isolated from the roots of *Avicennia lanata* collected from Setiu Wetlands, Terengganu [13]. A 5 mm x 5 mm diameter plug containing *Fusarium* sp. mycelium was cut from the edge of the colony and placed in the middle of a new malt agar plate to establish a fresh and pure colony. The plates were incubated at 27 ± 2 °C (Vindon Scientific Ltd., UK) for 7-15 days. Meanwhile, *Streptomyces* sp. SUK10 was streaked onto fresh ISP2 agar plates and incubated at room temperature for 7-15 days.

Independent cultures

The International Streptomyces Project (ISP) medium was prepared by adding 10.0 g of malt extract, 4.0 g of D-(+)-glucose monohydrate, 4.0 g of yeast extract and 1 L of distilled water, vigorously shaken until completely mixed and dissolved. The pH was adjusted ranging at 7.2-7.4 using 10% NaOH or 36.5% HCl, and autoclaved at 121 ℃ for 15 minutes. The independent

cultures of *Streptomyces* sp. strain SUK10 and *Fusarium* sp. were achieved in which each active growing strain on the agar plate was cut into small cubes and transferred separately into seven 500 mL Erlenmeyer flasks containing 100 mL of ISP medium. The cultures were incubated in an orbital shaker and shaken at 150 rpm and 28 °C for 7 and 15 days (seven replicates). The metabolites were extracted twice with equal volumes of ethyl acetate, homogenised and filtered. The organic layer was discarded into a 500 mL round bottom flask using liquid-liquid extraction technique to obtain an organic solvent that was then concentrated under vacuum using a rotary evaporator (Büchi, Switzerland) to afford crude extracts ± 10.0 mg. The crude extracts were kept at 4 °C prior to analysis.

Co-cultivation between *Streptomyces* sp. strain SUK10 and *Fusarium* sp.

The co-cultivation between *Streptomyces* sp. strain SUK10 and *Fusarium* sp. was achieved including sets FS7, FS15, F7S15, and S7F15. The co-cultivation of sets FS7 and FS15 were obtained by mixing the agar cubes containing active growing *Streptomyces* sp. strain SUK10 and *Fusarium* sp. at initial incubation in the ISP broth. The incubation of co-cultivation of set FS7 was continued until day 7, while the co-cultivation of set FS15 was incubated until day 15. The co-cultivation of set F7S15 was obtained in which the agar plugs containing *Streptomyces* sp. strain SUK10 were introduced into the *Fusarium* sp. culture after 7 days of incubation, and the incubation was continued until day 15. The co-cultivation of set S7F15 was obtained in which the agar plugs containing *Fusarium* sp. mycelia were introduced into the *Streptomyces* sp. strain SUK10 culture after 7 days of incubation, and the incubation was also continued until day 15. A 100 mL of ISP broth was used for each culture and the incubation was done in an orbital shaker at 150 rpm and 28 °C (seven replicates). The metabolites were extracted twice with equal volumes of ethyl acetate, homogenised, and filtered. The organic layer was discarded into a 500 mL round bottom flask using liquid-liquid extraction technique to obtain an organic solvent that was then concentrated under vacuum using a rotary evaporator (Büchi, Switzerland) to afford crude extracts ± 15.0 mg. The crude extracts were kept at 4 °C prior to analysis.

Dereplication using HRESI-LCMS

The dereplication strategy on the crude extracts was performed using HRESI-LCMS and processed with the MZmine software 2.40.1, an in-house macro coupled with the Dictionary of Natural Products (DNP) 2015 and SIMCA P+ 15.0 (Umetrics AB, Umeå, Sweden). The procedure and programme for HRESI-LCMS was set up as described here [23]. 1 mg/mL of each extract was dissolved in methanol and analysed on an Accela HPLC (Thermo Scientific, UK) coupled with a UV detector at 280 and 360 nm and an Exactive-Orbitrap high-resolution mass spectrometer (Thermo Scientific, UK). A methanol blank was also analysed. The mass spectral data was processed using the procedure by MacIntyre et al. [23] which was established in the Natural Products Metabolomics Group Laboratory at Strathclyde Institute of Pharmacy and Biomedical Sciences (SIPBS) as described here [13, 23]. The LC-MS chromatograms and spectra were viewed using Thermo Xcalibur 2.1 or MZmine 2.40.1.

Antibacterial activity using agar disk-diffusion

An antibacterial activity of the extracts from independent and co-cultures was conducted using the agar disk-diffusion method as described here [24]. Each extract was diluted with 2-fold dilutions in dimethyl sulfoxide (DMSO) with concentration values of 0.156 mg/mL, 0.313 mg/mL, 0.625 mg/mL, 1.25 mg/mL, 2.50 mg/mL, 5.00 mg/mL and 10 mg/mL. The inhibition zone diameter (IZD) was measured to the nearest millimetres. Minimum inhibitory concentration (MIC) was taken as the lowest concentration of the extracts that shows the inhibition zone. MIC values of the extracts against the Gram-positive and Gram-negative bacteria were determined by averaging the results of three independent assays. Six strains of Gram-positive bacteria namely *Staphylococcus aureus*, *Bacillus cereus* and *Micrococcus* sp. and Gram-negative bacteria - *Vibrio cholera*, *Salmonella* sp. and *Escherichia coli* from glycerol stock were obtained from the Microbiology Laboratory, Institute of Marine Biotechnology, UMT.

Statistical analysis

All data were presented as mean ± SD and statistically analysed with One-Way ANOVA in the comparison between selected fractions using statistical analyses software PRISM ver. 5. Data were significantly different at $p < 0.05$.

Results and Discussion

Dereplication study on crude extracts

Each extract was screened on antibacterial activity at different concentrations: 10 mg/mL to 0 mg/mL. The inhibition zone diameter (IZD) was measured to the nearest millimetres. The results showed that the minimum inhibition concentration (MIC) values of the extracts against the Gram-positive and Gram-negative bacteria were determined by averaging the results of three independent assays (Table 1). The co-culture extract F7S15 revealed marginal antibacterial activity on *Micrococcus* sp. and *S. aureus* with MIC values of 5 mg/mL and 10 mg/mL, respectively, as compared to the non-active independent and other co-culture extracts. Meanwhile, the antibacterial activity on the Gram-negative bacteria showed that all extracts were non-active in this screening test, thereby supporting further investigation of the biologically-active compounds from the co-cultivation extracts.

Total ion chromatogram for the extract of co-cultivation between *Streptomyces* sp. strain SUK10 and *Fusarium* sp. F7S15 (Figure 1) showed the distribution of known and unknown compounds present in the extract (Table 2). The dereplication studies revealed that the co-culture extract F7S15 possessed certain types of compounds including macrocylic aromatic compounds such as macrolide- oligomycin A and cyclic peptolides-icosalide A1 and A3, which have also been previously isolated from different *Streptomyces* and fungi species, respectively (Table 2). The values and predicted formulas of unknown compounds are also shown (highlighted rows). The extracts of co-cultivation between *Streptomyces* sp. strain SUK10 and *Fusarium* sp. as well as the independent cultures were preliminarily screened on antibacterial activity and subjected to HRESI-LCMS prior to multivariate analysis. A dereplication study was performed to obtain the metabolomic profile of each extract.

The relationship between the occurrence of the metabolites in the independent and co-cultivation extracts and their bioactivity on antibacterial activity were evaluated through multivariate analysis. The PCA scores plot showed strong separation of the extracts (Figure 2a). There was clear separation between the co-culture extract of F7S15 from other extracts. The PCA loadings plot (Figure 2b) predicted the metabolites in the extracts. Meanwhile, a supervised multivariate OPLS-DA score plot analysis (Figure 2c) exhibited a distinctive separation between the active extract F7S15, while other extracts were the non-active group. These predicted antibacterial active compounds by MVA were indicated with their MZmine IDs as listed in Table 2. Peak IDs used in this table corresponded to those designated for the chromatogram as shown in Figure 1.

Table 1. Antibacterial activity for independent and co-culture extracts (calculated as mean value percentage viability) at different concentrations ranging at 10 mg/mL to 0 mg/mL. Highlighted rows showed enhanced antibacterial activity

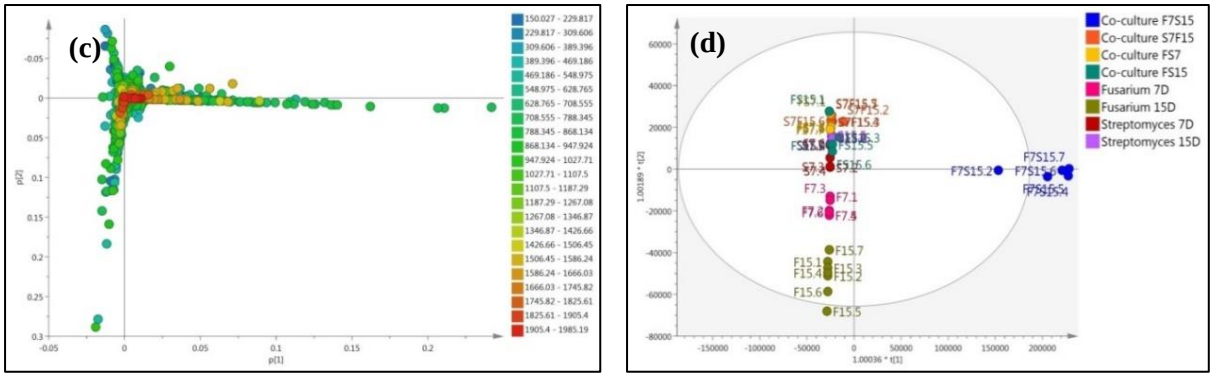

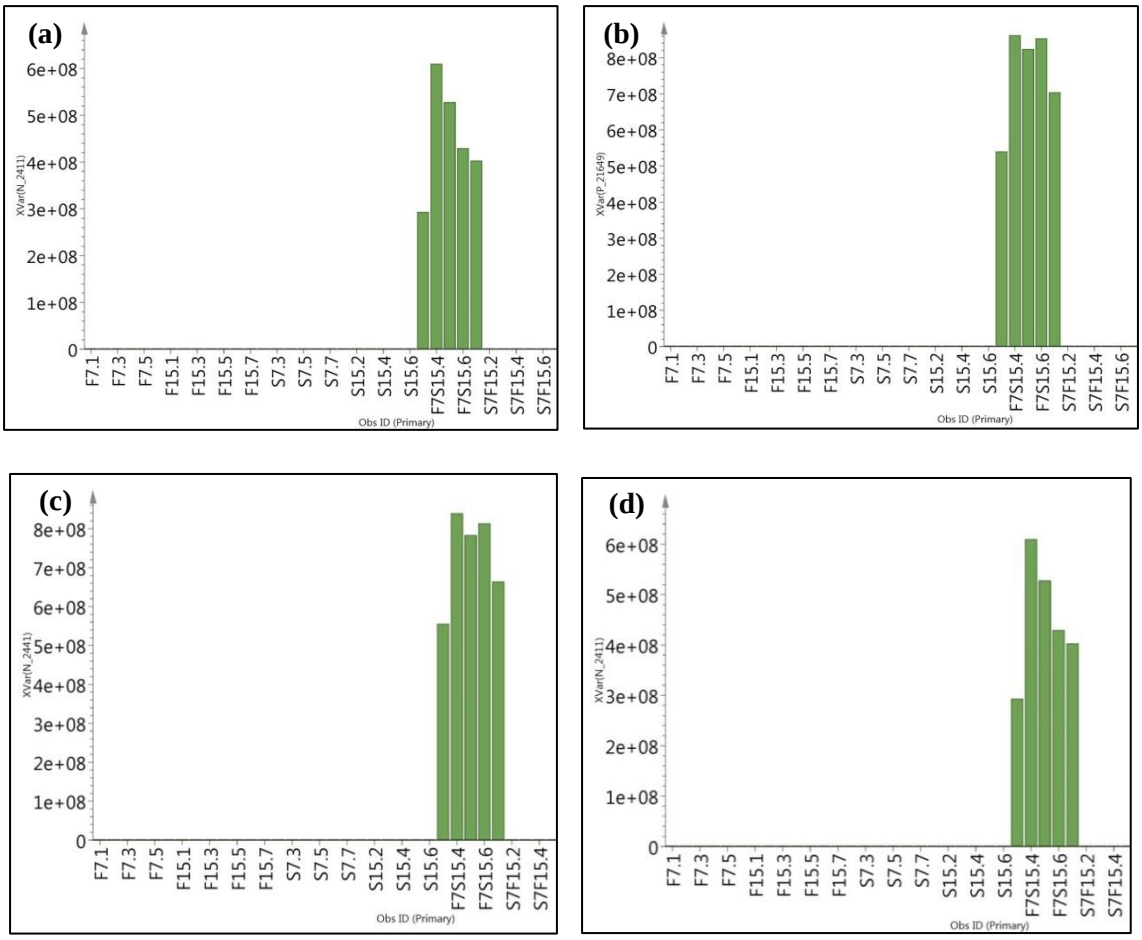

Figure 2. (a) Unsupervised PCA scores plot of mono- and co-cultivation extracts showed distinctive separation between the datasets. (b) PCA loadings plot showed the discriminating metabolites within the extracts. (c) OPLS-DA scores scatter plot of the extracts ($R^2(Y)$ = 1.00; Q^2 =0.998); Q^2(Y intercept). (d) Supervised OPLS-DA loadings plot showed the discriminating metabolites of the active co-culture extract F7S15 within the extracts. Asterisk specifies the identified metabolites from where the respective active extract F7S15. Legend: set F7.1-F7.7 = mono-culture *Fusarium* sp. incubation day 7; set F15.1-F15.7 = mono-culture *Fusarium* sp. incubation day 15; set S7.1-S7.7 = mono-culture *Streptomyce*s sp. SUK10 incubation day 7; S15.1-S15.7 = mono-culture *Streptomyces* sp. SUK10 incubation day 15; set F7S15.1-F7S15.7 = co-cultivation between *Fusarium* sp. and *Streptomyces* sp. SUK10 in which *Streptomyces* sp. SUK10 was added into *Fusarium* sp. culture after 7 days incubation and the incubation was continued until day 15; set S7F15.1-S7F15.7 = co-cultivation between *Fusarium* sp. and *Streptomyces* sp. SUK10 in which *Fusarium* sp. was added into *Streptomyces* sp. SUK10 culture after 7 days incubation and the incubation was continued until day 15, n=7.

The OPLS-DA loadings plot (Figure 2d) exhibited the discriminating metabolites in the active group F7S15 in which the ion peaks at *m/z* $[M+H]^+$ 713.469, 761.521, and 801.513 as well as *m/z* $[M-H]^-$ 777.519, 795.529, and 633.439 were outliers, indicating the presence of unique chemical profiles in the F7S15 extract. From the DNP database, it was putatively determined that the F7S15 extract contained polyketide and aromatic compounds [25-28] that perhaps contributed towards the antibacterial activity of F7S15. Some of the ion peaks in the F7S15 extract have been dereplicated as presented in Table 1. Characteristic metabolite for co-culture F7S15 extract observed at *m/z* $[M+H]^+$ 713.469 were putatively identified as icosalide A1, which has been identified from an *Aureobasidium* sp. fungus OSI 59166 [26, 29]. The ion peaks at *m/z* $[M+H]^+$ 761.521 and 779.531 were putatively identified as oligomycin A; 26-demethyl, 12-deoxy, and narasin D, respectively. Both compounds were isolated from *Streptomyces aureofaciens* [30, 31]. The *m/z* $[M-H]^-$ 795.529 was putatively identified as bovine seminolipid, which has been isolated from bovine spermatozoa [32]. Meanwhile, the ion peaks at *m/z* $[M+H]^+$ 801.513 and *m/z* $[M-H]^-$ 777.519 and 633.439 were the unidentified metabolites that were only produced in the active co-culture extract F7S15. The relative occurrence of the targeted putatively identified and unknown metabolites in the bioactive extract F7S15 is shown in Figure 3. Based on the predicted chemical formula of the unknown compounds, they may consist of at least one nitrogen atom that contributes to the presence of macrocyclic polyketide-membered rings. Isolation of polyketide compounds from *Streptomyces* sp. under normal condition is widely known [5, 33-35], and perhaps the discovery of most antibiotics in the market are from this species. However, the world is facing a multidrug resistant against bacteria. Thus, dual cultivation of different strains used in our preliminary study may enlighten the opportunity to discover more potential new drug candidates that could be further

explored. The optimization works in this study showed that the co-cultivation of F7S15 produced promising metabolites with enhanced antibacterial activity, which can be further scaled up to obtain larger volume extracts for isolation and identification of target metabolites that were absent in their parent culture. Our future study will focus on the identification of molecule structures of the unknown metabolites by using tandem mass spectrometry (MS/MS) analysis and one/two-dimensional nuclear magnetic resonance (1D/2D NMR) spectroscopy.

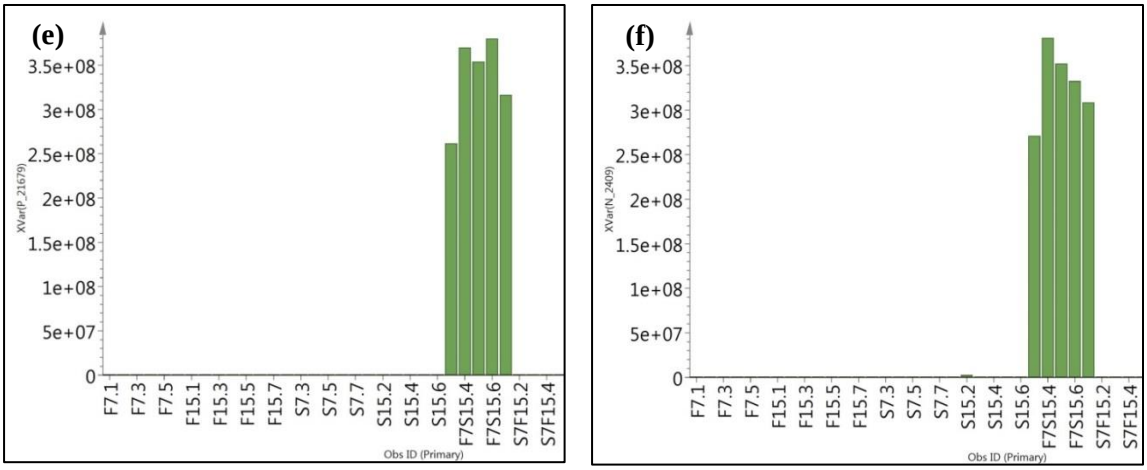

Figure 3. Relative abundance of target metabolites (a-f) which only present in the active co-culture extract of F7S15. Asterisk specifies the identified metabolites from where the respective active extract F7S15. (a) P_21186: *m/z* = 713.469, RT = 25.48 min; (b) P_21649: *m/z* = 761.521, RT = 16.45 min; (c) N_2496: *m/z* = 777.519, RT = 17.58 min; (d) N_2411: *m/z* = 795.529, RT = 16.03 min; (E) P_21679: *m/z* = 801.513, RT = 16.35 min; (F) N_2409: *m/z* = 633.439, RT = 16.19 min

Conclusion

The main aims in this study were to establish an optimum parameter to target and pinpoint the bioactive secondary metabolites directly from the extracts that were absent in the independent culture and subsequently imply the same parameter in the scale-up of the co-cultivation. By means of high-resolution liquid chromatography-mass spectrometry, the extracts obtained from mono- and co-cultivation were preliminarily screened for bioactive molecules and analyzed by multivariate analysis such as PCA and OPLS-DA. Dereplication study was used to screen the known metabolites and predict the novelty metabolites from the extracts which were not detected in single cultures, to avoid repetitive work on the same compounds with known bioactivity. Our future study will focus on the scale-up and isolation works of the targeted active metabolites from co-culture extract F7S15. In addition, identification of the molecule structures will be achieved using 1D and 2D-nuclear magnetic resonance (NMR) and high-resolution mass spectrometry (MS).

Acknowledgement

We wish to thank the Ministry of Higher Education Malaysia for the grant awarded to Noor Wini Mazlan FRGS/1/2018/STG05/UMT/03/2. The research described in this study has been done in IMB and Central Laboratory, UMT. The authors would like to thank Siti Aisha Mohd Radzi for assisting in the sample preparation.

Abstract

Poly (*N*-isopropylacrylamide) (PNIPAAm) is a well-known thermoresponsive polymer that shows a reversible coil-to-globule transition at the lower critical solution temperature (LCST) (32°C) in aqueous solution. Chemically modified PNIPAAm with hydrophilic/hydrophobic compound will tune its LCST. Below the LCST, PNIPAAm and its conjugate behave as an extended coil form in an aqueous solution, whereas it shrinks into a globule form above the LCST. In this study, a direct conjugate of PNIPAAm with a ternatin biomolecule and their physicochemical characterizations were investigated. Ternatin biomolecule is an anti-adipogenic cyclic peptide that has a potential as a new treatment approach for obesity and metabolic disorders. Poly (*N*-isopropylacrylamide)-chain transfer agent (PNIPAAm-CTA) was synthesized through reversible addition fragmentation chain transfer (RAFT) polymerization using 2-(Dodecylthiocarbonothioyltho)-2-methylpropanoic acid (DDMAT) as chain transfer reagent. One end-group of PNIPAAm-CTA was subsequently modified with maleimide to form PNIPAAm-Maleimide through aminolysis reaction. Thereafter, a carboxylic end-group of PNIPAAm-Maleimide was directly conjugated with a hydroxyl group of ternatin biomolecule (PNIPAAm-Ternatin) through esterification method. The chemical structure, molecular weight (Mw) and molecular weight distribution (Mw/Mn) of PNIPAAm were determined through the proton nuclear magnetic resonance (^{1}H-NMR), Fourier transform infrared (FTIR) and size exclusion chromatography (SEC) measurements. Moreover, the LCST of PNIPAAm and its conjugate were determined through light scattering intensity analysis. The results indicated that upon heating the solutions of PNIPAAm and its conjugates in 10 mM HEPES solution pH 7.4 at 25°C-40 °C, PNIPAAm-CTA, PNIPAAm-Maleimide and PNIPAAm-Ternatin solutions started to increase their light intensities at 32 °C, 34 °C and 35 °C, respectively. In conclusion, chemical structure modification of PNIPAAm could tune their LCST.

Keywords: poly (*n*-isopropylacrylamide), raft polymerization, ternatin biomolecule, conjugation, lower critical solution temperature

Abstrak

Poli (*N*-isopropilakrilamida) (PNIPAAm) adalah polimer termoresponsif terkenal yang menunjukkan peralihan gegelung-ke-globule yang boleh berbalik pada suhu larutan kritikal rendah (LCST) (32°C) dalam larutan akueus. PNIPAAm yang diubahsuai

secara kimia dengan sebatian hidrofilik/hidrofobik akan mengubahkan LCSTnya. Pada suhu di bawah LCST, PNIPAAm dan konjugatnya berbentuk gegelung di dalam larutan akueus, manakala ia akan mengecut menjadi bentuk globul pada suhu di atas LCST Dalam kajian ini, konjugasi secara langsung PNIPAAm dengan biomolekul ternatin dan sifat fizikokimianya dikaji. Biomolekul ternatin adalah peptida siklik anti-adipogenik. Ia berpotensi sebagai rawatan baharu untuk obesiti dan gangguan metabolik. Poli (*N*-isopropilakrilamida)-agen pemindahan rantai (PNIPAAm-CTA) disintesis melalui polimerisasi radikal hidup menggunakan asid 2-(dodekilthiokarbonothioiltho)-2-metilpropanoik(DDMAT) sebagai reagen pemindahan rantai. Selepas itu, satu kumpulan akhir pada PNIPAAm-CTA diubahsuai dengan maleimida untuk membentuk PNIPAAm-Maleimida melalui tindak balas aminolisis. Kemudian, kumpulan akhir karboksilik PNIPAAm-Maleimida dihubungkan secara langsung dengan kumpulan hidroksil pada biomolekul ternatin (PNIPAAm-Ternatin) melalui kaedah esterifikasi. Struktur kimia, berat molekul (Mw) dan taburan berat molekul (Mw/ Mn) bagi PNIPAAm dikaji melalui analisis proton resonans magnetik nuklear (^{1}H-NMR), spektroskopi inframerah Fourier transformasi (FTIR) dan kromatografi ekslusi saiz (SEC). Seterusnya, sifat LCST bagi PNIPAAm dan konjugatnya dikaji melalui analisis intensiti penyerakan cahaya. Hasilnya, setelah larutan PNIPAAm dan konjugat dalam larutan HEPES 10 mM pH 7.4 dipanaskan pada suhu 25-40 °C, intensiti cahaya bagi PNIPAAm-CTA, PNIPAAm-Maleimida dan PNIPAAm-Ternatin mula meningkat pada 32 °C, 34 °C dan 35 °C. Kesimpulannya, pengubahsuaian struktur kimia PNIPAAm dapat mengubah sifat LCST polimer.

Kata kunci: poli (*n*-isopropilakrilamida), pempolimeran raft, biomolekul ternatin, konjugasi, suhu larutan kritikal rendah

Introduction

Over the years, a great deal of effort has been devoted to the development of stimuli-responsive smart polymers that can provide a variety of applications for cosmetic, agriculture, biomedical and biotechnology [1-4]. Smart polymers are polymeric materials, in which the structure, function, and stability drastically change by slight changes in external stimuli. These stimuli could be temperature, pH, light, redox and/or photo [5-9]. In the case, whereby the external stimulus is the temperature change, the polymers are often referred as thermoresponsive polymers. Poly(*N*-isopropylacrylamide (PNIPAAm) is one of the well-known thermoresponsive polymer. PNIPAAm displays a lower critical solution temperature (LCST) of 33 °C [10-12]. PNIPAAm remains in coil conformation in water below LCST, meanwhile, it collapses into globule conformation above LCST [13, 14]. The LCST of PNIPAAm chain could be tuned by several approaches, such as modification of end-group with hydrophilic or hydrophobic compound, adding comonomers and/or changing its tacticity [15-17]. The introduction of hydrophilic compound into PNIPAAm chain leads to an increase of LCST, meanwhile, PNIPAAm incorporated with hydrophobic compound tends to decrease LCST. Moreover, a reported study demonstrated that PNIPAAm conjugated with a small interfering of ribonucleic acid (RNA) (siRNA) biomolecule using click chemistry tools tuned the LCST of PNIPAAm conjugates [18].

In the present study, a facile synthetic route for the conjugation of PNIPAAm with ternatin biomolecule was prepared to investigate the thermoresponsive behaviour. Ternatin biomolecule is a natural compound that is extracted from a plant, known as butterfly pea, or its scientific name *Clitoria ternatea* [19]. Ternatin is an anti-adipogenic cyclic peptide containing one or more *N*-methyl (or *N*-alkyl) amino acids [20, 21]. Furthermore, this study hypothesised that the modification of PNIPAAm chain with hydrophilic compound end-group and ternatin biomolecule would tune the thermoresponsive behaviour of PNIPAAm. Concisely, this study prepared PNIPAAm and its conjugate through controlled living radical polymerisation and esterification techniques (Figure 1). It is expected that the prepared facile synthetic route for the conjugation of thermoresponsive polymer with biomolecule and the resulted thermoresponsive behaviour in this study would be useful for further related field studies.

Materials and Methods

Materials

N-Isopropylacrylamide (NIPAAm), 2-(Dodecylthiocarbonothioyltho)-2-methylpropanoic acid (DDMAT), 2,2'-Azobis(2-methylpropionitrile) (AIBN), 1,4-dioxane, diethyl ether, ethanolamine, maleimide, tributylphosphine (TBP), HEPES solution, N-ethyl-N'-(3-dimethylaminopropyl) carbodiimide (EDC), 1-Hydroxybenzotriazole (HOBt), tetrahydrofuran (THF) and acetonitrile were purchased from Sigma-Aldrich, Malaysia. NIPAAm was purified by recrystallisation from n-hexane and dried in a vacuum. AIBN purification was performed by recrystallisation from cold methanol. Prior to the usage, 1,4-dioxane was purified using reflux condenser. Ternatin was purchased from Cayman Chemical (Ann Arbor, Michigan, USA). Deuterated methanol (MeOD) was purchased from Merck and it was used without further purification.

Synthesis of PNIPAAm–CTA

PNIPAAm-CTA was synthesised by dissolving NIPAAm (3.0 g, 30.0 mmol), DDMAT (110 mg, 0.3 mmol), AIBN (2.5 mg, 0.015 mmol) in 1,4-dioxane (10 mL) ([NIPAAm]: [DDMAT]: [AIBN] = 100: 1: 0.05, respectively). The solution was stirred at room temperature until a homogeneous mixture was formed. Next, the nitrogen gas was purged into the reaction for 15 minutes. The mixture was stirred and heated in an 80 °C oil bath for 12 hours. After 12 hours, the reaction solution was precipitated into cold diethyl ether to remove the unreacted monomer. The produced polymer was filtered using vacuum pump and dried in a desiccator for a day. Finally, the polymer was collected, weighted and stored in the refrigerator.

Synthesis of PNIPAAm–maleimide

PNIPAAm–Maleimide was synthesised by dissolving PNIPAAm-CTA (1.5 g, 0.27 mmol), ethanolamine (1.6 g, 27.20 mmol) and maleimide (0.26 g, 2.72 mmol) into the 1,4-dioxane (5 mL). The solution was stirred at room temperature until a homogeneous mixture was formed. Next, the nitrogen gas was purged into the reaction for five minutes. After five minutes, TBP (0.10 mL, 0.54 mmol) was added to the mixture ([PNIPAAm–CTA]: [maleimide]: [TBP]: [ethanolamine] = 1: 10: 2: 100, respectively). The mixture was stirred at room temperature for six hours. After six hours, the reaction solution was precipitated into cold diethyl ether to remove the unreacted monomer. The produced polymer was filtered using a vacuum pump and dried in a desiccator for a day. The polymer was collected, weighted and stored in the refrigerator.

Synthesis of PNIPAAm–ternatin

PNIPAAm–Maleimide solution was prepared by dissolving PNIPAAm-Maleimide (33.33 mg, 0.02 mmol) into 4 mL of 10 mM HEPES pH 7.4 buffer solution. The mixture was stirred for 20 hours at room temperature. After 20 hours, EDC (3 mg, 0.02 mmol) and HOBt (1 mg, 0.01 mmol) were added to the mixture and stirred continuously for three hours at room temperature to activate the carboxylate group. Next, the nitrogen gas was purged into the reaction for 15 minutes and 0.5 mL of 10 ppm ternatin was slowly added to the mixture. After 15 minutes, the mixture was stirred for 20 hours at room temperature. Thereafter, 4 mL of 10 mM HEPES pH 7.4 buffer solution was added to the mixture and cooled at room temperature. After two days, it was purified by centrifugation using ultra centrifugal filter (MWCO 3kDa, Millipore) to remove the unreacted molecules. Finally, the produced PNIPAAm-Ternatin was collected and stored in the refrigerator.

Molecular weight and molecular weight distribution

The polymer molecular weight and molecular weight distribution (Mw/Mn) was measured by using Waters® ACQUITY® Advanced Polymer Chromatography™ (APC) with THF, which was used as an eluent at a flow rate of 1.0 mL/min at 40°C using the standard polystyrene. The ACQUITY UPLC Refractive Index Detector ACQUITY APC Column were used.

Chemical structure characterisations

Fourier transform infrared (FTIR) spectra of the PNIPAAm-CTA and PNIPAAm-Maleimide were recorded with FTIR Nicolet 510 spectrometer in the 4,000 cm^{-1} – 400 cm^{-1} range. The samples were prepared by grinding the polymer with KBr pellets and compressing the mixture to form disks. For PNIPAAm-Ternatin, FTIR spectra was recorded with Shimadzu FTIR-8300 instrument in the 4,000 cm^{-1} - 600 cm^{-1} range. The polymer chemical structure and the conjugated polymers were also characterised using ^1H NMR spectra. It was conducted on a Bruker Spectrospin 400 MHz UltraShield Spectrometer. Chloroform-d ($CDCl_3$) and methanol-d (MeOD) were used as solvents.

Reversed-phase high-performance liquid chromatography analysis

Reversed-phase high-performance liquid chromatography (RP-HPLC) analysis was used to separate, identify and quantify each component in the produced polymer conjugated with ternatin. For polymer-peptide conjugate, the HPLC gradients consisted of eluent A with 0.1% formic acid in water and eluent B with 0.1% formic acid in acetonitrile. The flow rate was maintained at 0.5 mL/min, detected at 200 nm and the column temperature was at room temperature.

Light scattering intensity analysis

Light scattering intensity analysis was performed to determine the LCST of polymer by using Zetasizer Nano (Malvern Instrument Ltd.) at a detection angle of 173°. The sample solutions were prepared by dissolving the polymer, ternatin and its polymer conjugates in 10 mM HEPES solution (pH 7.4) (sample solution concentration at 0.5 mg mL^{-1}). It was measured at various temperatures from 25°C to 40°C. The results were presented as mean value of count rate in kilo counts per second (kcps) and the standard deviation was obtained from three times repetitions.

Results and Discussion

Chemical structure characterisation of PNIPAAm-CTA and PNIPAAm-Maleimide

The synthesised PNIPAAm-CTA possessed molecular weight, Mw at 20140 g/mol and had a narrow molecular weight distribution (Mw/Mn) of 1.26. The obtained molecular weight of PNIPAAm-CTA was purely theoretical. Furthermore, a quite narrow molecular weight distribution suggested that a successful controlled polymerization of PNIPAAm.

The chemical structure of PNIPAAm-CTA and PNIPAAm-Maleimide were characterised by ^1H NMR and FTIR analysis. The ^1H NMR spectrum of PNIPAAm-CTA in Figure 2 showed the presence of signal characteristic of PNIPAAm at δ = 3.9 ppm for CH connected to the NH, 1.15 ppm for CH_3, 1.61 ppm ($-CH_2-$) and 2.13 ppm (-CH-) [22, 23]. The formation of PNIPAAm-CTA was proven by the existence of trithiocarbonate functionality at the PNIPAAm-CTA

end-group, which was demonstrated in the ^{1}H NMR spectrum through the peak at 0.88 ppm (CH_3–$(CH_2)_{10}$–CH_2–S–) [24]. Furthermore, the ^{1}H NMR spectrum of PNIPAAm-Maleimide (Figure 3) confirmed the existence of maleimide at the peak of 8.55 ppm which belong to the -NH group in maleimide [25]. The disappearance of the peak at 0.88 ppm for trithiocarbonate group in the spectrum suggested the successful conversion into PNIPAAm-Maleimide through aminolysis reaction [26].

PNIPAAm-CTA and PNIPAAm-Maleimide chemical structures were further confirmed through FTIR analysis. In Figure 4, the FTIR spectrum for PNIPAAm-CTA showed that the formation was proven by the C=S stretching band of the chain at 1,065 cm^{-1} [27]. The C=S group was belong to the trithiocarbonate end in PNIPAAm-CTA. The FTIR spectra for PNIPAAm-CTA also represented the N-H stretch at 3,414 cm^{-1}, carbonyl group (C=O) at 1,554 cm^{-1} and 1,643 cm^{-1}, and C–N stretching at 1,462 cm^{-1} [28]. The FTIR spectrum for PNIPAAm–Maleimide showed that the aminolysis reaction was succeeded because the C=S stretching band (1,050 cm^{-1} – 1,080 cm^{-1}) of the trithiocarbonate end was no longer being observed after the aminolysis reaction [29]. Furthermore, there was a peak at 1,743 cm^{-1} for maleimide C=O stretching. For symmetric C-N-C stretch, the peak was situated at 1,457 cm^{-1}, which affirmed the existence of maleimide [30]. The FTIR absorption band, which was around 3,300 cm^{-1} – 3,500 cm^{-1} covered N-H stretching group bands in PNIPAAm and maleimide [31]. These results confirmed the polymerisation of PNIPAAm-CTA and the modification of its end-group to produce PNIPAAm-Maleimide.

Characterisations of PNIPAAm-Ternatin conjugate

The esterification method was used to synthesise the PNIPAAm-Ternatin. The chemical structure of PNIPAAm-Ternatin was confirmed by the FTIR. In Figure 5 (a) showed the FTIR analysis for PNIPAAm-Ternatin, whereby the band at 1,635 cm^{-1} and 1,185 cm^{-1} were attributed to the C=O and C-O stretching frequencies of ester linkage, respectively [32]. Therefore, it was suggested that the PNIPAAm-Ternatin was successfully synthesised through esterification method. A broad stretch at 3,286 cm^{-1} was indexed to the NH group in ternatin [33]. The NH stretching group in PNIPAAm and maleimide at 3,300 cm^{-1} – 3,500 cm^{-1} were overlapped by the broad stretch of OH group in the ternatin [34].

The HPLC chart for PNIPAAm-Ternatin is shown in Figure 5 (b). The purpose of this analysis was to identify the retention time of ternatin, PNIPAAm-Maleimide and PNIPAAm-Ternatin and also to calculate the concentration and conjugation percentages of ternatin biomolecule to PNIPAAm chain. As a result, it was confirmed that the peak at the retention time of 2.57 minutes and 3.06 minutes for ternatin and PNIPAAm-Ternatin, respectively, clearly appeared in the HPLC chart. The concentration and conjugation percentages of PNIPAAm-Ternatin were obtained at 8.75 ppm and 87.5%, respectively, which was calculated based on ternatin calibration. Consequently, the collected PNIPAAm-Ternatin through RP-HPLC was purified using centrifugation against 10 mM HEPES pH 7.4 buffer solution and conducted for further analysis.

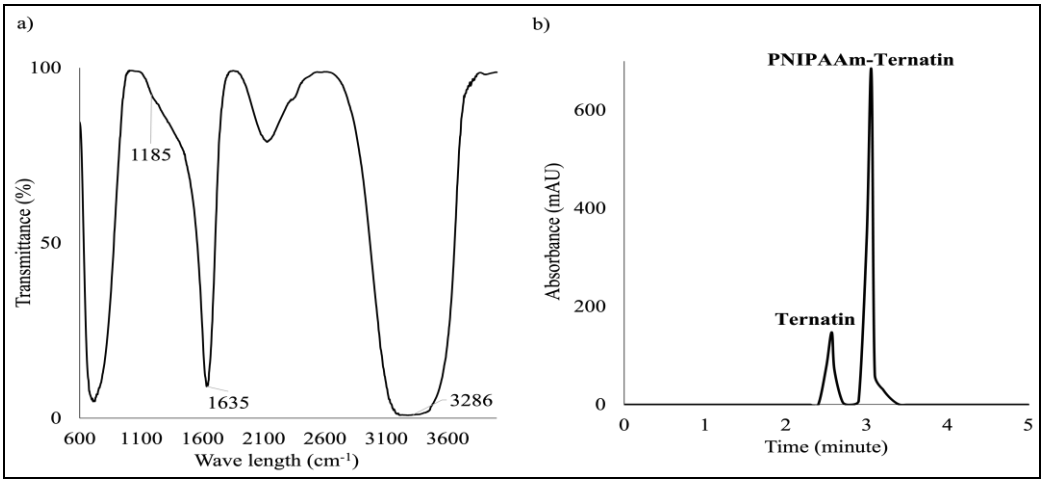

Figure 5. (a) FTIR analysis and (b) HPLC analysis for PNIPAAm-Ternatin

Thermoresponsive behaviour of PNIPAAm and its conjugate

The LCST of PNIPAAm and its conjugate were determined by light scattering intensity analysis. The resulting light scattering intensity of PNIPAAm and its conjugate are shown in Figure 6(a) for PNIPAAm-CTA, Figure 6(b) for PNIPAAm-Maleimide and Figure 6(c) for PNIPAAm-Ternatin. Upon heating solutions of PNIPAAm-CTA, PNIPAAm-Maleimide and PNIPAAm-Ternatin in 10 mM HEPES pH 7.4 from 25 °C to 40 °C, it could be seen that light scattering intensity of PNIPAAm-CTA started to increase at a temperature of 32 °C, whereas the change was shifted to the temperature at 34 °C in the case of PNIPAAm-Maleimide and at 35 °C for PNIPAAm-Ternatin. The increased light scattering intensity of PNIPAAm and its conjugate were due to the aggregation of globule form of PNIPAAm chain above the LCST [35]. The modification of chemical structure of PNIPAAm with hydrophilic or hydrophobic compound tuned the LCST of PNIPAAm [36]. Based on this study, the LCST for PNIPAAm-Maleimide and PNIPAAm-Ternatin were higher when compared to the LCST of PNIPAAm-CTA. This was due to the addition of hydrophilic maleimide compound and ternatin biomolecule at end-group of PNIPAAm chain that improved the LCST of the polymer. Therefore, the results indicated that the addition of hydrophilic compound increased the LCST of PNIPAAm. The small changes of LCST for PNIPAAm-Ternatin solution upon heating suggested that the conjugation of PNIPAAm with ternatin biomolecule did not contribute any effect on the thermoresponsive behaviour of PNIPAAm chain.

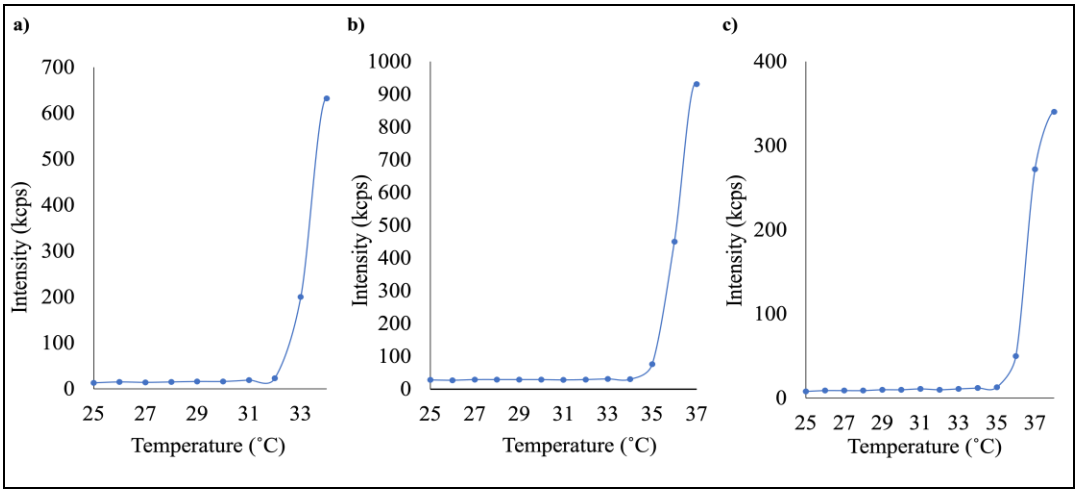

Figure 6. Light scattering intensities of (a) PNIPAAm-CTA, b) PNIPAAm-Maleimide and c) PNIPAAm-Ternatin solution at an indicated temperature in 10 mM HEPES pH 7.4 buffer solution

Conclusion

A thermoresponsive PNIPAAm conjugate was designed with ternatin biomolecule through controlled living radical polymerisation and esterification techniques. The synthesised PNIPAAm-CTA possessed molecular weight, Mw of 20140 g/mol and had quite a narrow molecular weight distribution (Mw/Mn) of 1.26, which revealed that the synthesised PNIPAAm through RAFT polymerisation was in a controlled structure. Moreover, PNIPAAm-Ternatin with conjugation percentage of 87.5% was successfully prepared through esterification technique. The synthesised PNIPAAm-CTA had a LCST at 32 °C. Meanwhile, the modification of PNIPAAm chain end-group by the addition of hydrophilic compound of maleimide (PNIPAAm-Maleimide) and the introduction of ternatin biomolecule (PNIPAAm-Ternatin) increased the LCST of PNIPAAm to 34 °C and 35 °C, respectively. Therefore, reported synthesised PNIPAAm and its chemical modifications are expected to provide a fundamental knowledge for further design and an excellent flexibility in tailoring for specific usage, particularly in the bioengineering and biomedical studies. Further studies on this topic are now in progress.

Abstract

In resolving the current energy crisis, it is vital to effectively use the abundant biomass to produce platform chemicals, for instance levulinic acid (LA). LA is very flexible for the formation of high value-added chemicals as it belongs to the family of carboxyl and ketone. This valuable platform chemical can be produced from cellulose (the most abundant biomass in nature). Palladium (Pd) as a noble metal was incorporated with catalyst supports (silica-alumina; SiO_2-Al_2O_3 and gamma-alumina; γ-Al_2O_3) by using wet impregnation method, aiming for 4 wt.% of noble metal on supports followed by catalyst calcination at 500 ˚C. The catalyst was characterized using Fourier-transform infrared spectroscopy (FTIR) and Brunauer–Emmett–Teller (BET). The effects of reaction parameters such as agitation speed, reaction temperature, and cellulose loading were investigated using this catalyst in a semi-batch reactor for 8 hours. The highest conversion of cellulose (73.9%) and yield of LA (43.3%) was achieved under these conditions: agitation speed of 1100 rpm, reaction temperature of 200 ˚C, and cellulose loading of 1.5 g with pre-reduction of Pd/SiO_2-Al_2O_3 catalyst (surface area and pore volume up to 485.6 m^2/g and 0.2459 cm^3/g, respectively) at 150 ˚C and agitation speed of 1300 rpm (in 5 bars of hydrogen, H_2 for 1 hour).

Keywords: Pd/SiO_2-Al_2O_3, cellulose, hydrolysis, levulinic acid

Abstrak

Dalam menyelesaikan krisis tenaga semasa, adalah sangat penting untuk menggunakan biojisim yang berkesan dalam menghasilkan bahan kimia platform seperti asid levulinik (LA). LA sangat fleksibel untuk pembentukan bahan kimia bernilai tinggi, kerana ia tergolong dalam keluarga karboksil dan keton. Bahan kimia platform yang berharga ini boleh dihasilkan dari selulosa (biojisim yang paling banyak terdapat di alam semula jadi). Paladium (Pd) sebagai logam adi boleh digabungkan dengan penampung mangkin (silica-alumina; SiO_2-Al_2O_3 and gamma-alumina; γ-Al_2O_3) yang dihasilkan menggunakan kaedah impregnasi basah yang bertujuan untuk 4% logam adi pada penampung mangkin diikuti oleh kalsinasi mangkin pada suhu 500 ˚C. Mangkin dicirikan menggunakan spektroskopi inframerah transformasi Fourier (FTIR) dan *Brunauer–Emmett–Teller* (BET). Kajian mengenai pengaruh parameter reaksi seperti kelajuan pengadukan, suhu tindak balas, dan pemuatan selulosa disiasat menggunakan mangkin ini dalam reaktor semi-kelompok selama 8 jam. Penukaran selulosa tertinggi (73.9%) dan hasil LA (43.3%) dicapai dalam keadaan ini; kelajuan pengadukan 1100 rpm, suhu tindak balas 200 ˚C, dan pemuatan selulosa 1.5 g

dengan pra-pengurangan mangkin Pd/SiO_2-Al_2O_3 (luas permukaan dan isi pori 485.6 m^2/g dan 0.2459 cm^3/g, masing masing) pada suhu 150 ˚C dan kelajuan pengadukan 1300 rpm (dalam 5 bar hidrogen, H_2 selama 1 jam).

Kata kunci: Pd/SiO_2-Al_2O_3, selulosa, hidrolisis, asid levulinik

Introduction

Cellulose, a part of biomass, is a major component of lignocelluloses as it comprises 40-50% of lignocellulose composition. It is formed by dehydration and condensation of glucose produced from photosynthesis [1]. Starch, which is likewise created by photosynthesis but having a different characteristic than cellulose, can be classified as biomass. Starch, a polymer with α-1→4 glycosidic linkages, is soluble in hot water and is the main constituent of corn, potato, and rice. Even though considerable attention has been given to the production of fuels and chemicals, starch should be prioritized as a dietary source [2].

Furthermore, the amount of cellulose is so enormous that it is wasteful to simply let it decompose without exploring its potential benefits. The commercial feasibility of producing sugar alcohols such as sorbitol and mannitol, which are particularly valuable in the food sector as sweeteners and preservatives, by using hydrogenation method is one way to utilize this enormous resource [3]. When it comes to catalytic cellulose hydrolysis, LA is the main product produced after cellulose undergoes a few processes; 1) hydrolysis 2) dehydration and 3) rehydration [4]. Figure 1 shows the reaction pathway for the production of LA from cellulose.

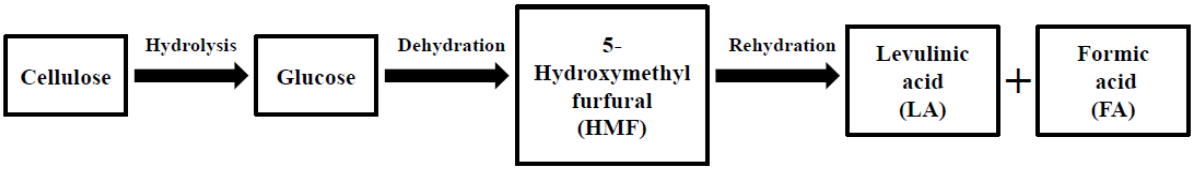

Figure 1. Reaction pathway for the production of LA from cellulose

LA is a water-soluble, organic compound that comes from the family of carboxylic acid and ketone, possessing a wide range of reactivity and functionality [5]. These two functional groups cause LA to be a very versatile building block for a vast chemical transformation of high-value organic chemicals, resin precursors, polymers precursors, and fuel additives with plenty of potential industrial applications [4]. Succinic acid and maleic anhydride are two high value-added chemicals that can be synthesized from LA and are useful in the food and textile industries, respectively. Aside from that, LA can be utilized as a starting material for the production of γ–valerolactone, as well as ethyl and methyl levulinate, making it a potential alternative to petroleum-based fuels or chemicals [6]. Aside from choosing LA as the final product, the reaction can be tuned up to produce various products with high yields, such as 5-hydroxymethylfurfural (HMF) and formic acid (FA).

Over the past decade, homogeneous catalysts have been used in many applications, including LA synthesis (using acids). Despite its efficiency, there are a few drawbacks to use this type of acid in the system, including the generation of additional wastes due to the difficulties of separation and recovery (environmental pollution). Besides that, this catalyst leads to equipment corrosion [7]. As a result, many researchers nowadays prefer to use heterogeneous catalysts in their systems, especially solid catalysts to overcome the issues that arise from the homogenous catalyst. Metal oxides, supported metals (nickel, Ni), H-form zeolites, carbonaceous acids, heteropoly acids, acid resins, magnetic acids, and functionalized silicas are the

examples of solid catalysts that have garnered attention as promising and appealing catalysts for the hydrolysis of cellulose [8].

Recently, there has been a noticeable growth towards employing cheap, non-noble metal-based catalysts such as Ni, yet the study on this catalyst's stability and recyclability needs to be emphasized as leaching and sintering can be mainly responsible for the decreasing catalytic activity [9]. Hence, in this research study, Palladium (Pd), a noble metal that can be regenerated and recycled up to 20 times without observing any significant loss of activity [10] was utilized as a catalyst. Even though Pd is relatively expensive when used individually, Pd can be incorporated into high dispersion and narrow sizes distribution of catalyst support such as silica (SiO_2) and alumina (Al_2O_3). Despite the high cost of Pd, it is widely acknowledged for its high chemical stability and catalytic abilities [11].

Therefore, this research was conducted to study the effects of various reaction conditions such as agitation speed, temperature, and substrate loading on the production of LA from cellulose using noble metal, Pd supported on different catalyst supports such as silica-alumina (SiO_2 -Al_2O_3) and gamma-alumina (γ-Al_2O_3). As a result, the most suitable catalyst that was effective in the conversion of cellulose to LA (under the conditions studied) could be determined throughout the experiments.

Materials and Methods

Materials

For the synthesis of catalyst, palladium (II) nitrate ($Pd(NO_3)_2$) with 40% w/w of Pd, SiO_2-Al_2O_3 grade 135 ($\leq$100%), and γ-Al_2O_3 (99.9%) were purchased from Sigma Aldrich and Alfa Aesar, respectively. As for the experimental work, microcrystalline cellulose (extra pure, 100%) from Acros Organics was used as substrates. In addition, glucose (>99.9%), HMF (>98%), LA (>98%), FA (>98%), and furfural (>99.9%) were used for standard reference calibration purposes. All the chemicals were analytical grade without further purification and distilled (DI) water was used for all the experiments.

Catalyst preparation

The solid noble catalyst was prepared using wet impregnation method. This method aimed to provide 5 g of 4 wt.% Pd on SiO_2-Al_2O_3 support. About 4.8 g of SiO_2-Al_2O_3 was weighed and spread on a petri dish. Then, 0.5 g of $Pd(NO_3)_4$ was dissolved in the minimum amount of DI water necessary to wet the SiO_2-Al_2O_3 support; this was found to be 3.3 ml of DI for 4.8 g of SiO_2-Al_2O_3. The diluted $Pd(NO_3)_4$ was dropped to the spread SiO_2-Al_2O_3 carefully using a syringe. The dropping was done in a circular motion where each $Pd(NO_3)_4$ droplet was at different point. After that, the $Pd(NO_3)_4$ was pressed using a spatula to achieve a homogenous mixture between $Pd(NO_3)_4$ and SiO_2-Al_2O_3. The prepared catalyst was dried using an oven at 110 ˚C for 12 hours to remove the excess moisture prior to calcination. The catalyst was then calcined at 500 ˚C for 5 hours. The catalyst was stored in a vial sealed with parafilm, and stored in desiccator prior to analysis and experimental work. The method was repeated to prepare 4 wt.% Pd on γ-Al_2O_3 support.

Catalyst characterization

The Fourier-transform infrared spectroscopy (FTIR) analysis was conducted with a Nicolet iS10 FTIR with a spectral resolution of 8 cm^{-1} at room temperature and accumulation of 5 scans in an open beam air background [12]. The spectrum ranged from 4000 cm^{-1} to 400 cm^{-1}. The Brunauer–Emmett–Teller (BET) method was used to determine the surface area and pore volume using Micromeritics 3Flex where the catalyst was degassed at 150 ˚C for 12 hours in N_2 prior to analysis.

Experimental procedure

The pre-reduction of catalyst and the experimental work for the catalytic conversion of cellulose to LA were carried out in a 100 ml stainless steel semi-batch reactor. The pre-reduction of catalyst was conducted with 5 bar of hydrogen gas (H_2). The desired temperature (130 ˚C and 150 ˚C) and agitation speed (600 rpm and 1300 rpm) were set according to the parameters studied for 1 hour. As for the reaction work, after the pre-reduction of catalyst, cellulose was loaded into the reactor containing catalyst and distilled water. The air inside the reactor was purged out using N_2

about three times. Once the desired temperature (170 ˚C and 200 ˚C) had been achieved, the stirring speed (1300 rpm) and timer were set accordingly. The reaction took place for 8 hrs. The samples were collected at the time interval of 0 min, 30 min, 60 min, 120 min, 180 min, and 480 min by opening the valve of the sample port. After releasing the gas inside the reactor, to stop the reaction, the reactor was quenched into a beaker with cold water.

The remaining solid product was collected and filtered using filter paper before drying in the oven at 100 ˚C overnight. The weight was recorded regularly until a constant weight of ±0.005 g was achieved. This data was essential for the calculation of cellulose conversion to products. The final weight of cellulose and cellulose conversion was calculated using Equations 1 and 2, respectively.

The weight of the cellulose could only be obtained at the end of the experiment because the reactor used was a semi-batch reactor. Thus, the remaining solid product could not be collected during the reaction process.

Product analysis

The liquid products were filtered to remove any impurities and analyzed using a High-Performance Liquid Chromatography (HPLC) system: Sugar SH1011 (SHODEX, Japan) with ion exclusion mode (column's physical size: 8.0 mm I.D X 300 mm) and UV as column and detector, respectively. An aqueous solution of sulphuric acid (0.05 M) at a flow rate of 1 ml/min was used as mobile phase and the column temperature was set at 40 ˚C [8].

$$\text{Weight}_{\text{final cellulose}}\,(a) = \text{Weight}_{\text{solid product after drying}} - \text{Weight}_{\text{filter paper}} - \text{Weight}_{\text{catalyst}} \quad (1)$$

$$\text{Cellulose conversion (\%)} = \frac{a - \text{Weight}_{\text{initial cellulose}}}{\text{Weight}_{\text{initial cellulose}}} \times 100\% \quad (2)$$

Results and Discussion

Catalyst characterization (FTIR)

The validation of the decomposition of precursor (nitrate) in the synthesized catalyst after calcination at 500˚C was verified by FTIR analysis. A FTIR spectrum comparison between catalysts before and after calcination was conducted, and the findings are presented in Figures 2 and 3. Table 1 shows the summary of the functional group present in this study.

Based on Figures 2 and 3, a similar trend of FTIR spectrum was obtained for each of the catalysts. The spectral range of 3600-3200 cm^{-1} and 1700-1600cm^{-1} were assigned to the stretching and bending modes of absorbed water molecules through hydrogen bonding, respectively [13,14]. The presence of C-O stretching band at the spectral range of 2400-2300 cm^{-1} represented atmospheric carbon dioxide (CO_2), an impurity and sign that contamination might have occurred [15,14].

The FTIR spectrum around 1450-1300 cm^{-1} proved the presence of nitrate precursor (NO_3^-) in the catalyst (before calcination) [16,17]. The diminishing intensity of the catalyst's peak after calcination implied that the decomposition of nitrate was successful at the calcination temperature of 500 ˚C [14]. As a result, it can be concluded that calcination temperature of 500 ˚C is effective in removing nitrate precursor. On the other hand, an extra peak was discovered from the FTIR spectra analysis for Pd/SiO_2-Al_2O_3 (Figure 2) at the range of 1200-1000 cm^{-1}, showing the presence of Si-O-Si [18,19].

Table 1. Summary of the functional group present in this study

Region	Wavelength (cm^{-1})	Peak Assignment
I	3600-3200	O-H stretching, strong, broad
II	2400-2300	C-O stretching
III	1700-1600	O-H bending
IV	1450-1300	NO_3^- (nitrate)
V	1200-1000 (for Pd/SiO_2-Al_2O_3)	Si-O-Si

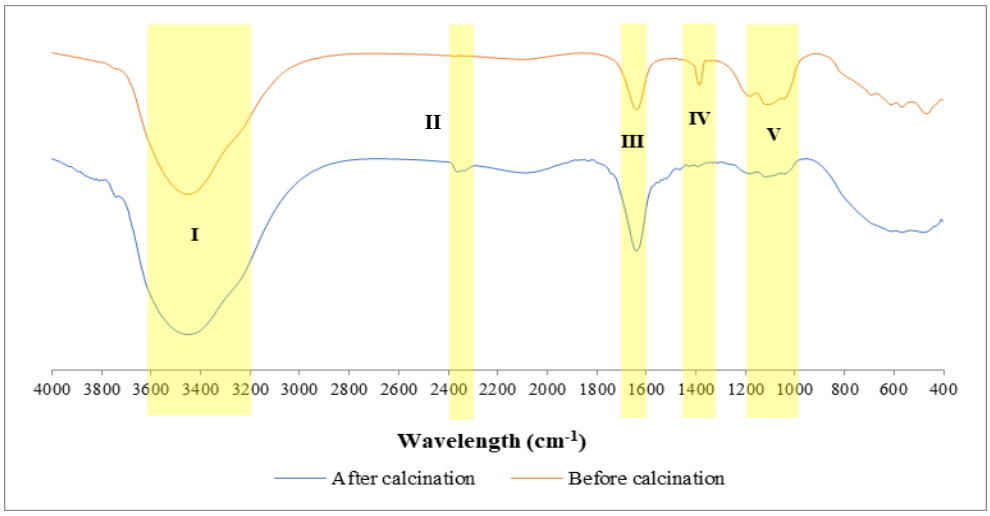

Figure 2. FTIR spectra before and after calcination for catalyst Pd/SiO_2-Al_2O_3

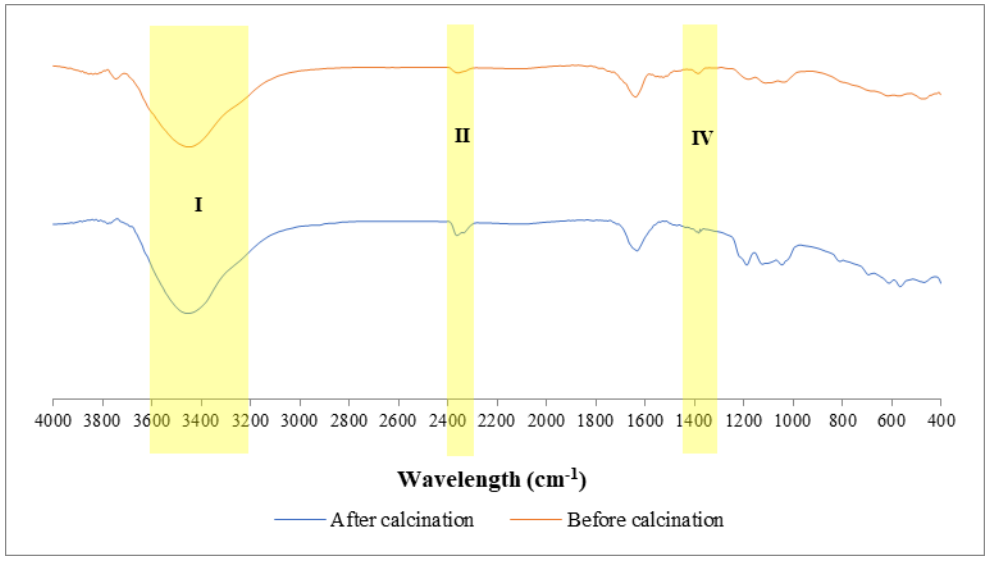

Figure 3. FTIR spectra before and after calcination for catalyst Pd/γ-Al_2O_3

Catalyst characterization (BET)

In heterogeneous catalysts, specific area and pore volume are significant factors to consider especially for the supported catalyst. The BET surface area and pore volume of raw supports and catalysts are listed in Table 2.

Based on Table 2, an increasing trend of surface area and pore volume was observed from raw SiO_2-Al_2O_3 to catalyst Pd/SiO_2-Al_2O_3 (after calcination). The surface area increased from 217.6 m^2/g to 485.6 m^2/g and the pore volume increased from 0.1068 cm^3/g to 0.2459 cm^3/g, which could be explained by the elimination of organic matters where many new pores were formed during the calcination [20]. However, for catalyst Pd/γ-Al_2O_3, the trend of the result was converse from that of the Pd/SiO_2-Al_2O_3 (after calcination) as the surface area and pore volume decreased from raw γ-Al_2O_3 to Pd/γ-Al_2O_3 possibly due to aggregation of catalyst, resulting in losing the surface area and decreasing the pore volume [21].

Catalyst Pd/SiO_2-Al_2O_3 possessed a high pore volume (0.2459 cm^3/g) and surface area (485.6 m^2/g) compared to catalyst Pd/γ-Al_2O_3 (pore volume and surface area of 0.0296 cm^3/g and 79.4 m^2/g, respectively) (Table 2). This could be due to the combination of materials such silica (SiO_2) and alumina (Al_2O_3) that significantly increased the porosity and surface area [22]. Moreover, this observation could be related to the findings according to Table 2 where the pore volume and surface area of the combined materials (SiO_2-Al_2O_3) were two times larger than raw γ-Al_2O_3.

Table 2. BET surface area, pore volume and particle size of raw supports and catalysts

Sample	Surface Area[a] (m^2/g)	Pore Volume[b] (cm^3/g)
SiO_2-Al_2O_3	217.6	0.1068
Pd/SiO_2-Al_2O_3 (After calcined)	485.6	0.2459
γ-Al_2O_3	101.3	0.0504
Pd/γ-Al_2O_3 (After calcined)	79.4	0.0296

[a]: Surface area is obtained from BET method,
[b]: Pore volume is obtained from BET method

Effects of agitation speed during pre-reduction of catalyst and reaction work

Based on Figure 4, at higher agitation speed, an increasing trend in the yield of LA was observed for both of the catalysts. This increasing trend of yield was also seen for HMF and FA, except for glucose possibly because glucose was converted to other products (HMF, LA, and FA). LA produced from cellulose was at the highest (33.5%) when the reaction agitation speed was at 1100 rpm with pre-reduction of Pd/SiO_2-Al_2O_3 catalyst at 1300 rpm. Up to 20.6% of cellulose was successfully converted to products. This high conversion of cellulose and production of LA might be due to the high agitation speed during the reaction; increasing the agitation speed increases the contact area and relative velocity between the two phases, and hence diminishes any external diffusion limitations [23]. Furthermore, the higher surface area and pore volume of Pd/SiO_2-Al_2O_3 catalyst (485.6 m^2/g and 0.2459 cm^3/g, respectively) caused the high conversion of cellulose and yield of LA as these properties led to the high availability of catalytic activity sites [24]. Thus, high catalytic activity could occur during the reaction compared to the usage of Pd/γ-Al_2O_3 catalyst, which possessed a smaller surface area and pore volume of 79.4 m^2/g and 0.0296 cm^3/g, respectively. Owing to these properties, an increment of only 6.4% of LA

yield was observed for catalyst Pd/γ-Al_2O_3 when an increase of reaction speed from 200 rpm to 1100 rpm was employed, with 12.2% of cellulose being converted to products.

Even though the usage of high agitation speed during the pre-reduction catalyst (activation) is not as crucial as high temperature [25], increasing agitation speed during the pre-reduction of catalyst might improve the performance of the catalyst by increasing the surface contact of the catalyst with H_2 which can activate the catalyst prior to the reaction [26]. The pre-reduction for both of the catalysts was aimed to reduce palladium oxide to metallic Pd. As a result, it can be concluded that the reaction agitation speed of 1100 rpm with the catalyst pre-reduction agitation speed at 1300 rpm was the most ideal condition in this study for further experimentation.

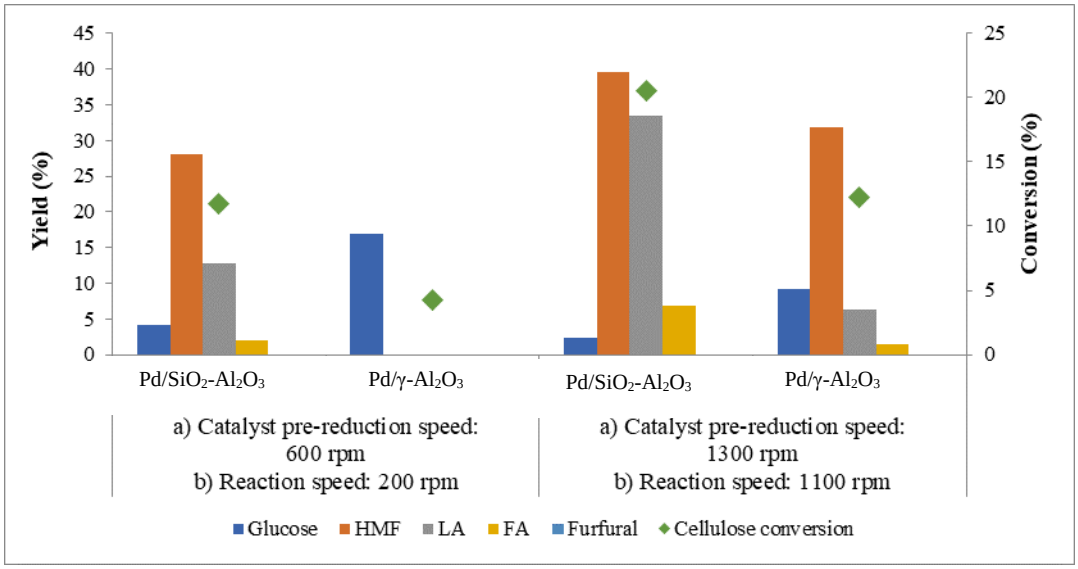

Figure 4. Effects of agitation speed on the conversion of cellulose to LA at 8 hours. Note: a) Catalyst pre-reduction condition: 0.5 g of catalyst, and 5 bar of H_2 at 130 ˚C for 1 hour; b) Reaction condition: 4 g of cellulose, 0.5 g of catalyst, reaction temperature of 170 ˚C, and reaction time of 8 hours.

Effects of temperature during pre-reduction of catalyst and reaction work

Temperature plays a significant role in the production of LA from cellulose, particularly at higher temperatures as demonstrated in a previous study [27]. The effects of temperature on the production of LA from cellulose at different cellulose loading is shown in Figure 5.

Based on Figure 5, a significant increment in the conversion of cellulose and production of LA was observed when the reaction temperature increased from 170 ˚C to 200 ˚C with catalyst pre-reduction at 150 ˚C. Except for glucose, the production of intermediate products and by-products such as HMF and FA, respectively also increased as the reaction temperature rose. According to this study, as the temperature increased (from 170 ˚C to 200 ˚C), the cellulose conversion increased gradually from 20.6% to 73.9% when Pd/SiO_2-Al_2O_3 catalyst (pre-reduction of catalyst at the temperature of 150 ˚C) was employed in the system where the highest LA was produced (up to 43.3%) possibly since the higher reaction temperature accelerated the rate of chemical reaction and provided a faster route for the cellulose to convert to products [8]. Furthermore, a higher reaction temperature promotes greater contact between cellulose and water molecules, resulting in a complete process of cellulose bond breaking to form LA [28]. A similar trend of results was observed with Pd/SiO_2-Al_2O_3 catalyst when

$Pd/\gamma\text{-}Al_2O_3$ catalyst was employed in the system; the conversion of cellulose and yield of LA increased as the reaction temperature increased. However, the conversion of cellulose and yield of LA were lower using $Pd/\gamma\text{-}Al_2O_3$ catalyst in the system compared to $Pd/SiO_2\text{-}Al_2O_3$ catalyst. The conversion of cellulose and yield of LA were only up to 37.1% and 9.5%, respectively.

Moreover, one of the parameters that improved the catalyst efficiency was increasing the temperature from 130 ˚C to 150 ˚C during the pre-reduction of the catalyst. It is advised to heat the catalyst at a high temperature during the catalyst pre-reduction for the metal to finely disperse on the support. Under these high temperatures during heating the catalyst, the mobility of the catalyst can be enhanced, increasing the active site of the catalyst, and thus greatly influencing the catalytic activity [25].

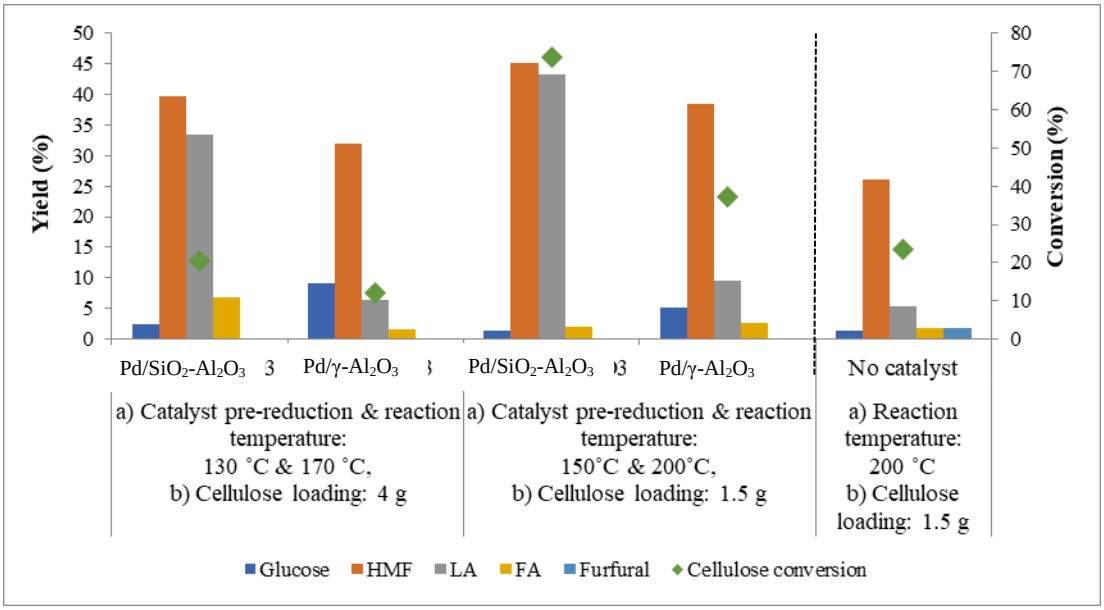

Figure 5. Effects of temperature on the conversion of cellulose towards LA at 8 hours. Note: a) Catalyst pre-reduction condition: 0.5 g of catalyst, agitation speed of 1300 rpm, and 5 bar of H_2 for 1 hour; b) Reaction condition: 0.5 g of catalyst, agitation speed of 1100 rpm, and reaction time of 8 hours

Effects of substrate loading

Based on Figure 5, the yield of LA increased gradually for all the catalysts ($Pd/SiO_2\text{-}Al_2O_3$ and $Pd/\gamma\text{-}Al_2O_3$) when 1.5 g of cellulose was used in the reaction (under high-temperature conditions). Increasing the substrates loading might lead to the increasing cellulose availability for the conversion, with a high concentration of LA being produced; however, the yield of LA was shown to eventually decrease as the cellulose loading increased. This might be due to the reactivity diminution or insufficient catalyst dosage for the additional cellulose [4].

Moreover, a blank experiment (without catalyst) was conducted for reference purposes. It was conducted under the ideal condition highlighted in this study. LA produced was at its lowest (5.3%) compared to the other reactions that used catalyst. This might be due to the side reaction that occurred during the reaction where it resulted in the production of furfural [29]. According to Figure 5, it can be highlighted that the production of HMF was more favorable if no catalyst was employed in the system.

Figure 6 shows the reaction profile of reaction using Pd/SiO_2-Al_2O_3 under the high condition in cellulose depolymerization, leading to the formation of LA. According to Figure 6, the yield of all products (HMF, LA, and FA) increased overtime except for glucose. An increasing yield of glucose was reported until 2 hours of reaction, then the yield subsequently decreased. This might be due to the glucose already being used up in converting to other products. Since the hydrolysis of cellulose to glucose was the rate-determining step, once glucose was formed, it was much easier to break down the glucose bond to other products. Hence, it resulted in the formation of HMF (5.73%), LA (17.4%), and FA (0.77%) at the 30 min of reaction time. As a result, 73.9% of cellulose was converted to products, and 43.4% of LA yield was produced at the end of the reaction.

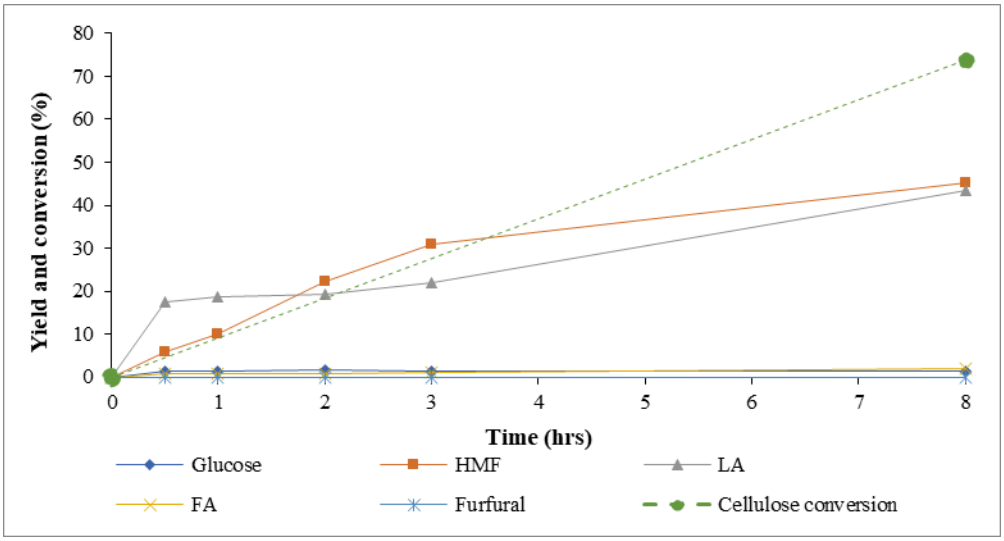

Figure 6. Reaction profile for catalyst Pd/SiO_2-Al_2O_3. Note: Reaction condition: 1.5 g of cellulose, 0.5 g of catalyst (pre-reduction at an agitation speed of 1300 rpm in H_2 at 150˚C for 1 hour), reaction temperature of 200 ˚C, agitation speed of 1100 rpm, and reaction time of 8 hours.

Conclusion

From this research, it can be concluded that the conversion of cellulose to LA is highly influenced by the reaction parameters: agitation speed (1100 rpm), temperature (200 ˚C), and substrate loading (1.5 g) with catalyst pre-reduction at the temperature of 150 ˚C and stirred at 1300 rpm for 1 hour. It was observed that under these conditions, the LA produced was at the highest which was 43.3% and the conversion of cellulose was up to 73.9%. Moreover, the higher surface area (485.6 m^2/g) and pore volume (0.2459 cm^3/g) of Pd/SiO_2-Al_2O_3 catalyst showed better performance to produce LA from cellulose compared to Pd/γ-Al_2O_3.

Abstract

Illicit methamphetamine seizures have risen significantly worldwide, and its widespread use threatens societal well-being. Thus, attention from various parties is required to stem methamphetamine trafficking; however, routine forensic analysis is generally limited to identifying and quantifying the controlled substances according to standard operating procedures. Although further analytical characterization and drug profiling via physical and chemical methods is not routinely conducted, it warrants further exploration for forensic comparison and intelligence. In this study, the physical and chemical profiles of seized illicit methamphetamine tablets were obtained employing various analytical techniques, including physical examination, attenuated total reflectance-Fourier transformed infrared (ATR-FTIR) spectroscopy, thin layer chromatography (TLC), and gas chromatography (GC). Physical characterization did not enable the identification of methamphetamine, but sample discrimination based on unique logos and dimensions was achieved. Based on ATR-FTIR and principal component analysis results, caffeine was found to be the most common adulterant, while the dyes used in the composition were identified via TLC analysis. GC analysis results confirmed the presence of methamphetamine and its quantity. Overall, a methamphetamine tablet profiling strategy was implemented to gather important information regarding the similarities and differences among illicit methamphetamine tablets, potentially beneficial for sample-to-sample, case-to-case, and seizure-to-seizure comparisons.

Keywords: forensic science, methamphetamine, drug profiling, physical examination, chemical analysis

Abstrak

Rampasan metamfetamin haram telah meningkat dengan ketara di seluruh dunia and penggunaannya secara meluas telah mengancam kesejahteraan masyarakat. Justeru, perhatian daripada pelbagai pihak adalah diperlukan untuk mengurangkan penjualan metamfetamin. Namun begitu, analisis forensik rutin secara umumnya dihadkan kepada pengenalpastian dan pengkuantitian bahan terkawal berdasarkan prosedur operasi standard. Sungguhpun pencirian analitikal dan pemprofilan dadah seterusnya melalui kaedah fizikal dan kaedah kimia tidak dilaksanakan secara rutin, hal ini membolehkan penerokaan selanjutnya untuk perbandingan dan perisikan forensik. Dalam kajian ini, profil fizikal and profil kimia pil metamfetamin haram

yang dirampas telah diperoleh dengan menggunakan pelbagai teknik analitikal, termasuk pemeriksaan fizikal, spektroskopi transformasi inframerah Fourier dengan pantulan keseluruhan dikecilkan (ATR-FTIR), kromatografi lapisan nipis (TLC) dan kromatografi gas (GC). Pencirian fizikal tidak membolehkan pengenalpastian metamfetamin tetapi diskriminasi sampel berdasarkan logo dan dimensi unik telah dicapai. Berdasarkan keputusan ATR-FTIR dan analisis komponen utama, kafien dinampakkan sebagai bahan adukan yang paling lazim, manakala pewarna yang digunakan dalam kandungan telah dikenal pasti melalui analisis TLC. Keputusan analisis GC telah memastikan kehadiran metamfetamin and kuantitinya. Secara keseluruhannya, satu strategi pemprofilan pil metamfetamin telah dilaksanakan untuk mengumpulkan maklumat penting berkenaan dengan kesamaan dan perbezaan antara pil metamfetamin haram. Hal ini berpotensi dalam memanfaatkan perbandingan sampel kepada sampel, kes kepada kes, dan rampasan kepada rampasan.

Kata kunci: sains forensik, metamfetamin, pemprofilan dadah, pemeriksaan fizikal, analisis kimia

Introduction

Methamphetamine acts on the central nervous system by stimulating excessive dopamine secretion [1]; thus, it has become one of the most abused stimulants worldwide, as evidenced by a sevenfold increase in global seizures thereof over the past two decades [2]. Although methamphetamine possession, trafficking, and manufacture is strictly enforced and punishable by law worldwide, cases of its abuse are increasing globally, especially in the United States, Europe, Australia, and New Zealand [2]. Users in East and South-East Asia account for more than 30% of the total estimated worldwide users of amphetamine-type stimulant (ATS) [2]. The severe societal well-being deterioration associated with illicit methamphetamine use necessitates collective strategic action, both domestically and internationally.

In recent years, methamphetamine manufacture in the United States, China, and the Islamic Republic of Iran has reportedly decreased, but a significant expansion of illicit methamphetamine drug trafficking has been encountered in Mexico, as well as in East and South-East Asia [3,4], suggesting a gradual shift in this illicit black market from North America to East and South-East Asia. Malaysia, the country where the present study was based, has reported a sharp increase in seized methamphetamine since 2015, wherein approximately 5.8 tons of crystalline methamphetamine and more than 1.6 million illicit methamphetamine tablets had been seized law enforcement authorities in 2019 alone [2]. Recent statistics and trend analyses have indicated that the expansion of the methamphetamine black market in East and South-East Asia has been driven by supply, as the organized crime groups have adapted their trafficking routes in response to law enforcement operations [5,6]. In fact, the growing methamphetamine manufacture in the region has also been supported by an increase in the diversion and trafficking of precursors and related chemicals [6].

Methamphetamine can appear in various forms: as an oily paste consisting of methamphetamine free-base, as a solid, which is the methamphetamine salt form, whereby high-purity methamphetamine salt can appear in crystalline form, commonly termed as “crystal” or “ice”. Methamphetamine is also commonly processed into tablet form known as “Yaba” tablets in Asia, especially in the golden triangle region bounded by Thailand, Laos, and Myanmar. Countries such as Malaysia, Australia, and China are inundated by transnational drug trafficking [7]. Transnational efforts to identify and disrupt the supply chain are therefore crucial. In routine forensic analysis, testing is frequently limited to identifying and quantifying the controlled substance in the illicit drug sample. However, limited information is retrieved regarding the source of origin, supply, trafficking, and distribution network thereof without further post-seizure profiling studies. Studies focused on the profiling of methamphetamine have been conducted, generally employing gas chromatographic techniques [8-10]. However, analytical characterization via physical and chemical methods is less likely to be conducted in forensic laboratories, and therefore gathering further information is required for subsequent forensic comparisons and intelligence. In non-ideal clandestine

laboratory production, the chemical composition of illicit drugs can vary significantly [11]. Illicit drug profiling involving the characterization of seized samples in a systematic manner should be conducted to elucidate the connection between suppliers, distributors, and users [11]. In this study, the physical and chemical profiles of illicit methamphetamine tablets were investigated employing various analytical techniques. Integrated approach for profiling illicit drugs could potentially support forensic intelligence [11-13] and be particularly useful for law enforcement authorities.

Materials and Methods

Standards and samples

Illicit methamphetamine tablets (164 samples) seized between January 2019 and December 2020 were used in this study. Methamphetamine, ephedrine, and caffeine standards were sourced from certified reference material suppliers, while various sugars, including glucose, lactose, dextrose, maltose, and mannitol were obtained from Merck (Whitehouse Station, NJ). For thin layer chromatography (TLC) analysis, various dye standards, including Amaranth, Rhodamine B, Erythrosine BS, Carmoisine, Red 2G, Ponceau 4R, Tartrazine, Sunset Yellow, Fast Green, Green S, and Brilliant Blue were sourced from Merck (Whitehouse Station, NJ). All solvents used, including glacial acetic acid, 25% w/w ammonia (S.G. 0.880), acetone, methanol, 2-propanol, n-butanol, and butanone, were of analytical grade. Nortriptyline HCl was used as the internal standard (IS) for gas chromatography (GC) analysis. Chloroform and methanol used to dissolve the standards and samples were of GC grade and were sourced from Merck (Whitehouse Station, NJ).

Physical examination

Physical examination was performed on the seized tablets by observation of the stamp or logo on each tablet, and that of their respective colors. The diameter and thickness of each sample (± 0.02 mm) were also measured using vernier calipers, while the weight (± 0.01 mg) was determined using an analytical balance. All physical characteristics were recorded and compared.

Attenuated total reflectance-fourier transform infrared spectroscopy

Various drug and adulterant standards, and the illicit methamphetamine samples in powdered form were analyzed directly using a Bruker Fourier transformed infrared (FTIR) Tensor 27 instrument (Bruker Corporation, Billerica, MA) equipped with a single-reflection zinc selenide attenuated total reflectance (ATR) sampling accessory, at a controlled ambient temperature (≈25˚C). Approximately 10 mg of the standard or sample was placed onto the ATR crystal to obtain their ATR-FTIR profiles. A background spectrum was recorded before each analysis run and absorbances were measured in the wavelength range between 4000 and 600 cm^{-1}. The resolution was set at 4 cm^{-1} and 16 scans were performed. The built-in software, OPUS 7.0.122 (Bruker Corporation, Billerica, MA) was utilized for spectrum acquisition. All spectra were recorded in duplicate, compared, and the differences evaluated. A repeatability test was performed by analyzing a representative sample thrice. A reproducibility test was also performed by analyzing a representative sample on three consecutive days. All spectral data were reported as absorbance values at each data point for subsequent interpretation and comparison.

It is often the case that the illicit drugs seized in forensic cases are normally in the form of mixture, which not only contain the drug alone but also adulterants and/or diluents. The influence of mixture composition on the respective ATR-FTIR profiles was investigated. Mixture samples consisting of methamphetamine and different adulterants in varying quantities were prepared. Based on the literature search, caffeine, ephedrine, and various sugars are more common [14,15]. Caffeine is a legal substance, inexpensive and readily available. The stimulant properties of caffeine could also create milder but very similar effect of methamphetamine. Ephedrine is the precursor during manufacturing, usually through Nagai pathway. On the other hand, sugars do not contribute to any additional effects on the methamphetamine but used to dilute or add the bulk of the illicit drugs. Being legal and readily available, sugars give greater margin to the illicit drug manufacturers [14,15]. In this study,

four commonly reported adulterants were used, namely caffeine, ephedrine, lactose, and mannitol. The mixtures (w/w) of methamphetamine and the respective adulterant were prepared at 100%, 90%, 75%, 50%, 25%, 10%, and 0%. All the prepared mixtures then underwent ATR-FTIR analysis.

For statistical analysis, data points of regions with noticeable variations, in the ranges of 3200-2550 cm^{-1} and 1800-600 cm^{-1}, were used. Data points of all ATR-FTIR spectra were transferred into Microsoft Excel® (Redmond, WA) and normalized to remove any possible variation resulting from inconsistent sample quantity. This was done by dividing the absorbance value at each data point to the total absorbance under the spectrum of the standards and samples. The normalized data were then analyzed using Minitab 18 software (Minitab Inc., State College, PA). Principal component analysis (PCA) was implemented for the characterization of illicit methamphetamine samples, and any potential differences among the samples were evaluated.

Thin layer chromatography

Prior to TLC analysis, the dye was extracted from the tablets to remove any sugars, fats, or other substances contained in a tablet [16,17]. The presence of any sugar might cause blurring of the spots upon TLC analysis [18]. Therefore, acidification coupled with alkaline treatment on the samples was suggested for the extraction of dye from tablet-coating formulations [17-19].

Dyes present in the samples were extracted for TLC analysis according to the following procedure. Approximately 10 mg of powdered sample was transferred into a vial. Acetic acid (5% v/v) was added to the vial, followed by the introduction of a knotted piece of white knitting wool, 5 cm in length. Knitting wool was knotted to avoid disassembling of the thread. Note that the wool was firstly washed with dilute ammonium hydroxide and water to minimize the effect of possible interference and to enhance the absorption of dye onto the treated wool. Warming of the mixture in a temperature range of 70-80ºC allowed the transfer of dye onto the knitting wool, and the entire procedure was complete within approximately 15 min. Then, the wool was carefully removed using tweezers and washed thoroughly with distilled water. The treated wool, now visibly colored, was dried and then placed into another vial. Dye extraction was performed by adding 1 mL of a solution consisting of equal volumes of acetone and 3N ammonia and warming for 15 min between 70-80ºC, after which time the wool was removed from the vial. Finally, the resultant dye solution was gently warmed in a water bath to evaporate the solvent and concentrate the solution. All the targeted dye standards were prepared following the above-described procedure for comparison.

TLC separation was performed using silica gel 60 F254 (Merck, Darmstadt, Germany). Four solvent systems were evaluated to select the optimal system for the separation of dyes possibly contained in illicit methamphetamine tablets. The four solvent systems were as follows:

(1) Solvent system A- isopropanol: ammonia (4:1)
(2) Solvent system B- n-butanol: glacial acetic acid: water (10:5:6)
(3) Solvent system C- acetone: butanone: ammonia: water (60:140:1:60)
(4) Solvent system D- isopropanol: ammonia: water (7:2:1)

The various dye solutions obtained from the samples were analyzed using the optimal solvent system. All the visible bands were compared to those of the reference dye standards. The TLC plates were also visualized under UV light to detect the presence of fluorescent spots. Any potential differences among the illicit drugs samples were evaluated based on their TLC profile and the respective dyes contained in the tablets were identified.

Gas chromatography

A methamphetamine standard containing a precisely known concentration thereof was used in both qualitative and quantitative analyses using gas chromatography-mass spectrometry (GC-MS) and a gas chromatography-flame ionization detector (GC-

FID), respectively. Prior to sample analysis, a calibration curve was constructed using the data obtained from the GC-FID analysis of methamphetamine calibration standards in a concentration range of 0.10 – 1.40 mg/mL. Such calibration range had allowed the determination of concentration of the target substance within an illicit tablet. Note that the GC method was adapted from United Nations Office on Drugs and Crime [20] and is utilized in the country of study for routine forensic analysis.

A Perkin Elmer Clarus 600 Gas Chromatographic system coupled with Mass Spectroscopy (MS) (Perkin Elmer, Waltham, MA) was used to confirm the presence of methamphetamine using a HP-5 capillary column (30 m × 0.25 mm i.d., 0.25 µm film thickness) (Agilent Technologies, Santa Clara, CA). Purified helium gas (99.99%) was used as the carrier gas at a constant flow rate of 1.5 mL/min. The front injection temperature was set to 270°C. The initial temperature was 80°C, and it was held for 1 min. The temperature was then increased to 200°C at 30°C/min, followed by a further increase to 270°C at 50°C/min. The final temperature was held for 1.0 mins. The temperature of the transfer line of the MS detector was set to 280°C. The data acquisition rate was 1.0 sec/scan and mass fragments were collected in the 50–500 m/z range. Turbomass Ver 5.4.2 Properties (Perkin Elmer, Waltham, MA) was used for data analysis. The spectra of the target compounds were interpreted, evaluated, and the resultant peaks were identified using the mass spectral library (NIST MS 2014 version 2.2) (National Institute of Standards and Technology, Gaithersbury, MD).

An Agilent 7890B Gas Chromatography system equipped with a split/splitless injector, and an FID (Agilent Technologies, Santa Clara, CA) was used for methamphetamine quantification upon positive identification based on GC-MS results. Liquid injection was performed at a constant inlet temperature of 270°C. Chromatographic separation was achieved using a HP-5 capillary column (30 m × 0.32 µm i.d., 0.25 µm film thickness). Purified helium gas (99.99%) was used as the carrier gas at a constant flow rate of 0.6 mL/min. The initial oven temperature was set at 150°C and held for 1 min. A temperature ramp of 30°C/min was selected to reach the maximum of 270°C and held for 2.5 min. Hydrogen flow, air flow, and the make-up flow were supplied to the detector at 30, 400, and 29.4 mL/min, respectively. Standard solution (1 µL) was introduced into the injector port. Chemstation software (Rev. B.04.02, Agilent, Santa Clara, CA) was used for GC automation and data analysis. All standards and IS were identified by comparison of the retention times.

The drug samples were prepared by weighing an accurately weighed amount of the powdered sample into a 10 mL volumetric flask. The sample was then dissolved using the IS solution to the levelling of mark and ultrasonicated for five minutes to allow for complete dissolution. An IS solution with a concentration of 0.60 mg/mL nortriptyline HCl was used. The solution formed upon the sonication was transferred into GC vial and properly labelled. All prepared samples were then introduced into the GC systems.

Upon analysis by GC-FID, the area under the chromatogram of each peak was integrated and the peak area ratio of the target substance was determined. The percentage of methamphetamine was calculated using Equation 1.

$$\% \text{ methamphetamine} = [(\text{Concentration} \times 10)/\text{weight of sample taken}] \times 100\% \quad (1)$$

where concentration is in mg/mL; 10 is the volume of dissolved sample in a 10 mL volumetric flask, and weight of sample taken is measured in mg. The purity among all the samples tested in this study was then compared.

Drug profiling strategy

A drug profiling scheme involving the physical characterization and chemical analyses of illicit methamphetamine tablets was conducted in that order. A comparative study was performed on the samples

and possible differences were determined on a case-by-case basis.

Results and Discussion

A total of 164 seized illicit methamphetamine tablets were analyzed in this study. Among them, six were green in color (3.7%), differing from the commonly encountered red tablets (96.3%). Therefore, the six green samples were labelled as G01-G06, while the remaining 158 samples were labelled as S001–S158.

Physical examination

Color

The samples analyzed in this study were predominantly red. However, the red color of each tablet differed slightly in terms of the hue, likely due to the use of different dyes. Some tablets appeared cherry-red, while some were maroon in color. Such variation in color could be due to the presence of different dyes or combinations of dyes that had been used in the manufacturing process, which can be determined by chemical analysis of the dye composition. In addition to the red tablets, six tablets were green in color. Generally, only one or two such green tablets are encountered in larger packages of seized samples containing 100 or 200 tablets.

Logo variant

All the methamphetamine tablets were round in shape with a deep convex center. A specific logo was observed on one of the sides, consisting of the letter's "w" and "y", as shown in Figure 1. However, different variations of the logo were noted, whereby "wY", "WY," or "wy" were present. In our case, the "wY" logo was dominant with 155 out of 164 samples (94.5%) being stamped with it [Figure 1(a)-(d)]. A slight variation in the size and positioning of the markings was also noted among the "wY"-labelled tablets, likely due to the use of different tableting machines. Some of the tablets exhibited deeply stamped logos, whereby the two letters could be seen clearly (Figure 1(a)-(b)), while most of the logos appeared very faint (Figure 1(c)-(d)).

Previous studies have indicated that such variations are a result of manufacture by different drug syndicates [21]. Tablets with the "wY" insignia were the most common in the sample set, and it is believed that they are produced by the United Wa State Army [21]. The other two variants, that is tablets bearing the "WY" and "wy" logos, were not common, being noted on only two (1.2%) [Figure 1(e)] and one sample (0.6%), respectively, [Figure 1(f)]. Reportedly, the former variant likely originated from the Myanmar National Defense Alliance Army, while the latter was produced by the Shah United Army 15. The "Wy" insignia was not observed among our seized samples; neither were other less common variants, such as "R", "OK", "888", and "Ã/99" [21,22]. None of the tablets bore an imprint on the reverse side.

The presence of a logo indicated the unique physical characteristics of the methamphetamine tablets, as it appeared on most of our tested samples. However, drug syndicates and trafficking groups other than those mentioned above reportedly stamp the same logos on their tablets, essentially counterfeiting illicit methamphetamine tablets [21,23]. As the samples tested in this study had all been seized, they could have been exposed to unknown physical and environmental conditions; thus, the faintness of the markings and/ or the rough texture of some tablets possibly resulted from exposure to moisture or due to transport and handling practices. Tablets whereby the logo on the surface could not be clearly determined through visual observation accounted for 3.7% of the total samples, or six out of 164 samples.

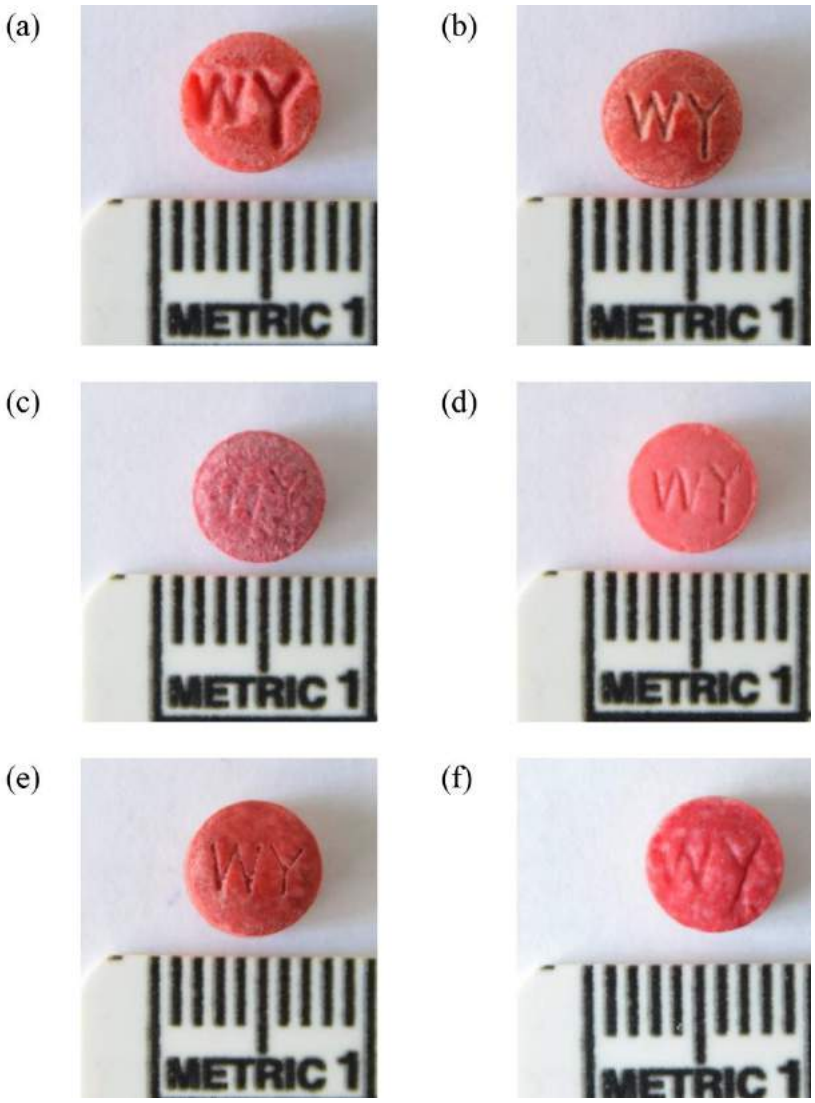

Figure 1. Physical observation of illicit drug tablets encountered in this study.

Dimensions

In terms of size, all of the tablets appeared very similar to each other, and the average diameter and thickness were 6.21 ± 0.21 mm and 3.06 ± 0.14 mm, respectively. Four of the samples were slightly larger in diameter, especially S077, measuring 8.16 mm in diameter. On the other hand, the diameter of S001 was relatively smaller at only 5.60 mm. The weight of each tablet was directly related to its dimensions. In this study, the average weight of the tablets was 97.63 ± 32.52 mg, but the range was from 26.50 mg to 474.95 mg, showing significant variation. The heaviest sample was S017, although its diameter and thickness were within the dimension range of the dominant group. Figure 2 illustrates the number and percentage of samples with a certain diameter, thickness, and weight.

In most instances, drug tablets produced using the same tableting machine present uniform dimensions and thickness [24]. A tableting machine compresses pharmaceutical powder with a specific formulation into tablet form, resulting in the production of tablets with uniform size, shape, and weight [24,25]. Thus, the variation in the physical characteristics could be as a

result of the use of different tableting machines in the production step [21,23]. Any differences in terms of the punches and dies of a tableting machine could potentially produce tablets that differ in diameter [21]. Tablet thickness could be affected by the compressive force, even when a consistent ingredient fills of the die is practiced [21,26]. Tablet weight is governed by the volume of the ingredient filling the die cavity in a tableting machine, and the size of the granule and void space would influence the weight [21].

For forensic intelligence, our findings suggested that the majority of illicit drug samples were likely to have similar physical characteristics, but several samples that showed significant variation from the dominant group were identified. Taking note of such variation could be beneficial for differentiating between batches and manufacturers, at least for sample-to-sample, case-to-case, and seizure-to-seizure direct comparisons [27]. The physical examination would additionally be supported by the information obtained from the chemical analyses for forensic characterization.

ATR-FTIR analysis

ATR-FTIR spectral comparison of illicit drug samples and standards

ATR-FTIR spectroscopy is a useful technique for analyzing and identifying samples, as well as for comparing various samples in numerous forensic applications [28,29]. All 164 illicit drug samples (158 red-colored and 6 green-colored samples) were analyzed using ATR-FTIR spectroscopy to determine their structure, compare their spectra with that of the methamphetamine standard, and to differentiate the seized samples. Prior to determination and comparative studies, repeatability and reproducibility tests were performed. A representative sample (S001) from the same seizure was used in the repeatability study, showing close agreement between three successive measurements under the same conditions [Figure 3(a)]. In the reproducibility study, no differences were observed in ATR-FTIR spectra when S100 was analyzed thrice on three consecutive days [Figure 3(b)], indicating that ATR-FTIR spectroscopy is capable of generating comparable results from multiple analyses and preparations of the same sample. For both repeatability and reproducibility tests, the intensity of three major peaks appearing at 1691, 1653 and 743 cm^{-1} were respectively measured, and their relative standard deviations were determined to be less than 5%.

Complex interacting vibrations were evident in the ATR-FTIR spectra of both the standards and samples. Figure 4 depicts the ATR-FTIR spectra of the methamphetamine standard and common adulterants, including caffeine, ephedrine, and various sugars [14,15], added during the manufacture of illicit methamphetamine tablets.

With reference to (Figure 4(a)), the absorbance pattern of methamphetamine contained major peaks in regions ranging from 3200 to 2550 cm^{-1} and 1800 to 650 cm^{-1} [29-31]. Broad absorbance bands were observed at 2972, 2726, and 2457 cm^{-1}, and were attributed to C-H ($C-CH_3$), NH_2, and C-N-C stretching vibrations, respectively. Meanwhile, two sharp absorbance peaks were also observed at 699 cm^{-1} and 747 cm^{-1}, likely arising from the aromatic C-H out-of-lane bending vibration. The existence of an aromatic ring stretching vibration (C=C-C) at 1602 cm^{-1} could be unique to aromatic ring bonding, while the absorbances at 1454, 1386, and 1046 cm^{-1} likely arose due to C-H bond deformation in the chemical structure. Absorbance peaks in the region of 1192 cm^{-1} possibly represented C-N stretching in a secondary amine structure of methamphetamine.

The ATR-FTIR profile of ephedrine (Figure 4(c)) appeared very similar to that of methamphetamine due to their similar structure. However, the distinguishing feature of the ephedrine spectrum was the presence of additional absorbance bands at 3400 and 3200 cm^{-1} ascribed to hydroxyl stretching. Additionally, the absorbance peaks of ephedrine appeared weaker than those of methamphetamine in the region of 2400-3100 cm^{-1}.

In the spectrum of caffeine (Figure 4(b)), prominent absorbance peaks were evident in the region of 1655-1705 cm^{-1}, attributed to C=O bond vibration, C=C bonds of cyclic hydrocarbons, and/or C=N bond stretching. The ketone group present in caffeine gave rise to peaks at 1025 and 1237 cm^{-1}. Additionally, C-N stretching gave rise to an absorbance peak at 1359 cm^{-1}, while C=C vibration contributed to the peak at 1486 cm^{-1}.

From the ATR-FTIR spectra of the five types of sugars tested in this study, glucose [Figure 4(d)] and dextrose (Figure 4(h)) had very similar profiles. As disaccharides, the spectra of lactose [Figure 4(e)] and maltose [Figure 4(f)] also appeared very similar to each other. Lastly, the spectrum of mannitol [Figure 4(g)], a type of sugar alcohol used as sweetener, was distinct, containing two intense absorbances at 1074 and 1015 cm^{-1}. Absorbance peaks in the ATR-FTIR profiles of sugars arise predominantly from skeletal C-C vibrations (1300-700 cm^{-1}), methyne C-H bending (1350-1330 cm^{-1}), and H-bonded OH stretching (3570-3200 cm^{-1}).

Visually, two unique ATR-FTIR spectral patterns were observed for the illicit drug samples tested in this study, as depicted in Figures 4(i) and 4(j). Careful analysis suggested that pattern A (Figure 4(i)) contained peaks similar to those of caffeine, while pattern B (Figure 4(j)) resembled the spectrum of mannitol. In this study, only one sample, namely S077, showed ATR-FTIR profile of pattern B. Experimental results can be used to determine the major adulterant added to the composition of illicit drug tablets during the manufacturing process. It was noted that the choice of adulterants can differ among the drug distributors and manufacturers, due to factors such as user preference, drug syndicate "trade-marks," the availability of these substances, and differing strategies for increasing the profit margin [32,33]. The ATR-FTIR profiles of the six green tablets did not differ from those of the red tablets, suggesting that the tablets had a similar composition, with the exception of the dye.

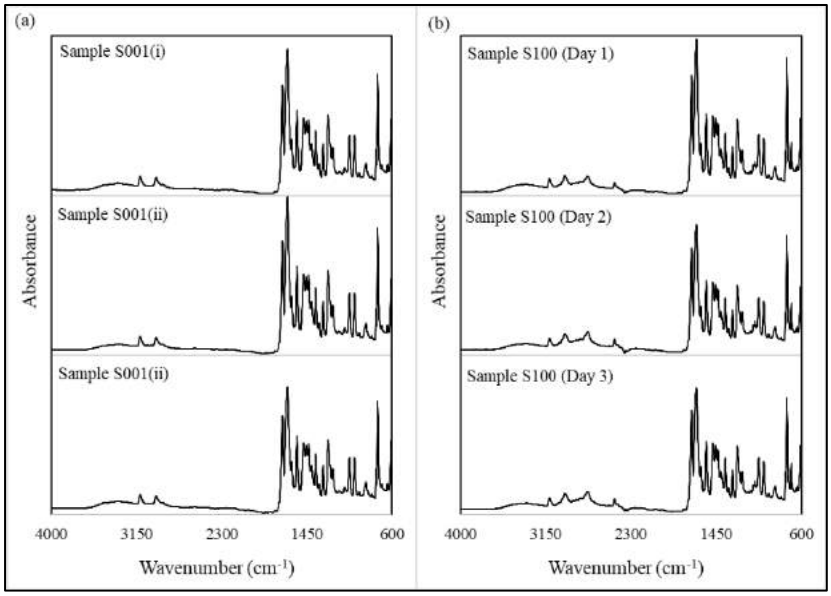

Figure 3. (a) Repeatability test using sample S001 as representative sample, and (b) reproducibility test using sample S100 as representative sample

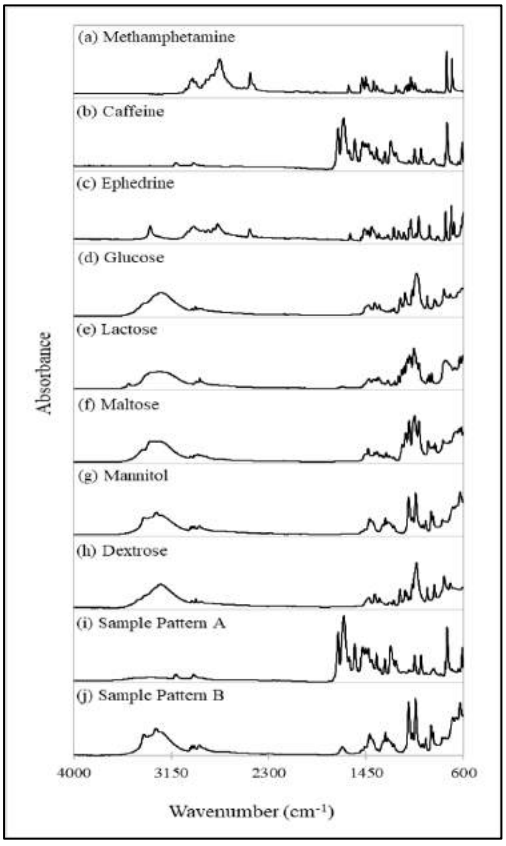

Figure 4. ATR-FTIR spectra of drug standards and seized illicit drug samples in the region of 4000 to 600 cm^{-1}

ATR-FTIR spectral comparison of adulterated methamphetamine at varying percentages

To further evaluate the inclusion of adulterants and their influence on the resultant ATR-FTIR profiles, varying ratios of methamphetamine and adulterants were prepared, and the spectra of the mixtures were examined. Figure 5 illustrates the comparison of the ATR-FTIR profiles of the methamphetamine standard containing varying adulterant amounts.

As evident in Figure 5, the ATR-FTIR profile of methamphetamine changed upon the addition of adulterants, regardless of the choice of adulterant. With increasing adulterant content, the prominent methamphetamine absorbance peaks gradually reduced in intensity or became concealed by the intense peaks originating from the adulterant. For instance, an increase in caffeine content in a mixture led to a gradual decrease in the intensity of the main absorbance peak at 699 cm^{-1}. When methamphetamine content reached 25% in the mixture, the peak was no longer detectable. Additionally, the broad absorbances within the wavenumber region of 3100-2400 cm^{-1} also underwent significant changes. On the other hand, absorbance peaks arising from caffeine were evident in the range of 1655-1705 cm^{-1} for a mixture containing 25% caffeine. Absorbance peaks in this region became more intense with increasing caffeine content. From Figure 5(a), the absorbance peaks attributed to methamphetamine were virtually absent for a mixture containing > 75% caffeine, and the spectrum resembled that of the pure caffeine standard. Based on the ATR-FTIR spectra of the methamphetamine and ephedrine standards, the spectrum of their mixture contained an additional peak at 3340 cm^{-1} due to the presence of a hydroxyl group in ephedrine (Figures 5(b)). When sugars were added to the composition, the dominant peaks from methamphetamine also decreased in intensity, gradually being replaced by the peaks arising from the sugars. In other words, the ATR-FTIR profile of the mixture started to resemble that of the sugars with increasing sugar concentration (Figures 5(c) and (d)).

Regardless of the adulterant added, the peaks ascribed to methamphetamine remained prominent in the ATR-FTIR spectrum when methamphetamine content was 75% and above. However, with the addition of 50% or more of any adulterant, the presence of methamphetamine was challenging to confirm using the ATR-FTIR profile of the mixture. A previous study has suggested the potential of using ATR-FTIR spectra to identify methamphetamine when the concentration thereof is >30% [34]; however, the presence of adulterants impeded the determination of methamphetamine in our study. In our case, at least 75% methamphetamine content was required for confident determination of its presence in a mixture. Thus, the ATR-FTIR technique has several limitations, particularly when the screening for the presence of methamphetamine as a controlled substance. However, the ATR-FTIR technique could be applied in clandestine laboratory settings where illicit drugs of very high purity have been synthesized prior to the packaging stage. In such cases, ATR-FTIR spectroscopic analysis would allow for rapid determination and portable on-site detection.

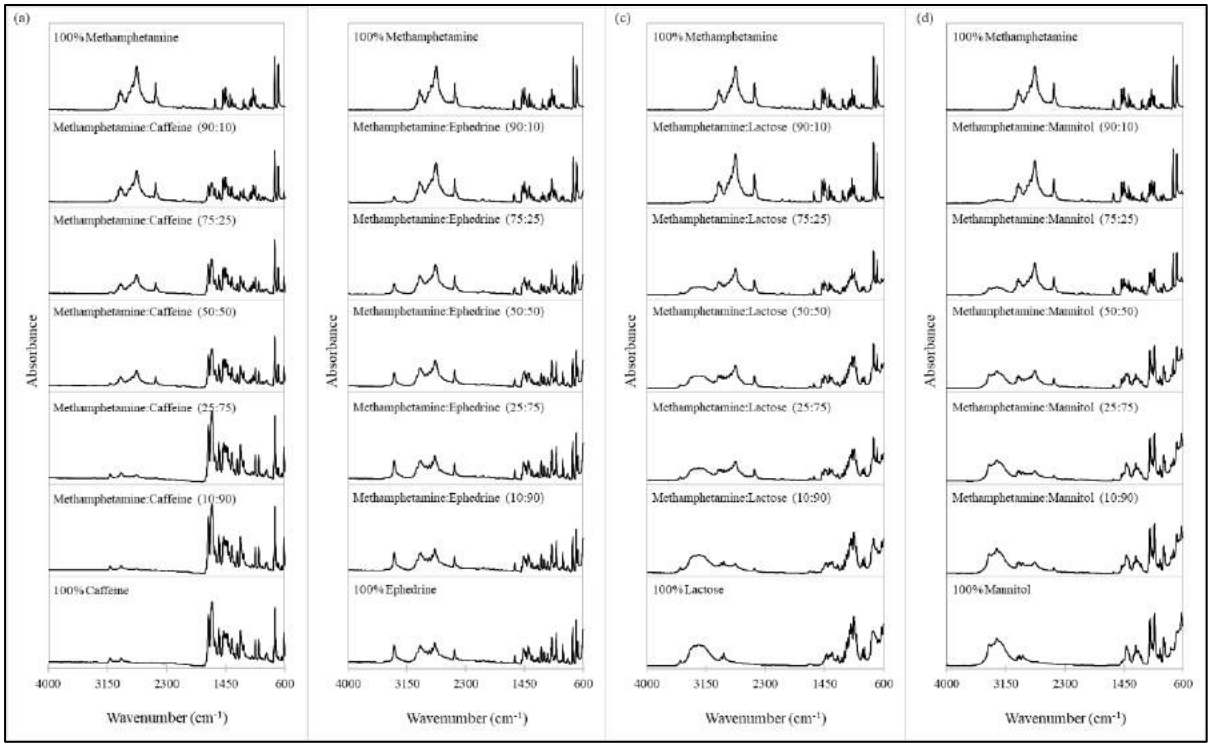

Figure 5. ATR-FTIR profiles of methamphetamine with varying percentage of adulterants

PCA decomposition of ATR-FTIR profiles

Our findings indicated that the determination of methamphetamine presence in illicit drug tablets using ATR-FTIR spectroscopy could be challenging. However, the identity of the adulterant in an illicit drug pill could be determined via this technique based on the obtained spectrum, and consequently, samples of differing composition can be differentiated. PCA was performed to decompose the large dataset into a smaller set that represented the variability of all the 164 samples tested in this study. Prior to the PCA, the ATR-FTIR spectra were pre-treated and normalized. From the ATR-FTIR spectra in Figure 4, the regions with noticeable variations among the standards and samples, namely those ranging from 3200 to 2550 cm^{-1} and 1800 to 650 cm^{-1}, were subjected to PCA. Figure 6 illustrates the two-dimensional score plot upon PCA decomposition of data for the 164 illicit drug samples and related standards.

The majority of the illicit drug samples tended to locate closely, as seen for cluster P in the score plot (Figure 6). These samples were clustered together with the caffeine standard, suggesting the similarity in their ATR-FTIR profiles. This observation was supported by the visual comparison of their ATR-FTIR spectra, wherein they appeared very similar, as demonstrated in Figures 4(b) and 4(i). On the other hand, the S077 sample was located away from the cluster P, while being close to the sugar standards, denoted as cluster Q. S077 could have been adulterated with any sugar, most likely mannitol, based on the similarities of its ATR-FTIR profile with that of mannitol (Figure 4(g)). The PCA grouped the green samples into cluster P, as the color did not contribute to significant changes in the ATR-FTIR profile.

The PCA score plot indicated that all the illicit drug samples were located very far away from the methamphetamine standard data point, found in the right bottom corner. This observation implied that the absorbance peaks comprising the ATR-FTIR profile of the methamphetamine standard were not useful for determining its presence in the illicit drug tablets, as

they were concealed by the peaks originating from the adulterants. It was noted that the ephedrine standard was located close to methamphetamine (cluster R), indicating significant similarities between their ATR-FTIR profiles. Generally, PC1 (52.8%) discriminated the majority of the samples from the standards and adulterants, including methamphetamine, ephedrine, and various sugars. PC2 (26.9%) further separated the methamphetamine and ephedrine standards from the data points consisting of various sugars. The presence of adulterant had modified the ATR-FTIR profiles of methamphetamine. As evident in Figure 7 demonstrating the score plot decomposing drug samples and the standard-adulterant mixtures, data points of the mixture carrying greater percentage of adulterant, in this case caffeine, had been dispersed away from cluster R to cluster P. Majority of the drug sample tested in this study could have contained less than 25% active compound and adulterated with caffeine. The sample S077 might have also contained a percentage of methamphetamine at a level of less than 10% and adulterated with sugar, probably mannitol based on the ATR-FTIR spectrum.

In this study, the discrimination of illicit drug samples was possible through the use of ATR-FTIR spectroscopy by recognizing the corresponding pattern and comparing it to that of the standards and adulterants. PCA allowed for more objective clustering and discrimination. The majority of the illicit drug samples tested in this study were adulterated with caffeine, except for one sample, namely S077, that likely contained mannitol. The literature has suggested the preference for utilizing caffeine as the adulterant during illicit drug production probably due to the similar stimulant effect of caffeine as in methamphetamine [15,23]. Perhaps more samples from different regions of the country should be included in future profiling activities to evaluate if the choice of caffeine was restricted to the east coast of the country, or generally, across the country and in nearby countries.

TLC analysis

Choice of Solvent System

Prior to TLC analysis, the dye was extracted from the tablets to remove any sugars, fats, or other substances contained therein [16,17] that could potentially cause blurring of the spots upon analysis [18]. Thus, the dye was transferred to a piece of wool via acidification and subsequently stripped from the wool by alkaline treatment [17-19,35]. All the dye standards used in this study underwent the same procedure as did the negative control. Upon TLC analysis, all the standards developed colored spot(s) on the plate when various solvent systems were applied, and their respective retention factor (R_f) values are given in Table 1.

Among the dye standards, the Rhodamine B dye standard exhibited strong fluorescence under long-wave UV light illumination; Erythrosine BS fluoresced weakly. Adequate separation of the dye standards could not be achieved using solvent systems B or C for TLC analysis. These solvent systems were excessively polar, and the dye components moved high up the plate due to insufficient interaction with the stationary phase. Solvent system A consisting of isopropanol and ammonia (4:1 v/v) reportedly achieves effective separation of synthetic food colorants with minimum tailing effects [17]. However, it was found that certain dye standards were not adequately separated using solvent system A, as evident from the very close R_f values of the color spots formed by Tartrazine and Brilliant Blue. The color spot generated from Brilliant blue dye was also very close to those formed by the two green-colored dye standards used in this study, namely Fast Green and Green S. These occurrences hamper interpretation, especially in the analysis of green tablets. In fact, the green color may be the result of a blue and yellow dye mixture.

Favorable separation among the dye standards was achieved with silica gel plates eluted with solvent system D consisting of isopropanol, ammonia, and water in a volume composition of 7:2:1, especially in the case of the red dyes. Furthermore, the greater separating distance between the spots formed by Tartrazine and Sunset Yellow dye standards resulting from the use of solvent system D would allow for more confident discrimination between these two dyes potentially found in the green tablets. Thus, solvent system D was used for the subsequent determination of dye components in the illicit drug samples.

Table 1. R_f values of the color dye standards upon TLC analysis

Standard	Solvent system A	Solvent system B	Solvent system C	Solvent system D
Amaranth	0.81	0.81	1.00	0.64
Carmoisine	0.88	0.91	1.00	0.70
Erythrosine BS	(0.93)	(0.94)	(1.00)	(0.82)
Ponceau 4R	0.81	0.87	1.00	0.65
Rhodamine B	(0.90)	(0.90)	(1.00)	(0.82)
	(0.74)	(0.87)	(0.88)	(0.76)
	(0.71)		(0.80)	(0.65)
Red 2G	0.84	0.90	1.00	0.73
Tartrazine	0.78	0.87	1.00	0.64
Sunset Yellow	0.83	0.88	1.00	0.73
Fast Green	0.83	0.88	1.00	0.68
	0.80	0.86		0.65

Determination of dye components in illicit drug samples

In pharmaceutical products, the addition of color aids in enhancing drug acceptability, discrimination among different drugs, and prevents counterfeiting 18. In illicit drugs, dyes are used to improve their external appearance, and to render them readily identifiable on the drug scene [36]. Figure 8 illustrates the percentages of drug samples that contained specific dye components. Upon examination, a total of 151 samples (95.6%) contained Ponceau 4R as the only dye. In addition to Ponceau 4R, Erythrosine BS (0.6%), Sunset Yellow (1.9%), and Tartrazine (0.6%) were also concurrently detected in certain drug samples, suggesting that the dye used during the manufacturing of certain drug samples was not restricted to a single type. Only two samples were found to be unique and not to contain Ponceau 4R (1.3%), namely S001 and S002, which contained Rhodamine B and Erythrosine BS. The six green-colored illicit drug samples were classified into two separate groups, according to whether they contained Tartrazine and Brilliant Blue (66.7%), or Ponceau 4R as well (33.3%). However, the presence of Ponceau 4R in the two green-colored samples possibly originated from contamination by red-colored tablets as they were all placed in the same packaging.

TLC analysis contributed significantly to the identification of the various dyes contained in the illicit drug samples. Importantly, the dye must be carefully extracted from the samples to ensure satisfactory TLC separation. Ponceau 4R was the most commonly used dye in red-colored samples, but a mixture of dyes was also encountered. Based on TLC analysis results, at least seven different groups of illicit drug samples were determined.

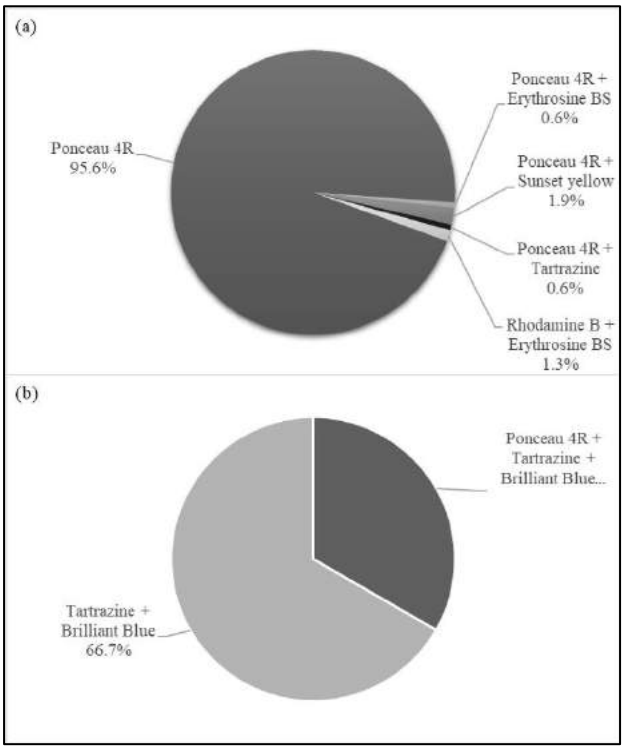

Figure 8. Percentages of samples of varying dye composition in (a) red-colored and (b) green colored illicit drug samples tested in this study

Gas chromatographic analysis

Confirmation of methamphetamine presence

Due to the excellent sensitivity of GC-MS, it was chosen to confirm the presence of methamphetamine [8,11]. Figure 9 shows a representative chromatogram showing methamphetamine and IS peaks upon sample analysis. The methamphetamine and IS peaks appeared at 3.72 and 7.27 min, respectively. The presence of caffeine was also evident in the majority of samples, supporting the findings of ATR-FTIR analysis. The caffeine peak dominated the chromatogram, appearing at a retention time of 6.33 min. The mass spectrum of methamphetamine displayed an M-1 peak with an m/z ratio of 148. The base peak was found at m/z 58, followed by m/z 91 and 134.

Of the 164 samples tested in this study, 162 of them were found to contain methamphetamine; samples S077 and G02 did not. A probability index of greater than 80% was considered for a positive determination of methamphetamine. It was noted that physical examination alone could not confidently indicate the presence of methamphetamine. As evident in these two samples, the target substance was not detected using our analytical method, either because it was absent, or its content was too low for detection.

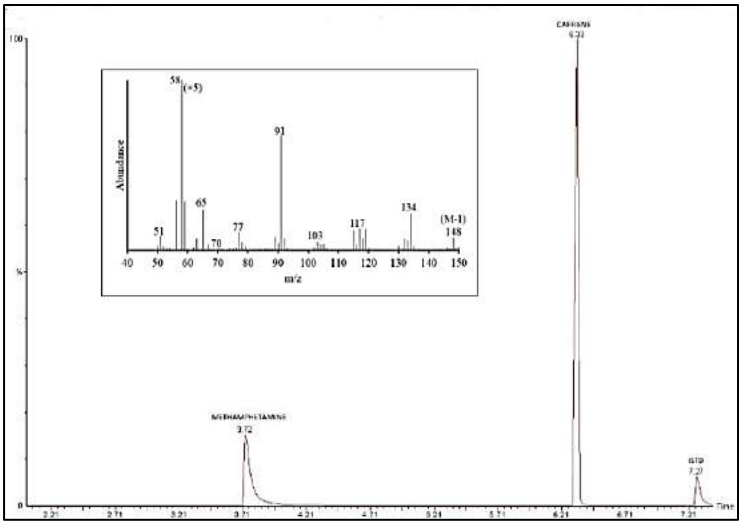

Figure 9. Representative chromatogram showing the peaks of methamphetamine, caffeine, and IS upon GC-MS analysis of sample S001 (Inset: mass spectrum of methamphetamine)

Quantification of methamphetamine in illicit drug tablets

A calibration curve was constructed using the GC-FID analysis results obtained for methamphetamine solutions of varying concentrations and linear least regression analysis, and the percentage of methamphetamine (w/w) in each illicit drug tablet was determined, as shown in Figure 10.

The mass of methamphetamine in individual samples was found to vary. Most of the samples contained 15.01% – 17.50% w/w of methamphetamine, accounting for 64.8% of the total samples. In fact, > 98% of the samples (159 samples) were found to contain < 20% methamphetamine. Our experimental data indicated that most of the tablets had been adulterated with caffeine to add bulk during the manufacturing and tableting processes; however, caffeine quantification was not pursued in this study. Considering the w/w ratios and the tablet weight, approximately 16 mg of methamphetamine was generally present in a single tablet.

Several samples were distinct in terms of their methamphetamine content, which was either significantly higher or lower than the average, allowing for their discrimination from the majority groups. The two samples with a relative higher percentage of methamphetamine were S082 (35.04% methamphetamine) and S094 (56.60% methamphetamine). In other words, they contained significantly lower amounts of adulterant. The empty space between the granules may have been larger, reducing their measured weights [21]. On the other hand, five samples (3.08%) were found to contain <10% methamphetamine. The lowest methamphetamine content was found in sample S002, wherein only 10 mg methamphetamine was detected for all 300 tablets encountered in a single packaging. The remaining w/w percentage of each tablet was principally made up of the adulterant. Samples with such low methamphetamine content are not commonly encountered as their effects upon consumption would be diminished. The other four samples within the same group contained approximately 7% methamphetamine.

Thus, the presence methamphetamine in seized drug samples was confirmed based on GC-MS analysis results and its quantity was determined through the GC-FID analysis. In this study, 98.7% of the samples contained methamphetamine, and only several tablets contained either very high or very low levels of methamphetamine.

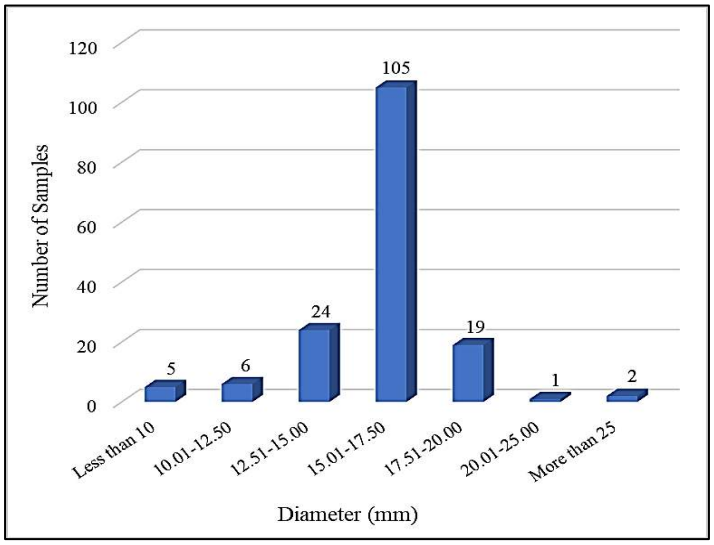

Figure 10. Percentages of methamphetamine (w/w) of 162 illicit drug tablets positively confirmed by GC-MS

General discussion

Based on physical characterization and chemical analyses results, valid information was retrieved regarding the composition of illicit drug samples [37]. In routine forensic analysis, the ultimate objective is to detect the presence of a controlled substance and quantify it. However, more in-depth analysis of illicit drug samples could contribute to a greater comparative study to gather information regarding sample-to-sample, case-to-case, seizure-to-seizure connections, especially when a large number of samples are encountered by the enforcement authorities [38-41]. To a certain extent, this approach could contribute to establishing the origins of illicit drug samples, the possible manufacturing pathway, as well as the potential trafficking and distribution network [42-43], enabling the tracking of drug syndicates or manufacturers.

In this study, illicit drug samples from various seizures were profiled for possible clustering or discrimination among them. Although physical characterization did not provide information on the identity of the substance in the illicit drugs, it allowed for the discrimination of a few samples from the major groups due to their unique physical appearance, especially in relation to their respective logos, diameter, thickness, and weight. ATR-FTIR analysis coupled with PCA indicated that the majority of the illicit drug samples were adulterated with caffeine. TLC analysis enabled the identification of the dyes that had been added to the tablets, whereby Ponceau 4R was found to be the most commonly used dye. Lastly, GC-MS analysis enabled the determination of the presence of methamphetamine as well as that of its content in each tablet through GC-FID. All the analytical results are summarized in Figure 11; the classification of samples into several groups was based on the drug profiling results. The proposed strategy can be used by law enforcement agencies and forensic laboratories to profile illicit drugs, in this case, methamphetamine tablets. Illicit methamphetamine samples tested in this study had demonstrated certain degree of physical and chemical differences. Differentiation among drug samples would be advantageous for sample-to-sample and seizure-to-seizure comparison. It was noted that this profiling study could have been restricted by the availability of methamphetamine samples, limited to the east coast region of Malaysia. A greater number of samples, perhaps from different regions of the country, would

provide information of the current situation of illicit methamphetamine in the country. Nonetheless, data from such analytical endeavors should be further collated as it is necessary for wider forensic intelligence to provide information on the possible connection among seized samples to law enforcement authorities.

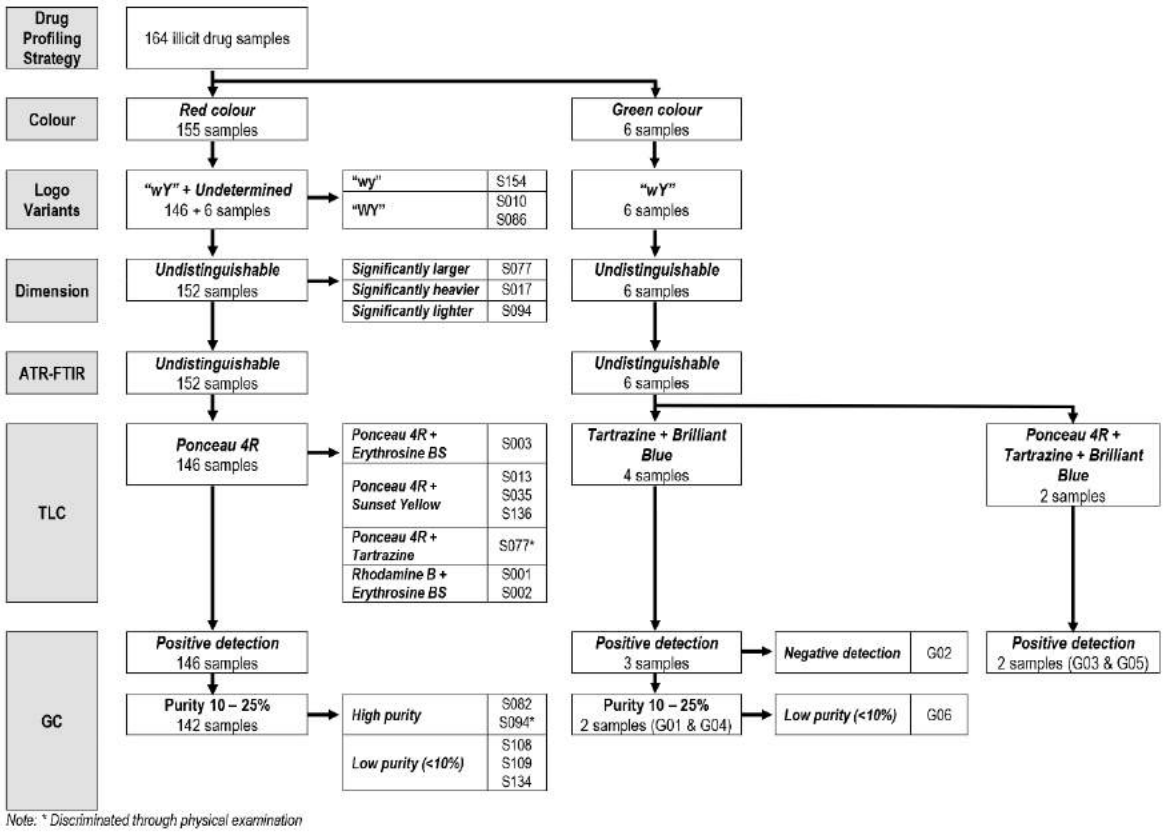

Figure 11. Drug profiling strategy and grouping of illicit drug samples

Conclusion

Forensic drug profiling was conducted with the aim of benefiting forensic investigation and intelligence. In this study, samples were differentiated based on several physical and chemical characteristics, allowing sample-to-sample comparison. With a greater number of illicit drug samples being processed, the linkages between seizures could be revealed, beneficial for tracking down the sources of these illicit drugs on the black market and their related distribution chain. Drug profiling strategies on a global level in accordance with comparative analyses of illicit drug samples would be advantageous for uncovering complex trafficking networks. This information could advance the body of knowledge useful to drug-related investigations and intelligence.

Abstract

The presence of naphthenic acid (NA) in crude oil leads to corrosion problems within oil refineries which may increase the maintenance cost and produce lower quality of crude oil. The objective of this study is to reduce the total acid number (TAN) of Petronas Penapisan Melaka (PPM)'s crude oil (TAN = 2.43 mgKOH/g) using 2-methylimidazole with the aid of Cu/Ce (10:90)/Al_2O_3 catalyst through the catalytic neutralization technique. A 10% of 2-methylimidazole in ethanol solution was used as the acid removal agent. Cerium oxide based catalysts with copper as a dopant were supported onto alumina and calcined at different calcination temperatures of 800 ℃, 900 ℃ and 1000 ℃. The potential catalyst was characterized by using TGA-DTG, FTIR and XRD for its physicochemical properties. The results showed TAN was reduced to 0.53 mg KOH/g with 78.2% reduction at catalyst calcination temperature of 900 ℃, 0.5% catalyst loading, reaction temperature of 27 ℃ and 10 minutes reaction time. The small particle size of catalyst calcined at 900 ℃ which was 18.02 nm led to bigger surface areas that enhanced the neutralization process. These structural properties contributed to the excellent catalytic performance which removed the NAs in the PPM's crude oil and concurrently reduced the TAN value below than one.

Keywords: catalyst, catalytic neutralization, crude oil, naphthenic acid

Abstrak

Kehadiran asid naftenik (NA) dalam minyak mentah membawa kepada masalah kakisan dalam kilang penapisan minyak yang boleh meningkatkan kos penyelenggaraan dan menghasilkan minyak mentah yang berkualiti rendah. Objektif kajian ini adalah untuk mengurangkan jumlah asid (TAN) minyak mentah Petronas Penapisan Melaka (PPM) (TAN = 2.43 mgKOH/g) menggunakan 2-metilimidazol dengan bantuan mangkin Cu/Ce (10:90)/ Al_2O_3 melalui teknik peneutralan pemangkin. 10% daripada 2-metilimidazol dalam larutan etanol digunakan sebagai agen penyingkiran asid. Pemangkin berasaskan serium oksida dengan kuprum sebagai dopan disokong pada alumina dan dikalsinkan pada suhu pengkalsinan berbeza 800 ℃, 900 ℃ dan 1000 ℃. Mangkin berpotensi dicirikan dengan menggunakan TGA-DTG, FTIR dan XRD untuk sifat fizikokimianya. Keputusan menunjukkan TAN dikurangkan kepada 0.53 mg KOH/g dengan pengurangan 78.2% pada suhu pengkalsinan mangkin 900 ℃, 0.5% pemuatan mangkin, suhu tindak balas 27 ℃ dan 10 minit masa tindak balas. Saiz zarah kecil pemangkin yang dikalsinkan pada 900 ℃ iaitu 18.02 nm membawa kepada kawasan permukaan yang lebih besar yang meningkatkan proses peneutralan. Ciri-ciri struktur ini menyumbang kepada prestasi pemangkin yang sangat baik yang mengeluarkan NA dalam minyak mentah PPM dan secara serentak mengurangkan nilai TAN di bawah satu.

Kata kunci: mangkin, peneutralan pemangkin, minyak mentah, asid naftenik

Introduction

Nowadays, crude oil had become one of the most important source of energy in the world. Since raw petroleum is an important source of energy, it is imperative to overcome the issue of acidic crude oil to have better oil production [1]. In recent years, acidic crude oil production has raised by 0.3% per year worldwide. The naphthenic acid (NA) compound present in crude oil leads to the high acidity of oil. The term “naphthenic acids” is used to account for all carboxylic acids present in crude oil including acyclic and aromatic acids, which is also referred to as complicated mixtures [2].

The acidity of petroleum crude oil is measured by its total acid number (TAN), which refers the number of milligrams of KOH required to reduce the corrosiveness in one gram of oil [3]. Currently, the treatment for acidic oil either relies upon weakening or caustic washing techniques to decrease the TAN number of overwhelming rough oils. Moreover, neither of these method is altogether attractive. For example, even though mixing high TAN unrefined petroleum with a low TAN unrefined petroleum might decrease the NAs content to a worthy level, the acidic mixes still remain [1]. Burning treatment can also considerably evacuate NAs, but the procedure creates critical measures of wastewater and emulsion that are problematic to treat. Specifically, once an emulsion is formed, it is exceptionally hard to evacuate [4, 5]. A series of homogeneous basic catalysts are widely used in the petroleum industry such as KOH and NaOH but these types of catalysts would induce an emulsion problem and no catalyst recovery. Solid acid catalysts have attracted a lot of attention in recent years in various industrial organic transformations, owing to their non-toxicity, non-corrosiveness, low cost, easy handling, recovery, and reusability. Among the several mesoporous materials, such as MCM-41 and SBA-16, the most important amphoteric substance is ɣ-alumina (ɣ-Al_2O_3), which is commercially accessible. It has been employed directly as a catalyst and as a catalyst support material in the automotive and petroleum industries due to its combination of textural features such as surface area, pore volume, and pore size dispersion.

Due to the fact that crude oil upgrading is important to ensure the crude oil produced is in a high quality with a good price, an extensive treatment will be carried out for the high acidic crude oil. In this study, the catalytic neutralization technique was introduced utilizing a 2-methylimidazole in ethanol solution with the aids of copper doped cerium based catalyst with alumina as a support.

Materials and Methods

Catalyst preparation and characterization

In this study, cerium oxides were used as catalysts of interest and supported onto alumina with copper as a dopant. Cerium nitrate and copper nitrate were chosen as the metal precursor as it is easily soluble in water.

The ratio of based-dopant used was 10 (dopant) to 90 (base) according to the metal precursor molar ratio and then calcined at a temperatures of 800 ℃, 900 ℃, and 1000 ℃ [6]. An aqueous Incipient Wetness Impregnation (IWI) method was used to prepare the catalyst. According to the desired ratio, each of the metal salts was weighted in a beaker and it was dissolved in small amount of distilled water. To homogenize the mixture, the solutions were mixed together and the mixture solution was stirred continuously by magnetic bar for 30 minutes at 27 ℃. The alumina (Al_2O_3) beads as a support material were immersed into the catalysts solution for 1 hour and the supported catalysts were transferred onto an evaporating dish covered with glass wool [7, 8].

To remove water and allow good coating of catalyst solution on the surface of alumina, it was then aged inside an oven at 80-90 ℃ for 24 hour. To eliminate all the metals precursor, excess water and impurities, this steps were followed by calcination in the furnace at 800 ℃ for 5 hours using a ramp rate of 5℃/min [9]. The preparation of the best catalyst was further optimized at temperatures of 900 ℃ and 1000 ℃ [4]. To study its physicochemical properties, the potential catalyst was characterized by a several methods. The data obtained were exceedingly valuable to comprehend the relationship between catalyst properties and its catalytic performance towards the neutralization activity. The characterization techniques that were used are X-ray Diffraction Spectroscopy (XRD), Fourier Transform Infrared Spectroscopy (FTIR), and Thermal Gravimetry Analysis (TGA-DTG) [10].

Feedstock and basic chemical

The materials were purchased from QReCTM and used as supplied. Feedstock used in this study was obtained from Petronas Penapisan Melaka (PPM), Malaysia with TAN of 2.43 mg KOH/g. In this study, the 2-propanol and toluene was used as titration solvents. The indicator used in the neutralization reaction is a phenolphthalein solution, 1% (w/v) in ethanol. Potassium hydroxide pellets and barium hydroxide were utilized as titrants [11, 12].

Catalytic neutralization reaction

Crude oil and 2-methylimidazole solution in ethanol by a certain mass ratio was stirred. A total of 10% (w/w) of imidazole derivative solutions in ethanol and cerium oxide as catalyst were added to Petronas Penapisan Melaka (PPM)'s crude oil. Then the mixture solution was put into 2 neck round bottom flask equip with a magnetic stirrer and thermometer to control the constant temperature. Parafin oil was used to ease the maintaining of the constant temperature that was 27 ℃, 40 ℃, 50 ℃ and 60 ℃ [13]. The mixture then was stirred at the various temperatures for 5, 10 and 15 minutes to study the effect of reaction time [2]. After the extraction process, the mixture was put into a centrifuge container and was centrifuge with a speed of 50×106 rpm for 30 minutes. The mixture was centrifuged to achieve the gravity separation of the reagent with the acidic compounds extracted from the crude oil sample. The reagent with ionic liquid was on top of the centrifuge tube, while the neutralized crude oil was collected at the bottom of the tube [9].

Total acid number (TAN) determination

A 0.2 g Melaka crude oil sample after neutralization treatment was measured and placed in a titration beaker. The titration solvent, 40 mL with a mixture of 2-propanol: toluene: distilled water (50:49.5:0.5) was poured into the crude oil sample in the titration beaker. Then, the petroleum crude oil sample was titrated with potassium hydroxide and barium hydroxide solution (0.01 mol/L).

TAN value for Melaka's crude oil (TAN = 2.43 mg KOH/g) was determined by semi-micro colour indicator titration method. The indicator used was phenolphthalein solution, 0.1 mL where the stable red colour was observed and indicated the end-point for the titration method. The titration method was performed on Melaka's crude oil before and after the catalytic neutralization reaction. In order to express the results, the TAN of the sample was calculated in milligrams of potassium hydroxide per gram of sample (mg KOH/g) by using Equation 1.

$$\text{TAN} = 56.1 \times c \times \frac{(V_{KOH} - V_B)}{m} \quad (1)$$

where 56.1 is the molecular mass of KOH (g/mol), c is the concentration of the standard volumetric potassium hydroxide solution (mol/L), V_{KOH} is the volume of titrant used to reach the equilibrium point (mL), V_B is the volume of titrant required for the blank titration (mL), and m is the sample mass (g).

Results and Discussion

Thermogravimetry analysis-differential thermal gravimetry (TGA-DTG)

TGA-DTG analysis was studied to obtain thermal stability of potential catalyst after being aged overnight in an oven at 80-90 ℃ [1]. TGA profile exhibited some well-defined sections of weight loss accompanied by different slopes of thermogravimetric trace (weight loss rate). The thermogram of the Cu/Ce(10:90)/Al_2O_3 catalyst showed three phases of weight loss as depicted in Figure 1 while the Table 1 tabulated the type of species deduction corresponding to the heating temperature.

The weight loss in the range of 100-200 ℃ was due to the loss of physisorbed water molecules and was assigned to the evaporation of chemically adsorbed water molecules[14]. Between the temperature of 200–380℃, the weight loss was attributed to the loss of hydroxyl molecules and lastly the weight loss at the range of 380–650℃ was due to the decomposition of nitrate precursors as shown in equation

$$2Ce(NO_3)_3 \rightarrow 2CeO_2 + 6NO_2 + O_2 \quad (2)$$

The theoretical mass loss when the nitrates were decomposed can be calculated in terms of the final mixture form (CeO_2/Al_2O_3) from 650 ℃ to 1000 ℃ for being a stable form [15]. From the overall of TGA–DTG analysis, it can be concluded that thermal treatment had eliminated the impurities and water from the materials with 14.50% of total weight loss in 8.15 mg of catalyst and the pure metal oxide was obtained after heating at 650 ℃ [16].

This observation is in agreement with the result shown in Figure 5 where by using Cu/Ce (10:90)/Al_2O_3 catalyst calcined at 900 ℃, the TAN value of PPM's crude oil can be reduced from the original TAN value as the catalyst calcined at this temperature show complete formation of metal oxide. The detailed weight loss and the deduction for each stages of weight loss is presented in Table 1.

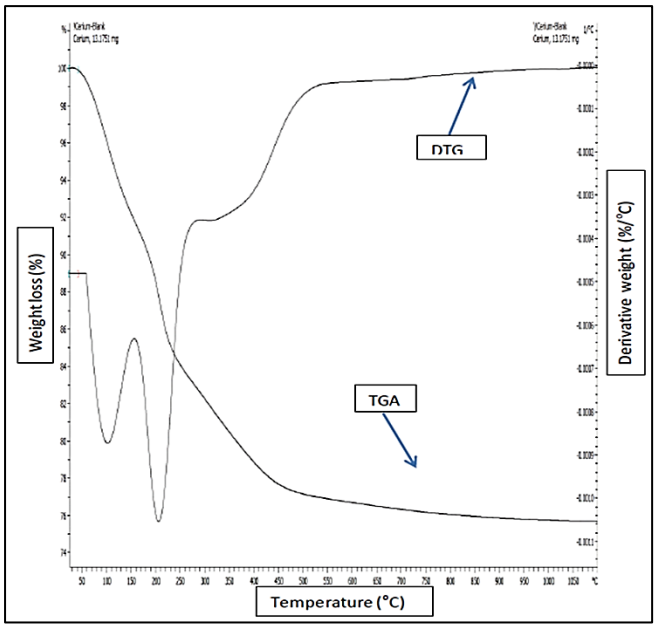

Figure 1. TGA-DTG thermogram of Cu/Ce (10:90)/Al_2O_3 catalyst after aging in an oven for 24 hours at 80-90 ℃

Table 1. TGA analysis results for Cu/Ce (10:90)/Al_2O_3 catalyst

Heating Temperature, ºC	Weight Loss, %	Deduction
100-200	14.50	Loss of crystal water and surface water molecule
200-380	8.20	Complete removal of water and formation of pure metal oxide
380-650	1.30	Loss of nitrate compound and surface hydroxyl molecule

X-ray diffraction

The XRD diffractogram for the bimetallic catalyst of Cu/Ce (10:90)/Al_2O_3 calcined at different temperatures of 800 ℃, 900 ℃, and 1000 ℃ were compiled in Figure 2. From the XRD diffractogram pattern, it can be seen that Cu/Ce(10:90)/Al_2O_3 catalyst calcined at 800 ℃ and 900 ℃ were less crystalline compared to the catalyst calcined at 1000 ℃. Typically, the calcination process of a catalyst involves the loss of chemically bound water or precursors, modification of the texture through sintering, modification of the structure, generation of an active phase and stabilization of mechanical properties which result in the development of an increased surface area of these catalysts [17].

The polycrystallinity phase of the catalyst calcined at 800 ºC and 900 ºC was dominated by the CeO_2 face-centered cubic (fcc) species and some of the alumina orthorhombic (o) phase. The broadening of CeO_2 peak calcined at 800 ℃ and polycrystalline of CeO_2 calcined 900 ℃ were attributed to the presence of a mixture of metal oxides and also due to loose arrangement of atom in the compound [18]. The high crystallinity of CeO_2 peak observed at 1000 ºC calcination temperature is in agreement with the finding from [19] who stated that the size of catalyst will increase as it was calcined at high temperature. Increasing in particle size of catalyst will lead to the smaller surface area. Therefore, 900 ℃ was an ideal calcination temperature for Cu/Ce (10:90)/Al_2O_3 catalyst in order to reduce the NAs content of PPM's crude oils.

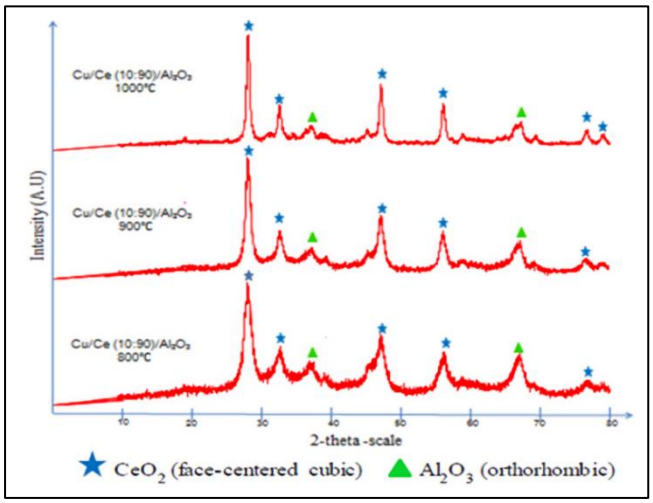

Figure 2. The XRD diffractograms of Cu/Ce(10:90)/Al_2O_3 catalyst calcined at temperatures of 800, 900 and 1000 ℃ for 5 hours

Fourier transform infrared spectroscopy

The FTIR spectra of Cu/Ce (10:90)/Al_2O_3 is shown in Figure 3. The peaks assignments for the catalyst is tabulated in Table 2. The results showed a group assignment for peak at 567.46 – 541.32 cm^{-1} at calcination temperature of 900 ℃ before and after neutralization process was due to the stretching mode of metal oxide group which resulted from the complete formation of pure metal oxide catalyst as also reported by Roy and Bhattacharya [20]. Based on the figure, it can be observed that after deacidification process (b), the new peak appeared at stretching frequency of 1310.65, 1478.24, 2810.87, and 2987.87 due to the attachment of impurities on the surface of the catalyst. It could be suggested that the catalyst should be pre-treated before use in the next cycle of reaction.

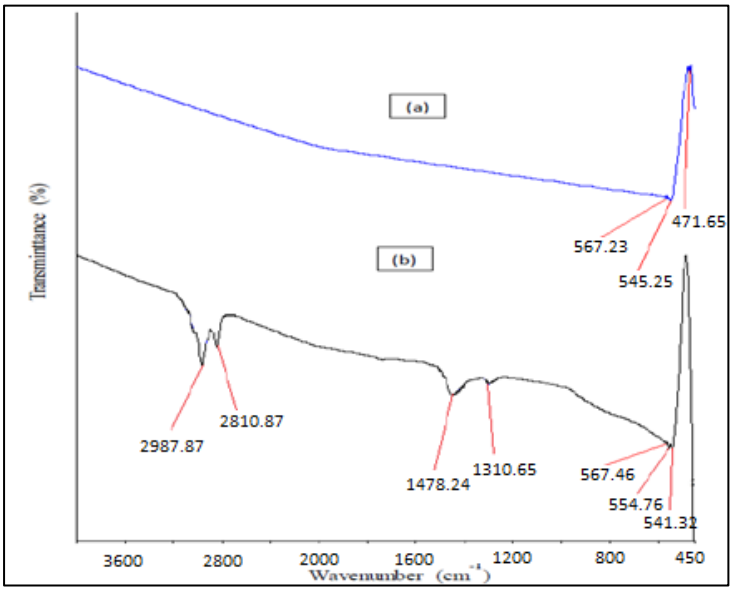

Figure 3. FTIR spectra of Cu/Ce (10:90)/Al_2O_3 catalyst at calcination temperatures of 900 ℃, (a) before neutralization reaction (b) after neutralization reaction

Wavenumber, cm^{-1}	**Peak Assignment**
2987.87 and 2810.87	sp^3 C-H stretching
1478.24	sp^2 C-H stretching
1310.65	Stretching mode of free nitrate (NO_3^-) group from metal precursors
567.46 – 541.32	Stretching mode of Metal=Oxygen (M=O)

Table 2. FTIR peak assignment of Cu/Ce (10:90)/Al_2O_3 catalyst

Effect of reagent concentration towards crude oil TAN without catalyst

Shi et al. [13] had reported the effect of different imidazole derivatives on the reduction of TAN value of PPM's crude oil. It could be seen that when ethanol was used to extract NA from crude oil, the acid removal rate reached up to 17.6%. The polar NAs could be partially dissolved in alcohol especially the smaller molecular weight ones with larger polarity were more easily dissolved in ethanol according to the

similar dissolve mutually theory. Due to this theory, when imidazole derivatives were added into ethanol solution, the acid removal rate was significantly improved. The stronger the alkalinity of imidazole derivatives, the easier the reaction to occur because NA is a weak acid.

Figure 4 shows various amount of 2-methylimidazole concentration from 5% to 15% that were tested in order to reduce the TAN of untreated PPM's crude oil sample. When higher percentages of 2-methylimidazole were used, the TAN value of PPM's crude oils was further decreased. The best result showing the highest concentration of 2-methylimidazole (15%) reduced TAN value from 2.43 mg KOH/g to 1.10 mg KOH/g is when the percentage removal of NA was 55%.

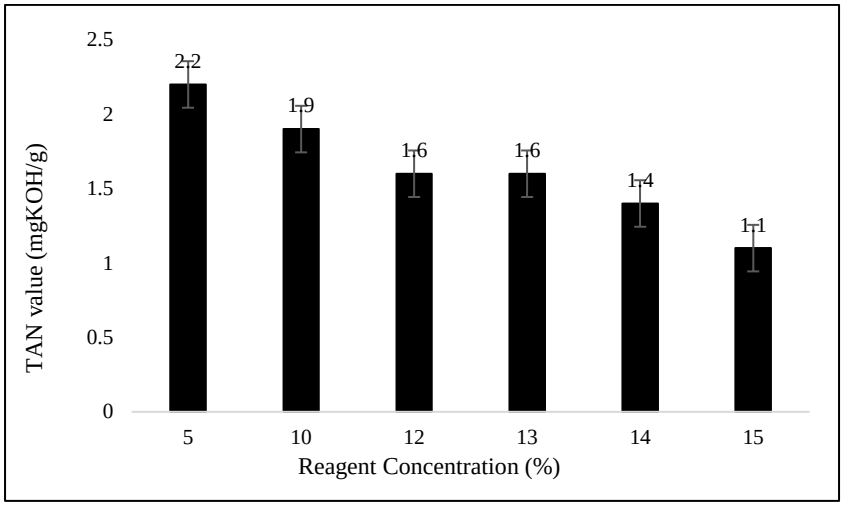

Figure 4. Effect of different reagent concentration towards TAN value without presence of catalyst

Effect of catalyst calcination temperature

An investigation on this parameter was conducted to determine the effect of calcination temperature on the alumina supported catalyst by using 10% of 2-methylimidazole. Figure 5 showed the trends of TAN value based on different catalyst calcination temperature. The trend of TAN value of PPM's crude oils decreased from calcination temperature of 800 ℃ to 900 ℃ and increased when the catalyst calcined at 1000 ℃. The catalysts which calcined at lower calcination temperatures (800 ℃) showed poor performance in this study while the catalyst functioned well in the removal of NAs process when calcined at a medium calcination temperature of 900 ℃. At 900 ℃ calcination temperature, it showed an improvement in reducing acidic content of crude oil due to the larger surface area of the catalyst from smaller particle size as supported from the BET results obtained by [4]. Thus, it provided sufficient surface sites for an excellent NAs removal process [21].

Lower performance was shown by this catalyst calcined at 1000 ℃, which gave TAN value of 1.87 mg KOH/g which is above than one. This is probably due to the fact that increasing calcination temperature will increase particle size of the catalyst which leads to a smaller surface area because of high crystallinity of the catalyst observed by the narrow peak as shown by diffractogram in XRD analysis. Therefore, 900℃ was selected as the ideal calcination temperature for removal of NA for PPM's crude oil samples [6].

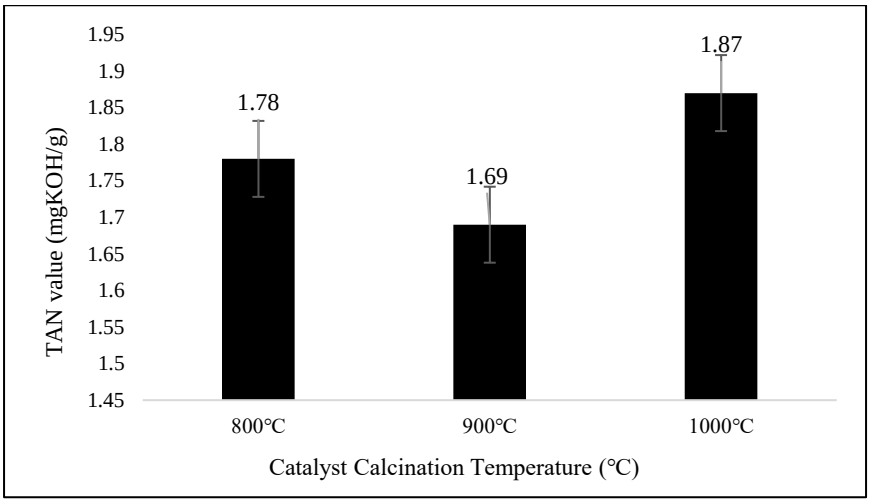

Figure 5. Effect of different calcination temperature towards TAN value

Effect of catalyst loading

Catalyst loading is the percentage of the catalyst used by calculating the weight of catalyst used over mass of crude oil. In this study, this parameter was observed to study the effectiveness and efficiency of various catalyst loading towards TAN value. Figure 6 showed the trend of TAN value for PPM's crude oil based on different catalyst loading. The trend of TAN value for PPM's crude oils was decreasing with an increase in the percentage of the catalyst loading. It could be seen that the highest catalyst loading of 0.5% successfully reduced TAN value to 0.53 mg KOH/g while the lowest loading percentages that was 0.1% only reduced the TAN value to 1.69 mg KOH/g. An increased in the catalyst loading made the catalytic reaction became faster and more efficient.

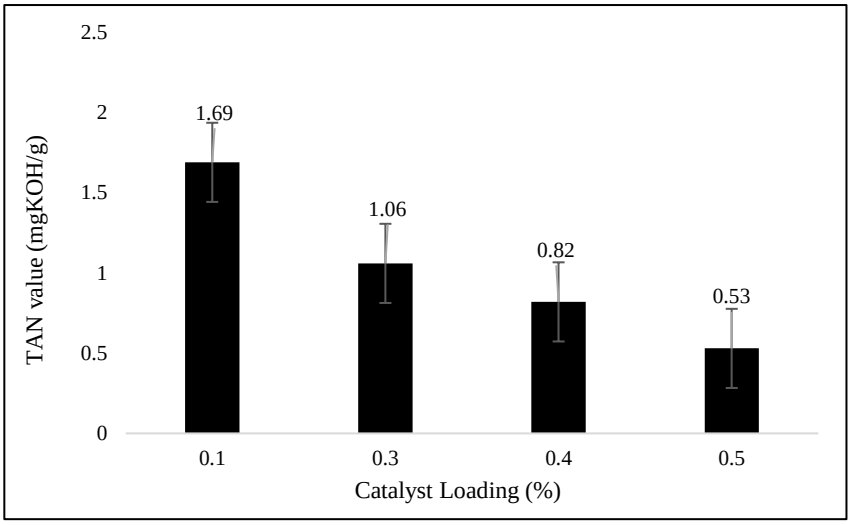

Figure 6. Effect of different percentage of catalyst loading towards TAN value (Catalyst calcination temperature: 900 ºC)

Effect of reaction temperature

In this study, different reaction temperatures were studied for catalytic neutralization process on PPM's crude oils. The temperature can be used to determine the speed of the neutralization reaction and can also decrease the viscosity of the crude oil, making the crude oil more accessible to the 2-methylimidazole. The trend of TAN for PPM's crude oils was increased when the reaction temperature increased as shown in Figure 7.

The percentage of catalytic neutralization activity decreased from 27 ℃ until 40 ℃ for PPM's crude oil samples as the TAN value for 27 ℃ reduced from 2.43 to 0.53 mg KOH/g while at 40 ℃, TAN reduced from 2.43 to 0.74 mg KOH/g and at 50 ℃ it decreased to 1.24 mg KOH/g and lastly, for 60 ℃ the TAN decreased from 2.43 to 1.44 mg KOH/g. This was because the reaction occured at higher temperature was not profitable for the reaction between 2-methylimizadole and NAs in crude oil as the higher temperature can increase the viscosity of the crude oil. This occurrence probably stabilized the NA in crude oil and inhibited the reagent to react with NA effectively. In addition, this study offered an environmental friendly process because lower reaction temperature can lead to lower energy consumption and at the same time can reduce air pollution [3].

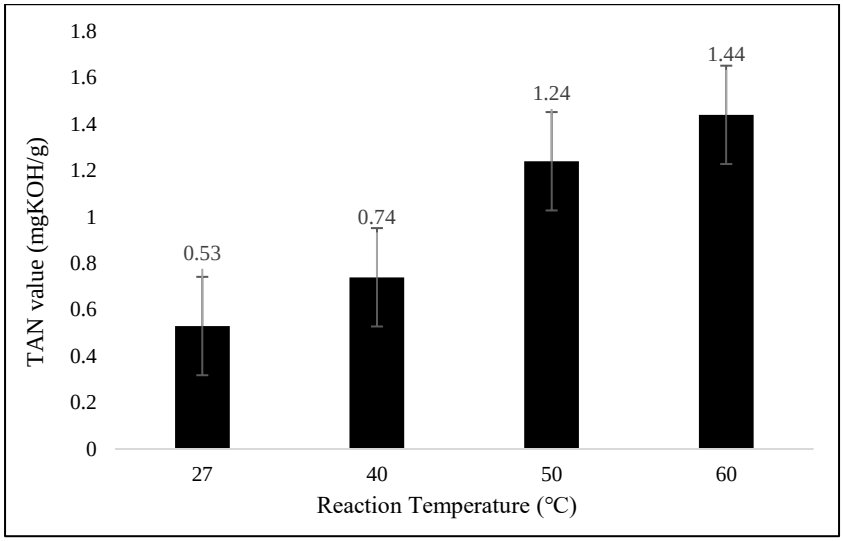

Figure 7. Effect of different reaction temperature towards TAN value (Catalyst calcination temperature: 900 ℃, catalyst loading: 0.5%)

Effect of reaction time

The effect of different reaction times on the neutralization process with Cu/Ce (10:90)/Al_2O_3 catalyst calcined at 900 ℃ with addition of 0.5% catalyst loading, 10% of 2-methyl imidazole concentration, and reaction temperature of 27 ℃ was performed on PPM's crude oils shown in Figure 8. The results illustrated that the TAN values decreased when the reaction time was increased from 5 to 15 minutes. This substantial reduction of the TAN value was attributed to the elevated opportunity for a reaction between 2-methylimidazole aided by a catalyst and NA in the crude oil. The longer the reaction time, the longer the duration for which the solution was stirred, which consequently meant the more markedly the 2-methylimidazole aided by Cu/Ce (10:90)/Al_2O_3 catalyst in the solution reacted to remove NA in PPM's crude oils.

According to Shi et al. [13] when the reaction time was increased above 15 minutes, the TAN values became constant for PPM's crude oil samples. This is because after 15 minutes, reagent successfully reduced and removed all NAs in crude oils. As a longer reaction time will only consume more energy, the optimum reaction time recommended is 10 minutes for the basic chemical to remove NA effectively and the best TAN value reduced is to 0.53 mg KOH/g for PPM's crude oils. It was observed that the acid-removal rate was increased by increasing the reaction time from 5 minutes to 10 minutes at 27 ℃, but showed very small improvement of TAN value when the reaction time is between 10 minutes and 15 minutes. TGA–DTG analysis concluded that thermal treatment had eliminated the impurities and water from the materials with 14.50% of total weight loss in 8.15 mg of catalyst and the pure metal oxide was obtained after heating at 650 ℃.

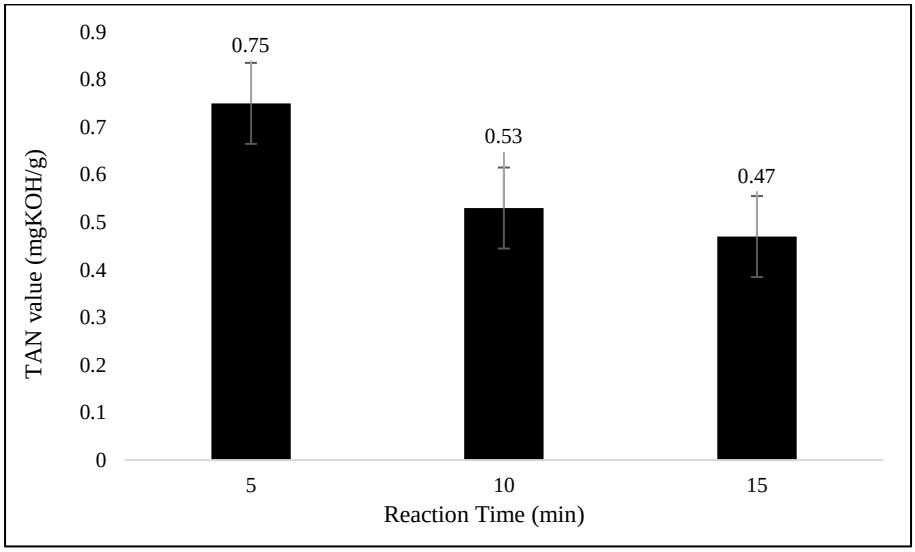

Figure 8. Effect of the different reaction times on the TAN values of PPM crude oils

Conclusion

The catalytic neutralization technique had successfully been applied in this study for the removal of NA and simultaneously solved the corrosion and emulsion problem by meeting the PETRONAS benchmark for TAN value less than 1 mg KOH/g. PPM's crude oil which possessed an initial TAN value of 2.43 mg KOH/g was reduced to 0.53 mg KOH/g with addition of 10% of 2-methylimidazole, catalyst calcination temperature of 900 ℃, 0.5% of Cu/Ce (10:90)/Al_2O_3 catalyst loading (4 beads), reaction temperature of 27 ℃ and reaction time of 10 minutes. XRD results revealed the polycrystallinity phase of the catalyst which was dominated by the CeO_2 face-centered cubic (fcc) species and some of the alumina orthorhombic (o) phase. As a recommendation for further study, other instruments to characterize the physicochemical properties of catalyst such as Brunauer–Emmett–Teller (BET), and Transmission Electron Microscopy (TEM) could be implemented.

Abstract

The encapsulation of tetrakain hydrochloride (TC-HCl) in α-cyclodextrin (α-CD), β -cyclodextrin (β-CD) and hydroxypropyl-β-cyclodextrin (HPβ-CD) has been studied by UV-Visible at different temsperatures. The appearance of isosbestic points as well as hyperchromic and bathochromic shifts on the different UV-Visible spectra confirm the complexes formation. From the complexation constants values the stability of the 1:1 type complexes is in the order of α-CD < HPβ-CD < β-CD and decreases with increasing temperature for each complex. All complexation processes are spontaneous, with a favorable enthalpic contribution and an unfavorable entropic term as deduced from Van't Hoff plot analysis. The negative values obtained for ΔCp ° indicate that the apolar part of TC-HCl is encapsulated in the cavities of the CDs.

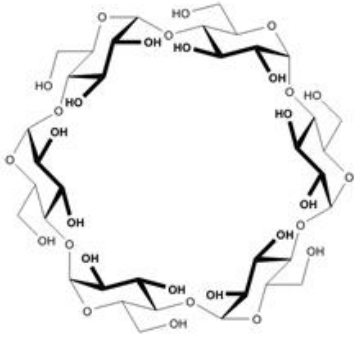
Keywords: UV-Vis spectrophotometry, cyclodextrins, tetracaine drug, temperature effect, Van't Hoff analysis

Abstrak

Pengkapsulan tetrakain hidroklorida (TC, HCl) dalam α-siklodekstrin (α-CD), β-sikloododekstrin (β-CD) dan hidroksipropil-β-siklodekstrin (HPβ-CD) telah dikaji mengunakan spektrofotometri UV-cahaya nampak pada suhu yang berbeza. Kemunculan titik isosbestik serta pergeseran hipokromik dan bathokromik pada spektrum UV-cahaya nampak yang berbeza mengesahkan pembentukan kompleks. Daripada nilai pemalar kompleks, kestabilan kompleks jenis 1: 1 berada dalam urutan α-CD <HPβ-CD <β-CD dan menurun dengan kenaikan suhu bagi setiap kompleks. Semua proses pengkompleksan adalah spontan, dengan sumbangan entalpik yang menggalakkan dan istilah entropik yang tidak menguntungkan seperti hasil analisis plot Van't Hoff. Nilai negatif yang diperoleh untuk ΔCp ° menunjukkan bahawa bahagian tidak berkutub TC-HCl dikemas dalam rongga CD.

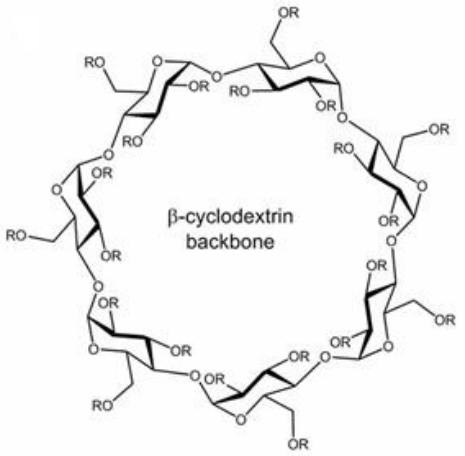
Kata kunci: spektrofotometri UV-cahaya nampak, siklodekstrin, dadah tetrakain, kesan suhu, analisis Van't Hoff

Introduction



The administration of local anesthetics such as tetracaine or procaine during ophthalmologic or dentistry surgeries often shows adverse side effects such as irritations and sometimes cardiac arrhythmias and neurological after effects [1-3]. To reduce these discomforting effects an alternative approach consisting in reformulating these anesthetics as

molecular complexes with adapted complexing agents, has emerged. In this option, the complexing agent is generally a molecule with a peculiar structural conformation shaping a hydrophobic pocket-like site suited to fully encompass the anesthetic molecule or a part of it. Molecules such as cyclodextrin, crown-ether and calixarene are examples of these complexing agents and they operate based on the molecular recognition principle better known as host-guest interaction [4-6].



Cyclodextrins (CDs) represent the most used molecules in host-guest processes because of their biodegradability, non-toxicity and aqueous solubility. They are cyclic oligomers comprising many α(1,4) bound glucopyranose units. They are often schematized in the form of a torus-shaped molecule having a dual nature with hydrophilic external faces and a hydrophobic cavity making them able to form non-covalently bonded inclusion complexes with a variety of hydrophobic molecules in an aqueous solution. The size of each cyclodextrin (CD) varies according to the number of glucose units forming the structure (α-, β- and γ-CD contain respectively 6, 7 and 8 units of D-glucopyranosyl) [7-9] (Figure 1a). The stability of the formed complex is therefore depending partly on the size compatibility between the host and the guest molecule and in the other part on the nature of interacting forces. According to the chemical nature of the guest molecule different interactions may take place as Van der Waals interactions, hydrophobic effect, solvent reorganization, hydrogen bonding, charge transfer, etc. [10, 11]. So, structural information such as complex stoichiometry and geometry are important to know as well as thermodynamic parameters as the association constant, the variation of the free enthalpy (ΔG^0) and the entropy (ΔS^0) of binding. All these are necessary to achieve the best formulation of these complexes [12, 13].

In this present study, the formation of complexes made of tetracaine-hydrochloride (TC-HCl) and different CDs in an aqueous solution are investigated by UV-Visible spectrophotometry from a thermodynamic point of view. The guest molecule (Figure 1b) is a potent local anesthetic, primarily used for topical anesthesia and spinal block, but has a fairly toxic effect resulting in cauda equina syndrome among other compelling side effects [14]. Chemically, TC-HCl is an amino ester where the ester group links a hydrophilic ammonium group to an aromatic lipophilic ring. These peculiarities allow TC-HCl to behave both as a surfactant molecule and as a weak acid with a PKa of 8.5 [15].

Materials and Methods

Materials

4-(Butylamino)benzoic acid 2-(dimethylamino)ethyl ester monohydrochloride, called tetracaine hydrochloride (TC-HCl) was obtained from Sigma in the crystalline form and was used without further purification. The β-cyclodextrin (β-CD), *α*-cyclodextrin (α-CD), and hydroxypropyl-*β*-cyclodextrin (HPβ-CD) were purchased from Sigma. 6-Hydroxypropyl-β-cyclodextrin (HPβ-CD), containing an average of 0.64 hydroxypropyl groups per glucopyranose unit. All of them, with 99% purity or greater, were used without further purification. All the solutions were freshly prepared with a distilled/deionized water of a conductivity value lower than 2 µS/cm. The homogeneity of the initial solutions was assured by sonicating them in an ultrasonic bath.

UV-Vis measurements

The UV-Vis spectra were recorded with a Specord 200plus double-beam UV-Vis spectrophotometer (Germany), from 190 to 400 nm with 1 nm intervals at 15, 20, 25 and 37 °C, which temperature was kept constant with thermostated cell. Data acquisition of UV-Vis spectra was performed with software (Winspec) supported by the manufacturer and converted to ASCII format for their analysis. On the experiments with the Drug/water binary systems, the (TC-HCl) concentration was varied from 0 to 0.1mM, while for the CD/Drug/water ternary systems, the drug concentration was kept constant at 10^{-5} mol.l^{-1} and CD concentration was varied from 0 to 10 mmol.l^{-1}.

Modeling stoichiometry and association constants

Assuming that a 1:1 complex between any CD and the drug is formed, the following chemical equilibrium takes place.

$$CD + G \leftrightarrows CD\text{-}G \quad (1)$$

If one takes that the activity coefficients of all species are equal to unity, the equilibrium constant K can be written as:

$$K = \frac{[CD-G]}{[CD][G]} \quad (2)$$

The laws of mass conservation for all species require that

$$[CD]_0 = [CD] + [CD-G] \quad (3)$$

$$[G]_0 = [G] + [CD-G] \quad (4)$$

with $[CD]_0$: initial (total) concentration of host molecule, $[G]_0$: initial (total) concentration of the guest molecule. [CD], [G], [CD-G]: equilibrium concentrations of host, guest and complex respectively. The combination of these equations gives the expression of K the equilibrium constant as a function of initial concentrations of the host and the guest molecules as well as one of the formed complexes:

$$K = \frac{[CD-G]}{([CD]_0 - [CD-G])([G]_0 - [CD-G])} \quad (5)$$

So, to compute the equilibrium constant one has to determine the concentration of the formed complex since all other quantities are available. This quantity can be extracted from any technique for which intensity variation is proportional to the concentration of the complex. Amongst all available techniques, UV-Vis spectrophotometry represents the most used technique because of its simplicity and repeatability. For this technique, it is well known that the absorbance or optical density is proportional to the concentration of the absorbing chromophore so the observed absorbance for a system constituted of CD, guest and complex species is expressed as:

$$A_{abs} = A_{CD} + A_G + A_{CD-G} \quad (6)$$

A_{CD}, A_G and $A_{CD\text{-}G}$ represent respectively the absorbance of the host, the guest and the complex. Taking that the length of the optical path is fixed to 1 cm, the different absorbances can be expressed as a function of the molar extinction coefficients ε of each absorbing species in solution.

$$A_0 = \varepsilon_G [G]_0 \quad (7)$$

$$A_{CD} = \varepsilon_{CD}([CD]_0 - [CD-G]) \quad (8)$$

$$A_G = \varepsilon_G([G]_0 - [CD-G]) \quad (9)$$

$$A_{CD-G} = \varepsilon_{CD-G}[CD-G] \quad (10)$$

where A_0 represents the absorbance of the drug in absence of cyclodextrin and A_{CD}, A_G and $A_{CD\text{-}G}$ are absorbances of CD, Guest and the complex in the solution. Assuming that CD doesn't absorb light in the near-UV-Visible domain and combining equations 5 to 10 gives after a rearrangement the following equation (11) [16].

$$\Delta A = [\varepsilon_G - \varepsilon_{CD-G}]\left[\left([G]_0 + [CD]_0 + \frac{1}{K}\right) - \sqrt{\left(\left([G]_0 + [CD]_0 + \frac{1}{K}\right)^2 - 4[G]_0[G]_0\right)}_0\right] \quad (11)$$

which relates the difference in absorbance $\Delta A = A_{abs} - A_0$ to the equilibrium constant K. The use of a nonlinear regression permits to extract simultaneously the values of Δε and K from the experimental curve of the variation of ΔA versus [CD].

Results and Discussion

The UV-Visible spectra of the drug TC-HCl in an aqueous solution at different concentrations at 25 °C are reported on Figure 2(a).

It can be observed that the spectra show three peaks centered at wavelength 190, 227 and 312 nm, corresponding to π-π* and n-π* electronic transitions of the unsaturated C = C bonds of the aromatic ring and the non-binding doublets of the nitrogen and the oxygen atoms [17]. With increasing drug concentration no significant wavelength shift occurs but the absorbance (A) increases obeying to a typical Lambert-Beer law (2*b*). This means that in this concentration range the solutions are dilute and no important intermolecular interactions exist as well as any solvent effect. From the linear fitting of the absorbance data as a function of drug concentration, the molar absorption coefficient, ε=20604 is determined for λ_{max}=312nm. The extracted value is comparable to one published by Merino *et al* for procaine hydrochloride anesthetic which possesses an identical chromophore as tetracaine, they reported a value of ε=19825 for λ_{max}=311nm [18].

Figure 3 shows the UV spectra of aqueous solutions of TC-HCl at a constant concentration of 10^{-5}M in the absence and the presence of β-CD, at three different temperatures. The analysis of the obtained three spectra shows the presence of isosbestic points which indicates the occurrence of chemical equilibrium between the free and the complexed TC-HCl. For the spectrum at 15°C both absorbance and wavelength variations (ΔA and Δλ) are obvious but for the spectra at 25 and 37°C the wavelength shift Δλ diminishes considerably with temperature increase. When the same sets of experiments are

conducted with α-CD and HPβ-CD instead of β-CD different behaviors are noted as shown in Figure 4.

Figure 4 shows, as an example, the experiments performed at 25 °C. For α-CD only one isosbestic point is visible at λ=329 nm and only absorbance variation ΔA is observed. For HPβ-CD both ΔA and Δλ variation are noticeable and many isosbestic points close to ones observed for β-CD appear. All these observations underline that an inclusion complexation has occurred between these CDs and the drug [19]. These results agree with ones reported by García et al. using the fluorimetry method [20].

The analysis of the obtained three spectra shows the presence of isosbestic points which indicates the occurrence of chemical equilibrium between the free and the complexed TC-HCl. For the spectrum at 15°C both absorbance and wavelength variations (ΔA and Δλ) are obvious but for the spectra at 25 and 37°C the wavelength shift Δλ diminishes considerably with temperature increase. When the same sets of experiments are conducted with α-CD and HPβ-CD instead of β-CD different behaviors are noted as shown in Figure 4.

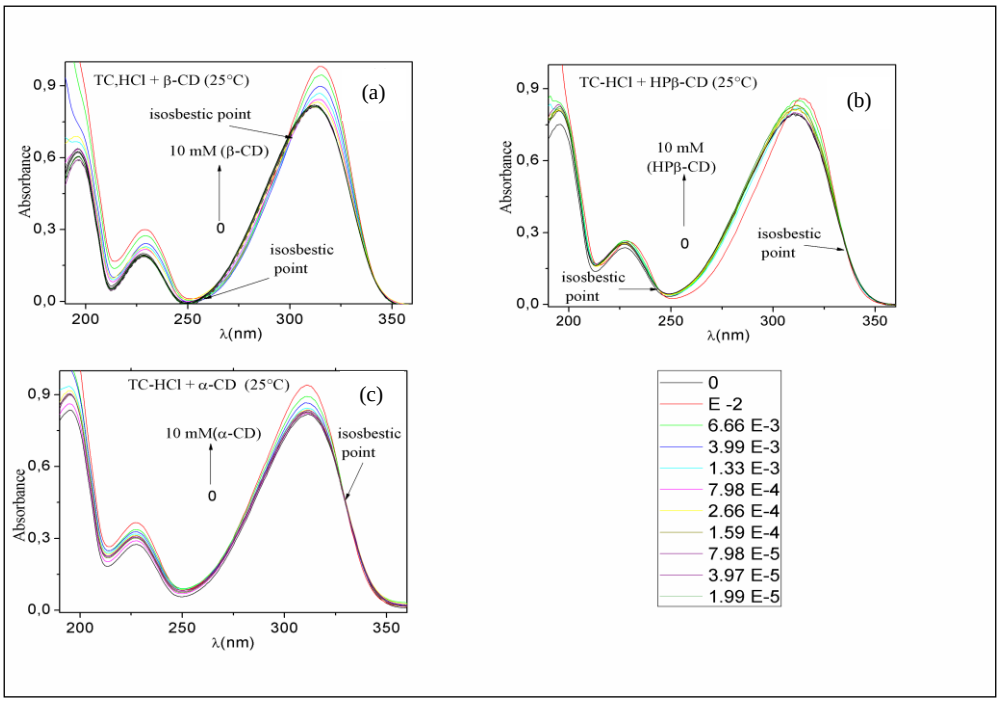

Figure 4. UV-Visible spectra of aqueous solutions (TC-HCl) 10^{-5}M in the presence of different host molecules. (a) β-CD, (b) HPβ-CD and (c) α-CD at 25 °C

In order to confirm the formation of complexes the same set of experiments were carried out in the presence of d-(+)-glucose at amounts analogous to ones used for CD's experiments at 25 °C. Because CDs are oligomers of glucose molecule units, they have mainly the same elemental composition but different spatial conformational characteristics. With this choice one tries to preserve the solvent-molecule interaction (water-CD interaction are supposed close to water-glucose one) and letting the geometry differences be the only influencing parameter. From Figure 5 it is easy to note that for d-(+)-glucose no isosbestic points exist, only a slight red shift of the order of 1 nm is obtained with a very weak effect on absorbance values.

From the variation of the curve of ΔA against CD concentration it is possible to extract the K values by a nonlinear regression method [19]. As an example, Figure 6 shows the variation of ΔA against CD's concentration at T=25°C. The same method was applied for all the studied systems at different temperatures and the corresponding association constants are reported in Table 1.

The dependence of equilibrium constants with the temperature can be noticed in Table 1, where the affinity of all cyclodextrins for the drug decreases as long as the temperature increases. Our results at T=25 °C agree with the findings of Takisawa and al. [21] who studied the inclusion of TC-HCl into α-CD and β-CD using the potentiometric method using drug-sensitive electrodes. They reported that the (β-CD/TC-HCl) formed complex is more stable than (α-CD/TC-HCl) one. From the preceding results, it is possible to determine some thermodynamic parameters of complexation from the variation of R$\ln K$ against $1/T$. Figure 7 shows the Van't Hoff plots of all association processes using both linear ($\Delta C_p°=0$) and non-linear ($\Delta C_p°\neq0$) fitting functions.

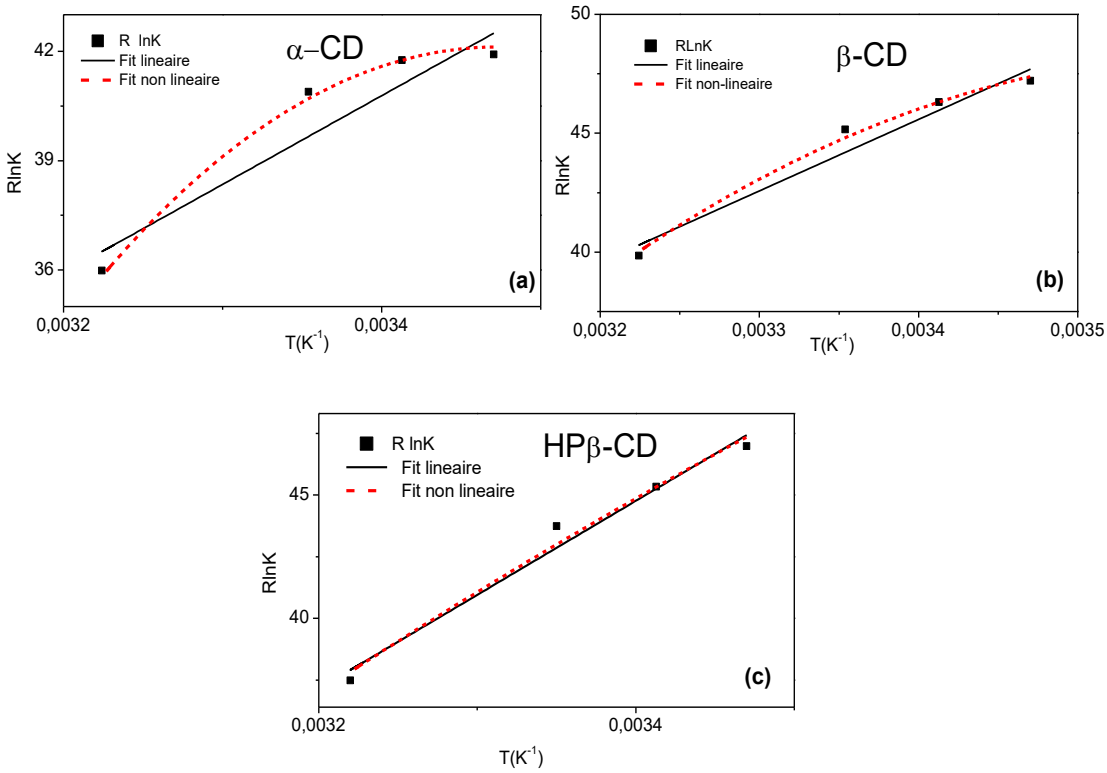

Figure 7. Van't Hoff plot for the association of TC-HCl with a) *α*-CD, *b)* β-CD and c) HPβ-CD

From the slopes of the linear fits of the data to the classical Van't Hoff equation *(R*ln*K= −ΔH°/T + ΔS°),* values of *ΔH°* equal to -24.3, -30.06 and -38.08 Kj.mol^{-1} are obtained respectively for α-CD, β-CD and HPβ-CD complexes (Table 2). Negative values of the binding enthalpy are the sign that the drug establishes favorable interactions with cyclodextrins. In such association, the enthalpy change is the result of two main conflicting contributions: the favorable enthalpy associated with van der Waals forces coupled to the host/guest hydrogen bonds formation and the unfavorable enthalpy associated with the desolvation of the guest polar groups [11-13]. Van der Waals interactions become maximal when a perfect size fitting between cyclodextrin and the drug takes place while the hydrogen bonds formation optimization is reached when drug polar groups prefer forming hydrogen bond with the cyclodextrin prior to the surrounding water molecules. Thus, an unfavorable binding enthalpy usually indicates that the desolvation is not enough to permit the inclusion of the guest molecule. However, the enthalpic contribution is not the sole provider of the stabilization of the complex and one has to consider the entropic contribution *ΔS°*. Two major terms contribute to the entropy of binding; the first one is the favorable desolvation entropy change which originates from the release of water molecules as the drug molecule and the binding cavity undergo desolvation upon binding [11-13].

The second term is related to the conformational entropy change which is almost always unfavorable since during the binding process both the drug and the cyclodextrin molecules induce the loss of conformational degrees of freedom. Thus, for our studied system, from the intercepts of Van't Hoff plot, *ΔS°* values equal to −41.8, -56.63 and -84.73 J.K^{-1}.mol^{-1} are extracted for α-CD, β-CD and HPβ-CD complexes respectively (Table 2). For all cases it can be observed that the drug bind to CDs with a favorable enthalpic term *(ΔH° < 0)* and an unfavorable entropic term *(ΔS° < 0)*. All processes are exothermic and enthalpy driven (*|ΔH°| > T|ΔS°|*), as usually found for such associations [10, 22]. With its negative entropy *ΔS° < 0* the complexation seems

to be mainly driven by Van der Waals attractive forces ($\Delta H° < 0$; $\Delta S° < 0$) and solvent reorganization effects. The contribution coming from the hydrophobic effect seems to be negligible especially for HPβ-CD ($\Delta S°$ =-84 J.mol^{-1}.K^{-1}).

For HPβ-CD a linear relationship has been found in the Van Hoff plot, revealing independence of both the $\Delta H°$ and the $\Delta S°$ of the association processes with *T*. For β-CD and α-CD, Van Hoff plots are better described by nonlinear curves as usually reported for this kind of processes by different authors [10, 22]. With its hydroxypropyl hydrocarbon chains the HPβ-CD second rim is a relatively flexible structure compared to one belonging to native βCD which is more rigid since hydrogen bonds belt is thought to exist all around the rim. These hydrocarbon chains can hinder the complete inclusion of the guest molecule and decrease the desolvation process and thus diminish the strength of the desolvation positive entropy contribution. So, the contribution of solvent reorganization and hydrophobic effects couldn't be similar in both inclusion processes which make the binding of β-CD and TC-HCl energetically more favorable than that of HPβ-CD with TC-HCl. The proposed architecture of the complexes formed can then be illustrated in Figure 8.

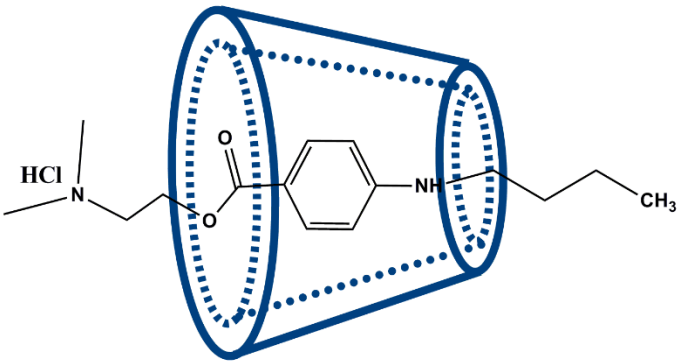

Figure 8. Architecture of inclusion complexes TC-HCl/CD

The negative value of all the ΔC_p° in table 2 obtained from the fitting of the experimental data with the non-linear Van Hoff equation ($R.\ln K = [-(\Delta H° + (T-T_o)\ \Delta C_p^\circ)/T + \Delta S° + (\Delta C_p^\circ \ln(T/T_o))]$) are close to values generally found when apolar solutes are encapsulated in CD's [23]. The difference found in the values of ΔC_p° for β-CD and HPβ-CD confirm the fact that the β-CD complex is more stable than the HPβ-CD one probably due to the diminution of the OH groups on the HPβ-CD molecule, which limit the formation of hydrogen bonds with the surrounding water.

The β-CD secondary face diameter is larger than the α-CD one and could better accommodate the inclusion of a guest molecule bearing a benzene structure. This hypothesis is confirmed by the appearance of shifts of the absorbance and wavelength λ and consequently the attractive Van der Walls interactions must be optimal for the TC-HCl/β-CD complex compared to the TC-HCl/α-CD one. The hyperchromic effect is usually attributed to the dissociation of the hydrogen bonds and the bathocromic is related to change of drug surrounding environment which become more apolar. According to Bernardi's theoretical DFT calculation in water the terminal nitrogen end of tetracaine possesses appreciable hydrophilicity which can reach the ester function close to the benzene cycle whereas the hydrocarbon butyl chain is completely hydrophobic [23, 24]. So, it can be proposed that the drug penetrates deeply in the β-CD cavity to an extent where both hydrophobic butyl chain and the benzene aromatic structure are influenced by the cavity walls which explain the simultaneous variation of ΔA and Δλ. For α-CD because of its narrower rim diameter only hydrophobic chain is penetrated and hyperchromic signature is revealed by UV-Visible spectrophotometry.

Table 2. Values of ΔH°; ΔS°, and ΔC_P^0 for the association of TC-HCl with different CDs obtained from the linear and nonlinear fitting of Van't Hoff equation

CD	Fitting	ΔH° (KJ.mol^{-1}) linear	ΔS° (J.mol^{-1}.K^{-1})	ΔC_P^0 (J.mol^{-1}.K^{-1})
α-CD	Linear	-24.3 ± 7.74	-41.8 ± 25.9	-
	Nonlinear	-23.0 ± 0.077	-39.29	-2311 ± 464.4
β-CD	Linear	-30.06 ± 6.68	-56.63 ± 22.4	-
	Nonlinear	-29.23 ± 0.00	-53.40 ± 4.81	-1000 ± 4.85
HPβ-CD	Linear	-38.08 ± 6.06	-84.73 ± 20	-
	Nonlinear	-37.78 ± 5.10	-83.57 ± 17.08	-300

Conclusion

Employing the spectrophotometry technique for the inclusion complexation of tetracaine hydrochloride in different type of CDs (α-CD, β-CD and HPβ-CD) was demonstrated. The occurrence of the complexation is confirmed by the appearance of isosbestic points, hyperchromic and bathochromic shift effects on the UV-Visible spectra. From the values of complexation constants, the strength of the complexation increases from α-CD to β-CD in accord with the majority of the studies earlier reported by different authors with other techniques. From the Van't Hoff analysis, the studied complexation processes are spontaneous, with a favorable enthalpic contribution and an unfavorable entropic term. This means that the complexation seems to be driven by Van der Waals attractive forces (ΔH° < 0; ΔS° < 0) and to the solvent reorganization effects. Van't Hoff plots well show that for the drug/HPβ-CD association process linear fitting function is sufficient to describe the phenomena. However, for the α-CD and β-CD a non-linear fitting is necessary (ΔCp°≠0) to characterize their association with the drug.

Abstract

In the present study, natural rubber composites filled with sepiolite and silica were prepared. The effects of the two fillers by loading (1–10 phr) on viscosities, stress relaxation, curing, and mechanical properties of the composites were investigated. Viscosity of rubber usually increased with filler loading about 7–22% with sepiolite and about 3–37% with silica, depending on filler content. Smaller rate of stress relaxation was found with sepiolite filler in comparison with silica filler. Furthermore, shorter curing cycle with greater crosslink density and hot temperature reversion resistance were achieved through the use of sepiolite filler in NR. Lorenz-Parks and Kraus models utilized for assessing rubber-filler interactions revealed stronger interactions of sepiolite filler with the rubber matrix. As a result of the good interactions between sepiolite filler and rubber matrix, larger reinforcement indexes and tensile strengths were achieved with sepiolite filler in comparison with silica filler. This was due to the higher aspect ratio of sepiolite (~5.32) compared to that of silica (~1.09) as demonstrated by SEM analysis. The highest tensile strength was achieved at 1 phr sepiolite loading which was about 17% improvement over unfilled sample.

Keywords: composites, fillers, rubber, sepiolite, silica

Abstrak

Komposit getah asli yang diisi dengan sepiolit dan silika telah disediakan dalam kajian ini. Kesan kedua-dua pengisi dengan memuatkan (1-10 phr) pada kelikatan, kelonggaran tekanan, tempoh pematangan dan sifat mekanikal komposit telah disiasat. Kelikatan getah biasanya meningkat dengan pengisi yang memuatkan dari 7-22% dengan sepiolite dan kira-kira 3-37% dengan silika, bergantung kepada kandungan pengisi. Kadar kelonggaran tekanan yang lebih kecil didapati dengan sepiolit berbanding

dengan pengisi silika. Juga, tempoh pematangan yang lebih pendek dengan ketumpatan sambung silang yang lebih tinggi dan rintangan perkembalian suhu panas dicapai dengan menggunakan pengisi sepiolit dalam getah asli. Model Lorenz-Parks dan Kraus yang digunakan untuk menilai interaksi pengisi getah mendedahkan interaksi yang lebih kuat dari pengisi sepiolit dengan matriks getah. Indeks pengukuhan yang lebih tinggi dan kekuatan tegangan dicapai dengan pengisi sepiolit daripada pengisi silika. Ini disebabkan oleh interaksi pengisi getah yang lebih baik yang timbul daripada nisbah aspek sepiolit yang lebih tinggi (~ 5.32) daripada silika (~ 1.09) seperti yang kemudiannya didedahkan oleh analisis SEM. Kekuatan tegangan tertinggi dicapai pada 1 phr pemuatan sepiolite iaitu kira-kira 17% peningkatan berbanding sampel yang tidak diisi.

Introduction

Generally, introducing one or more fillers is a strategy for improving the properties of natural rubber (NR). The use of a filler is convenient, effective, and relatively cheap for enhancing the properties of rubber [1, 2]. Among the different properties, modulus, tensile strength, tear strength, abrasion resistance, and service life of rubber can be improved, depending on size and shape of filler particles as well as the filler-matrix interactions [3, 4]. Various types of filler have been applied in rubber composites, and carbon black and silica are the most commonly used fillers in the rubber industries [5, 6]. Several studies have tested sepiolite filled rubber composites since sepiolite has unique needle-like particle shape with tunnel-like micropore channels, possibly improving the thermal, mechanical, and barrier properties of the composites [7-11].

Sepiolite belongs to nontoxic phyllosilicates, is abundant in the nature, and has a low cost. Regarding its chemical structure, sepiolite comprises microcrystalline-hydrated magnesium silicate with the unit cell formula $Si_{12}Mg_8O_{30}(OH,F)_4].(H_2O)_4 \cdot 8H_2O$ [11]. It is microfibrous with 2–10 μm particle length and tunnel-like micropore channels, providing efficient adsorption and high specific surface area for strong interaction with the rubber matrix. Comparative studies of sepiolite with other fillers, assessing reinforcing abilities, have been conducted recently [7, 9, 12-14]. Bokobza et al. [7, 9] investigated the relation of filler shape (silica particles and sepiolite fibers) with the mechanical properties of NR and styrene butadiene rubber (SBR), prepared by sol-gel process. They demonstrated that the sepiolite filler imparted more reinforcement in comparison with the spherical silica particles in NR. However, it had less interaction with SBR because the sepiolite interacts less with SBR than NR, leading to poor interaction between the rubber and filler and poor dispersion in the SBR matrix. Bhattacharya et al. [12] investigated the impact of various nanofillers, namely, montmorillonite clay, sepiolite, hectorite, carbon nanofiber, and expanded graphite, and their dispersion methods on the properties of NR nanocomposites. They found that the mechanical and physical properties, including modulus, tear, and tensile strength, depended strongly on specific surface area, aspect ratio, filler volume fraction, and dispersion of filler. Lowe et al. [13] prepared NR nanocomposites reinforced with unmodified and modified clay and sepiolite. They observed that overall better properties were obtained for nanocomposites filled with clay. In case of sepiolite filler, the modified sepiolite exhibited relatively small improvements (only 3%) compared to the neat sepiolite. Winya and Hansupalak [14] compared the effects of sepiolite and silica on mechanical properties and thermal stability of NR/EPDM blend. They reported that both properties were similar for the two fillers, in the loading range investigated (0–12.5 phr), but the sepiolite was preferred over silica, as a lower loading achieved comparable mechanical and thermal properties.

Up to now, there is little work studying property changes of sepiolite and silica filled NR composites in the literature. The objective of the current study was to understand the effects of the two types of filler (i.e., sepiolite and silica) by small loading level on mechanical properties of NR composites. The study results are discussed considering certain properties, including viscosity, stress relaxation, curing, and tensile properties. The rubber-filler interactions are discussed based on Lorenz-Parks and Kraus models.

Materials and Methods

Materials

Table 1 summarizes the details of the various chemical ingredients utilized in compound preparation and their quantities expressed in part(s) per hundred parts of rubber (phr). All the ingredients were used as received.

Preparation of composites

The composites of NR with sepiolite or silica filler were prepared on a laboratory-sized two-roll mill with a 1.5 mm nip and a 12 cm guide. The chemical ingredients were added in the sequence displayed in Table 2. NR was firstly masticated for 2 min, followed by incorporation of ZnO and stearic acid, and milled for 1 min. The filler (sepiolite or silica) was then added to the mix and milled for 9 min. Next, MBTS was fed to the mix and milled for 2 min. Finally, sulfur was added to the mix and milled for 1 min. After completion of the mixing with total mixing time of 15 min, the rubber compounds were then vulcanized through compression molding with a hydraulic press at 160 °C following their respective curing times (t_{90}) in order to obtain 1 mm thick vulcanized sheets.

Mooney viscosity and Mooney stress relaxation measurement

Mooney viscosity and Mooney stress relaxation of the different rubber composite samples were investigated through the use of a Mooney viscometer, MV 3000 Basic (MonTech, Germany), according to ASTM D1646. The tests were carried out at 100 °C using the large rotor. The stress relaxation was fit with the power law model in equations 1 and 2:

$$M = kt^{a}, \quad (1)$$

$$\log M = \log k + a \log t, \quad (2)$$

where M refers to the torque during relaxation, k is a constant, t is the relaxation time, and the relaxation rate a denotes the slope visible in a log-log plot of M versus t.

Curing characteristics

The curing characteristics of the NR compounds, in terms of maximum torque (M_H), torque difference (M_H-M_L), cure time (t_{90}), and cure rate index (CRI), were determined at 160 °C through the use of a moving die rheometer (Montech MDR 3000 BASIC, Buchen, Germany). The CRI was defined by equation 3.

$$CRI = \frac{100}{t_{90} - t_{s1}} \quad (3)$$

Reversion resistance

The measurement of the reversion resistance of the composites at elevated temperature was performed using the percentage of reversion in the rubber compound after 300s, from the time at maximum torque (R_{300}), as shown in equation 4 [15, 16]:

$$R_{300} = \frac{M_H - M_{300}}{M_H} \times 100, \quad (4)$$

where M_H is the maximum torque in the curing curve and M_{300} is the torque at 300s after M_H.

Rubber-filler interactions

The extent of these filler-matrix interactions was estimated through the use of the Lorenz-Parks [17] and Kraus models [18]. The Lorenz-Parks model is as follows:

$$\frac{Q_f}{Q_g} = ae^{-z} + b, \quad (5)$$

where Q is the amount of solvent absorbed, f and g indexes refer to filled and gum rubber vulcanizates, a and b are constants (the model parameters tuned to fit data), and z denotes the weight fraction of filler. The Q can be obtained via equation 6 [19]:

$$Q = \frac{\text{Swollen wt. - Dried wt.}}{\text{Original wt.}}. \quad (6)$$

The Kraus equation is as follows:

$$\frac{V_{ro}}{V_{rf}} = 1\text{-}m\left(\frac{f}{1\text{-}f}\right), \quad (7)$$

where V_{ro} and V_{rf} refer to the volume fractions of elastomer in the solvent swollen gum vulcanizate and filled sample, f is the volume fraction of filler, and m is the rubber-filler interaction parameter. V_{rf} is expressed by the equation of Ellis and Welding [20], as follows:

$$V_{rf} = \frac{(W_d - fW_0)/\rho_r}{(W_d - fW_0)/\rho_r + A_s/\rho_s}, \quad (8)$$

where W_d and W_0 are the deswollen and the initial weights of the composite samples, f is the volume fraction of filler in the composite, ρ_r is the density of rubber, A_s is the content of solvent absorbed, and ρ_s is the density of solvent. V_{ro} is given by equation 9:

$$V_{ro} = \frac{(W_d - W_f/\rho_r)}{(W_d - W_f/\rho_r + W_s/\rho_s)}, \quad (9)$$

where W_f denotes the weight of filler in the composite sample.

Tensile properties

The tensile properties including tensile strength, elongation at break, and reinforcement index (the ratio of the moduli at 300 and 100% elongations, or M300/M100, RI) of crosslinked NR composites were studied through the use of a universal tensile testing machine, LR5K Plus (LLOYD Instruments, UK) in accordance with ISO 37. The averages of five dumbbell-shaped specimens are reported, and the test was conducted at ambient temperature with a crosshead speed of 500 mm/min. The RI was defined by equation 10 [21-23]:

$$\text{Reiforcement Index, RI} = \frac{\text{M300}}{\text{M100}} \quad (10)$$

where M300 and M100 refer to the stresses at 100% and 300% strains, respectively.

Morphological test

The dispersion of sepiolite and silica fillers throughout the rubber matrix was investigated through the use of a scanning electron microscope (SEM; FEI Quanta 400 FEG, the Netherland). All composite specimens were immersed in liquid nitrogen and subsequently fractured before sputter-coating with gold in order to eliminate electrostatic charge buildup during examination. The SEM photomicrographs of cut surfaces were taken at magnification of 500x.

Results and Discussion

Mooney viscosity and Mooney stress relaxation measurement

The Mooney viscosities of the NR composite compounds filled with sepiolite or silica are shown in Figure 1. It is observed that in general the Mooney viscosity increased with filler loading. This is usually attributed to hydrodynamic effects, following the Guth and Gold equation [24].

$$\eta_{rel} = \frac{\eta_f}{\eta_u} = 1+2.5\phi + 14.1\phi^2 \quad (11)$$

where η_{rel} is the relative Mooney viscosity, η_f refers to the Mooney viscosity of filled rubber composite, η_u denotes the Mooney viscosity of neat rubber compound, and ϕ is the volume concentration of filler. As the filler loading increases, the viscosity should increase. However, a reduction of viscosity after adding 5 phr silica was observed, which was probably attributed to the formation of large silica aggregation as will be discussed later.

Figure 2 illustrates the Mooney stress relaxation rates of the composite compounds. The filler content had a great effect on the rate of relaxation, and the relaxation rates of sepiolite filled NR composites were slower than those of the silica filled ones. It has been reported that the choice of filler and its interactions with the polymer matrix considerably impacted the rate of stress relaxation. Interactions between filler particles and rubber chains hindered the molecular mobility, thus decreasing the relaxation rate [25, 26]. Considering the type of filler, composites filled with sepiolite relaxed slower than the silica filled ones. Since stronger interactions between filler and rubber matrix could better retard the relaxation rate as mentioned earlier, it is assumed that sepiolite gave stronger filler-matrix interactions than silica. The stronger filler-rubber interaction of sepiolite was attributed to the smaller size with higher aspect ratio of sepiolite dispersion in the rubber matrix as will be discussed later in the morphological observation part. The higher aspect ratio provided the higher surface area to interact with the rubber through chain entanglement and physical adsorption of rubber molecules onto the filler surfaces. It is well accepted that surface area is a major factor in the rubber composite structure. The larger the surface area of the filler is, the higher the possibility of filler-rubber contact takes place, resulting in efficient retardation of rubber molecules during relaxation.

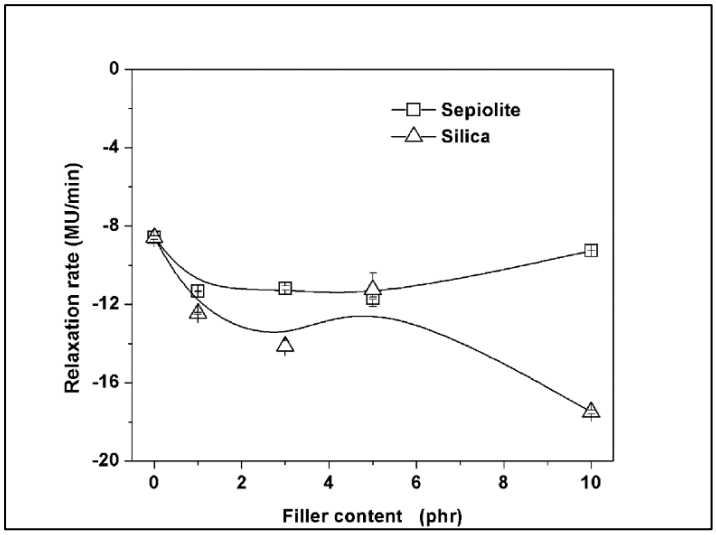

Figure 2. Mooney stress relaxation rates of NR compounds filled with sepiolite or silica

Curing characteristics

Curing properties in terms of M_H, M_H-M_L, t_{90}, and CRI, obtained from rheometric tests of the different rubber compounds, are presented in Figure 3(a)–Figure 3(d). It is noticed that the changes in curing properties were more pronounced for the sepiolite filled compounds in comparison with those for the silica filled ones. The M_H and M_H-M_L (Figures 3(a) and 3(b)) tended to increase with sepiolite loading, while they were approximately constant when silica was incorporated to the NR compounds. It is well known that M_H and M_H-M_L are related to molecular rigidity and crosslink density, respectively, for rubber compounds. The higher molecular rigidity and crosslink density were achieved with sepiolite filler because of the larger aspect ratio and surface area for contacting with the rubber molecules. The adsorbed rubber chain fragments on filler surfaces forming physical interaction restrict the chain mobility in the rubbery matrix and serving as additional crosslinks in the

composites. Consequently, the rigidity and crosslink density of the composites were improved. It has been reported that large improvements in M_H and M_H-M_L for composites with small filler loadings are attributed to stronger rubber-filler interactions [27-29]. Therefore, stronger interactions of rubber and filler can be assumed for sepiolite compared to those for silica in filled NR compounds.

Considering t_{90} of both sepiolite and silica filled compounds (Figure 3(c)), different phenomena are observed based on the filler type. Incorporation of sepiolite in NR tended to reduce t_{90}, while silica slightly prolonged it. A reduction of the t_{90} in sepiolite filled composites can be explained by the magnesium oxide (MgO) contained in the sepiolite structure. It is generally accepted that MgO is an activator of vulcanization reaction in rubber compounds, as it acts as a cation activating the crosslinking process at the diene backbone of the rubber [30]. On the contrary, the slight increase in t_{90} noticed for the silica filled compounds was probably a result of the highly polar nature of silica, leading to the absorption of the curing ingredients, including ZnO, stearic acid, and accelerators, and thereby resulting in a delayed curing process [31, 32].

The influence of metal oxide in sepiolite filled compounds on vulcanization process was later confirmed by increased CRI (Figure 3(d)), which indicated that curing reactions occurred faster with sepiolite filler than with silica filler. The CRI is a measure of rate of vulcanization based on the difference between cure time and scorch time. The higher the value of cure index, the faster the curing process [30].

Reversion resistance

Reversion resistances, R_{300}, for the composites with sepiolite or silica filler in NR vulcanizates were estimated by exposing the rubber composites to shear at an elevated temperature for a certain period of time. A larger R_{300} indicates more reversion [15, 33]. Figure 4 illustrates the reversion resistances of NR composites filled with sepiolite and silica. It is observed that the filler type and loading had a considerable effect on R_{300} within the experimental range probably because of relatively small filler loading. However, a larger R_{300} was seen for the silica filled NR composites, indicating that they had poorer reversion resistance in comparison with sepiolite filler. This can be because the greater sepiolite dispersion and better rubber-filler interactions improved the crosslink density of sepiolite filled NR composites. The better filler dispersion to gather with the higher overall crosslinking degree retarded the mobility of the rubber chains, and this enhanced the thermal stability of the rubber composites [8]. Furthermore, sepiolite itself could contribute to thermal stabilization and flame retardant properties of the filled polymer, as it served as a heat quencher and an initiator for formation of char on the polymer surface, inhibiting diffusion of oxygen [10].

Rubber-filler interactions

In order to evaluate the extent of interactions between rubber and filler, Lorenz-Parks and Kraus models were employed. Figure 5 presents Lorentz-Parks plot for the NR composites filled with sepiolite and silica. The value of rubber-filler interaction (Q_f/Q_g) generally reduced with sepiolite content but remained almost constant for the silica filled composites. Since the Q ascribed to the amount of solvent absorbed by rubber sample, the reduction of Q_f/Q_g was due to the better restricted diffusion of solvent molecules through the rubber matrix, resulting from greater extent of interaction between rubber and filler. The smaller value of Q_f/Q_g denotes stronger filler-matrix interactions [19, 28, 34, 35]. Since the Q_f/Q_g of sepiolite filled NR composites was below that of the silica filled composite at each loading level, the stronger rubber-filler interactions were achieved in the sepiolite filled composites. In contrast, the constant value of Q_f/Q_g in the composites filled with silica implies less interaction between silica and rubber matrix.

The rubber-filler interactions were further confirmed through the use of the Kraus model (plot of volume fraction ratio (V_{ro}/V_{rf}) versus volume ratio of filler (f/1-f)), and the results are displayed in Figure 6. It was observed that V_{ro}/V_{rf} decreased with filler loading. The negative slope in the plot of V_{ro}/V_{rf} versus f/1-f is an

indication of a good reinforcing effect [19, 28]. The negative slope was due to strong rubber-filler interaction, resulting from a reduction of the solvent uptake (solvent sorption) in the rubber composites. Consequently, the V_{rf} value decreases, resulting in a reduction in V_{ro}/V_{rf} value (V_{ro} is constant). More negative slope is noticed for the composites with sepiolite filler, implying that sepiolite was more effective in reinforcing the composite than the silica.

Based on the Lorenz-Parks and Kraus models, it is confirmed that sepiolite provided stronger rubber-filler interactions of the two fillers, leading to greater reinforcement within the range tested in the present study. The good interactions between sepiolite and rubber were attributed to the fact that the rubber chains can easily interact with the narrow channels in the sepiolite structure [9, 36]. Moreover, the larger specific surface area of sepiolite (364 m^2/g) [36] over silica (175 m^2/g) [37] may facilitate the rubber-filler interactions.

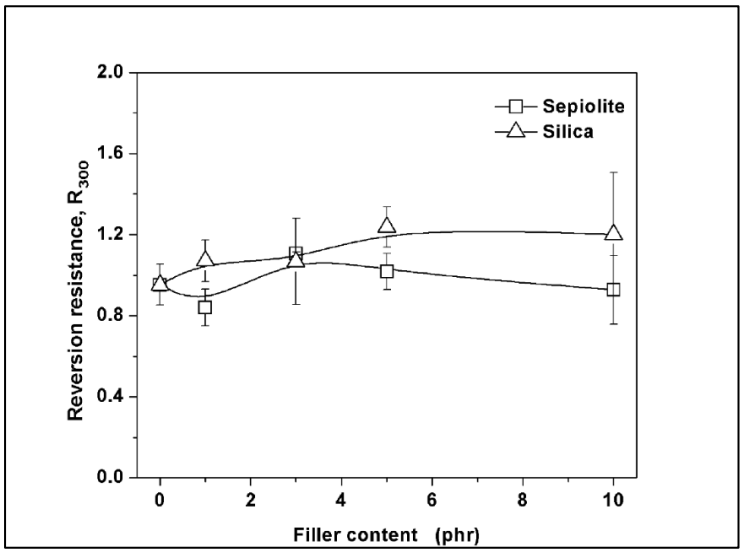

Figure 4. Reversion resistances of NR composites filled with sepiolite or with silica

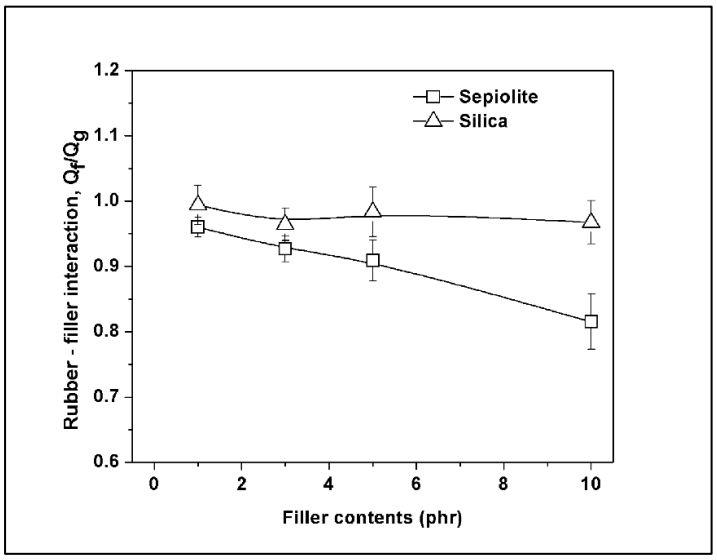

Figure 5. Lorentz-Parks plot of NR composites filled with sepiolite or silica

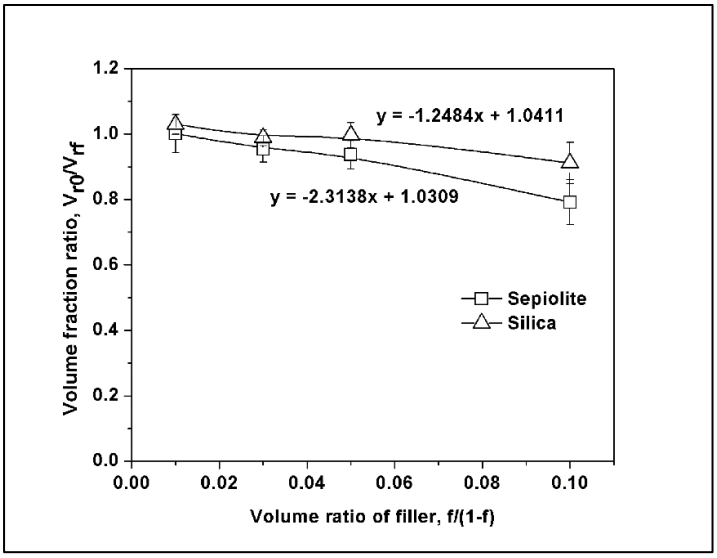

Figure 6. Kraus plot of NR composites filled with sepiolite or silica

Tensile properties

Figure 7 displays reinforcement index (M300/M100) for the NR composites filled with the two tested fillers. It is generally observed that the reinforcement index of sepiolite filled NR composite was greater than that of the silica filled composite. This was simply due to the stronger interactions between rubber and sepiolite filler, as previously discussed. The tubular-shaped with high specific surface area of sepiolite may act as stress transferring agent, which would increase the reinforcing index. This finding is in agreement with previous literature [5, 7, 9, 38], reporting that sepiolite fibers provided more reinforcement than spherical silica particles due to their high aspect ratio. The aspect ratios of sepiolite and silica found in the current study were approximately 5.32 and 1.09, respectively, which are in line with the previous report [38].

Figure 8 displays the variation in tensile strength of NR composites filled with sepiolite and silica. It can be clearly noticed that incorporation of sepiolite provided slightly higher tensile strength than silica, because of the better rubber-filler interactions. The highest tensile strength was about 17% improvement over unfilled sample found at 1 phr sepiolite loading, probably due to the greatest rubber-filler interactions as previously suggested by the stress relaxation and filler-rubber interaction results (Figures 2, 5, and 6). As a result of filler incorporation, the extensibility of rubber usually decreases due to either good rubber-filler interactions, restricting the movements of rubber chains, or poor filler dispersion, with agglomerates serving as stress concentration points. Thus, the elongation at break of composites reduced with filler loading, as presented in Figure 9. Similar observation was found in previous report [30]. The better rubber-filler interactions of sepiolite provided a slightly superior extension capability, particularly at low filler loadings.

In case of NR composites filled with silica, the highest tensile strength was found at 5 phr (about 12% over neat NR) which was considered to be optimum. Further increase in the silica incorporation slightly reduced the tensile strength because of the increment of silica aggregation, as will be discussed later in the morphological part. The aggregation of silica served as stress concentration point, resulting in a reduction of elongation at break. It is also found that the tensile strength of NR composites filled with sepiolite and silica was not much different due to relatively small filler loading. However, smaller loading of sepiolite required to obtain maximum tensile strength than silica would be benefited for preparation of rubber composite containing small filler loading.

Morphological property

Figure 10 presents the SEM micrographs of cryo-fractured surfaces of sepiolite (Figures 10(a) and 10(b)) and silica (Figures 10(c) and 10(d)) filled NR composites. It is noticed that the morphology of rubber composites comprises different sizes and shapes of filler dispersion, based on loading and type of filler. In the composites filled with sepiolite (Figures 10(a) and 10(b)), small size of filler with tubular-shaped was dispersed throughout the rubber matrix. The length (L) and diameter (D) of sepiolite in NR/Sepiolite 1 were about 1.34 - 3.15 μm and 0.34 - 0.91 μm, respectively. Meanwhile, they were about 2.45 - 5.50 μm and 0.45 - 1.12 μm, respectively, in NR/Sepiolite 5. Thus, the average aspect ratios of rubber composites filled with 1 and 5 phr sepiolite were about 5.32 ± 3.44 and 4.88 ± 3.36, respectively. Less amount of tubular-shaped particulates was observed in sample containing 1 phr sepiolite due to small amount of sepiolite added. However, such dispersion is sufficient to assist the stress transfer to each other. Large size of sepiolite aggregation was seen when the sepiolite loading was up to 5 phr. Such dispersion would be responsible for a reduction in tensile strength and elongation at break.

Considering the composites filled with silica, the L and D of silica in NR/Silica 1 (Figure 10(C)) ranged within 0.46 - 3.02 μm and 0.44 - 2.80 μm, respectively, whereas they were within 1.34 - 6.72 μm and 1.12 - 7.05 μm, respectively, for NR/Silica 5 sample (Figure 10(D)), resulting in the aspect ratio of about 1.06±0.04 for NR/Silica 1 and 1.03 ± 0.2 for NR/Silica 5. It was also found that the size of silica dispersion increased with filler loading, suggesting that filler-filler interaction was preferred at high silica loading. Smaller aspect ratio of silica dispersion than those of sepiolite can be confirmed which was in well agreement with previous report [39].

Based on the SEM observation, it is clearly evident that the aspect ratio of sepiolite dispersion was greater than that of silica. The higher aspect ratio created larger surface area contact between rubber and filler, providing better stress transfer between the components. Therefore, the better restricted chain relaxation and the higher tensile properties were obtained with incorporation of sepiolite.

Conclusion

Composites of NR filled with sepiolite or with silica were prepared in the present study, and the influence of filler type and loading level on properties of the composites was investigated. From Mooney viscosity, stress relaxation, and rheometric tests, the results revealed that sepiolite filled NR exhibited a slower relaxation rate with larger torque difference and better reversion resistance than that with the silica filled compounds, suggesting better rubber-filler interactions than in silica filled composites. Increased addition of filler improved the viscosity of rubber by approximately 7 - 22% with sepiolite and approximately 3 - 37% with silica, depending on filler loading. The stronger rubber-filler interactions in the sepiolite filled composites were later confirmed through the use of the Lorenz-Parks and Kraus models. The greater extent of interaction between rubber and filler resulted in the greater restricted diffusion of solvent molecules through the rubber matrix. As a result of the good interactions between sepiolite filler and rubber matrix, larger reinforcement indexes and tensile strengths were achieved with sepiolite filler than with silica filler in the composites. This was due to the higher aspect ratio of sepiolite (~5.32) compared to that of silica (~1.09) as revealed by SEM analysis. The highest tensile strength was achieved at 1 phr sepiolite loading which was about 17% improvement over unfilled sample.

Abstract

Hydrotalcite ($Mg_6Al_2(OH)_{16}CO_34H_2O$) is a naturally occurring anionic clay with a layered crystal structure. Hydrotalcites is classified as heterogeneous catalysts that exhibit an excellent separation post-reaction. Furthermore, commercial hydrotalcites are environmentally friendly. Organically synthesised hydrotalcites have attracted numerous researchers. The compounds are crucial solid base materials for several organic reactions, such as the Aldol condensation, Knoevenagel, Claisen-Schmidt, and Michael addition reactions. The present review covers the synthesis of magnesium aluminide (MgAl) hydrotalcites with varying magnesium to aluminium (Mg/Al) molar ratios employed to prepare the catalyst. Additionally, the characterisation of MgAl hydrotalcites with X-ray diffraction (XRD), Brunauer-Emmett-Teller (BET), and scanning electron microscopy (SEM) are highlighted. The instruments were utilised to identify the physicochemical properties of the catalyst, including crystallinity, surface area, and morphology. The catalytic activity of MgAl hydrotalcite was explored in the isomerisation of glucose into fructose as a model reaction for the catalytic performance.

Keywords: MgAl hydrotalcite, Mg/Al molar ratio, physicochemical properties, catalytic activity

Abstrak

Hidrotalsit ($Mg_6Al_2(OH)_{16}CO_34H_2O$) ialah tanah liat anionik yang wujud secara semula jadi dengan struktur kristal berlapis. Hidrotalsit dikelaskan sebagai pemangkin heterogen yang mempamerkan pemisahan selepas tindak balas yang sangat baik. Tambahan pula, hidrotalsit komersial adalah mesra alam. Hidrotalsit yang disintesis secara organik telah menarik ramai

penyelidik. Sebatian tersebut merupakan bahan asas pepejal yang penting untuk beberapa tindak balas organik, seperti tindak balas kondensasi Aldol, Knoevenagel, Claisen-Schmidt, dan penambahan Michael. Ulasan semula ini meliputi sintesis magnesium aluminida (MgAl) hidrotalsit dengan pelbagai nisbah molar magnesium kepada aluminium (Mg/Al) digunakan untuk menyediakan mangkin. Selain itu, pencirian hidrotalsit MgAl dengan pembelauan sinar-X (XRD), Brunauer-Emmett-Teller (BET), dan mikroskop elektron pengimbasan (SEM) diserlahkan. Instrumen ini telah digunakan untuk mengenal pasti sifat fizikokimia mangkin, termasuk kehabluran, luas permukaan, dan morfologi. Aktiviti pemangkin hidrotalsit MgAl telah diterokai dalam pengisomeran glukosa kepada fruktosa sebagai tindak balas model untuk prestasi pemangkin.

Kata kunci: MgAl hidrotalsit, nisbah molar Mg/Al, sifat-sifat fizikokimia, aktiviti pemangkin

Introduction

Hydrotalcite is a magnesium-aluminium hydroxy-carbonate, a naturally occurring mineral with the chemical composition $Mg_6Al_2(OH)_{16}CO_34H_2O$ that exhibits a layered crystal structure [1]. The layers consist of positively charged hydroxide layers, while the interlayers contain carbonate anions and water molecules, as displayed in Figure 1. The general formula of hydrotalcites is $[M^{2+}_{(1-x)}M^{3+}_x(OH)_2]_{x+}(A_{x/n})^{n-}.yH_2O$, where M^{2+} and M^{3+} are the metal components with divalent and trivalent cations, respectively, and A^{n-} is an interlayer anion [2]. Aluminium (Al) is partially substituted in magnesium hydroxide ($Mg(OH)_2$) and is a brucite structure in magnesium aluminide (MgAl) hydrotalcite, the typical representation of hydrotalcites [3]. The charge imbalance when a trivalent cation replaces the divalent is counterbalanced by the placement of available anions, such as CO_3^{2-}, NO_3^-, Cl^-, SO_4^{2-}, and OH^-, in the interlayers along with water molecules [4].

The MgAl hydrotalcites are solid bases that exhibit potential catalytic activity and good stability under required reaction conditions [6]. Moreover, hydrotalcites possess two representative and prominent properties, the ability to capture and exchange organic and inorganic anions and the memory effect due to their unique structures [7]. The unique characteristics resulted in the wide range of applications of the compounds as anion exchangers, absorbing agents, stabilisers for polymers, catalysts, electroactive materials, and pharmaceuticals. Hydrotalcite is classified as a heterogeneous catalyst with numerous advantages over homogeneous catalysts, including catalyst reusability, high purity by-products, and good separation and purification [8]. The wide applications of hydrotalcite catalysts have brought more functionality to the industry. Researchers in the scientific field generally employ hydrotalcite catalysts in organic synthesis reactions [9]. The catalysts are regarded as crucial solid base materials for various organic reactions, including Aldol condensation [10], Knoevenagel [11], Claisen-Schmidt [12], and Michael addition [13] reactions.

Numerous methods, such as co-precipitation, urea, sol-gel, and hydrothermal synthesis, could be utilised to prepare MgAl hydrotalcite [14, 15]. In this review, the preparation of MgAl hydrotalcite via co-precipitation, urea, and simple methods are discussed in detail. Furthermore, the current review highlights the characterisation of MgAl hydrotalcites with X-ray diffraction (XRD), Brunauer-Emmett-Teller (BET), and scanning electron microscopy (SEM). The instruments identified the physicochemical properties of the catalyst, including crystallinity, surface area, and morphology. The catalytic properties of MgAl hydrotalcite as base catalysts were confirmed by the isomerisation of glucose to fructose. The influence of the preparation method on the physicochemical properties and activity of MgAl hydrotalcites as solid base catalysts based on the characterisation results and the catalytic activities observed are discussed and compared.

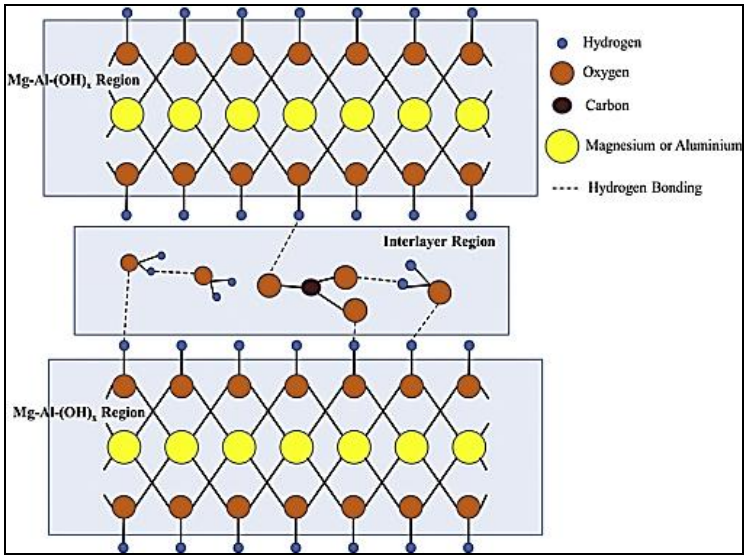

Figure 1. MgAl Hydrotalcite Structure [5]

Preparation of MgAl hydrotalcite catalyst

Researchers have employed numerous methods to synthesise MgAl hydrotalcite catalysts, such as co-precipitation, urea, and simple methods. The techniques are applicable in the isomerisation of glucose into fructose. The most common method to prepare hydrotalcite catalyst is the co-precipitation method. The pH of the solution plays a vital role in the technique. If the pH of the solution utilised is low, not all ions would precipitate, while a high pH would result in the dissolution of the metallic ions present [5]. Consequently, it is essential to control the pH of the solution to obtain the hydrotalcite catalyst successfully. Park et al. [14] performed the preparation of MgAl hydrotalcite catalyst via the co-precipitation method by adding aqueous solution B, sodium hydroxide and sodium carbonate in distilled water dropwise into solution A that consisted $Mg(NO_3)_2.6H_2O$ and $Al(NO_3)_3.9H_2O$ dissolved in distilled water. During the addition of solution B into solution A, the pH of the solution need to be maintained at approximately 9.5. The resulting solution was vigorously stirred at room temperature for 18 h before proceeding with the filtration process by washing it with distilled water several times. Subsequently, the solid product was dried overnight at 100 °C. The molar magnesium to aluminium (Mg/Al) ratio utilised in the study was three. The report found that the ratio resulted in a promising catalyst for various base-catalysed reactions due to its excellent base catalytic properties.

The utilisation of varying Mg/Al molar ratios affected the catalytic performance of the MgAl hydrotalcites catalyst obtained [16]. Kang et al. prepared MgAl hydrotalcite via the co-precipitation method with different Mg/Al atomic ratios of from 0.5 to 3.5, which was dissimilar to the investigation by Park et al., where the only Mg/Al molar ratio employed was three. In a similar investigation to [14], Yu et al. reported synthesising fresh, calcined, and rehydrated MgAl hydrotalcite catalysts with the Mg/Al ratio of three [17]. The calcined MgAl hydrotalcite was prepared by calcining the synthesised MgAl hydrotalcite at 450 °C for 10 h in an airstream. In contrast, the rehydrated MgAl hydrotalcite was obtained by hydrating the calcined MgAl hydrotalcite in decarbonated water with vigorous stirring in an inert atmosphere at 60°C for a day followed by filtration and drying overnight at 80 °C.

Urea hydrolysis is one of the techniques employed to acquire MgAl hydrotalcite. The alternative precipitating agent utilised in the method is urea, while the co-precipitating technique employs Na_2CO_3 as the

precipitating agent [5]. The MgAl hydrotalcite with Mg/Al = 3 was prepared by Park et al. [16] according to this procedure. A solution of $Mg(NO_3)_2.6H_2O$, $Al(NO_3)_3.9H_2O$, urea, and distilled water was added into a three-neck flask equipped with a condenser . The reaction was conducted at 95℃ for two days, while the pH of the solution was measured every 15 min during the hydrolysis. After the reaction was completed, the resulting mixture was cooled in an ice bath for 30 minutes, filtrated, washed, and dried at 80 ℃. Another method employed by the same researchers was the simple method. The technique was based on the hydration of metal oxides obtained by calcination of metal nitrates in the air at 450 ℃ for 10 h. Subsequently, suitable amounts of MgO and Al_2O_3 were dissolved in distilled water, and the resulting solution was aged at 60 ℃ for a week. A white precipitate was obtained after the solution was filtered and dried overnight at 80 ℃. The method was simpler than the other two techniques as no particular controlled variables were involved with metal oxides [7].

Characterization of MgAl hydrotalcite catalyst

The formation of MgAl hydrotalcite was confirmed with various characterisation tools such as XRD, SEM, and BET. The XRD is one of the most common characterisation tools employed to confirm the layered structure of hydrotalcite. Park et al. [16] reported that the typical XRD pattern of MgAl hydrotalcite exhibits definite crystalline phases observable in fresh catalyst obtained from every method, attributing to the reflections of 2θ = 11.6° (003), 23.3° (006), 34.8° (009), 60.7° (110), and 62.0° (113), as shown in Figure 2. The results indicated that the MgAl hydrotalcite with Mg/Al = 3 retained the layered double hydroxide structures even though they are prepared differently. The XRD patterns in Figure 2(b) demonstrated a slight shift of the peaks at the (003) plane, depending on the preparation method employed. The observation was due to the different anions located in the interlayer spaces of the hydrotalcite procured from the three preparation techniques.

Figure 3 displays the XRD pattern of the MgAl hydrotalcite synthesised by Yu et al. [17]. Only the synthesised and rehydrated MgAl hydrotalcites exhibited the characteristic hydrotalcite XRD peaks similar to the planes reported by Park et al. [16]. No XRD peaks corresponded to the layered structure of hydrotalcite in the calcined MgAl hydrotalcite due to the destruction of the structure by the calcination process. Conversely, the calcined MgAl hydrotalcite maintained the spinel structure of MgAl mixed oxide. Surprisingly, the rehydrated MgAl hydrotalcite preserved the layered structure of hydrotalcite, proving the memory effect of hydrotalcite.

Figure 3 exhibits the XRD peaks for (003) planes in the rehydrated MgAl hydrotalcite, which was much broader compared to the synthesised MgAl hydrotalcite. The observation was due to the exfoliation and vertical breaking of layers in the structure of hydrotalcite, resulting in a smaller crystallite size of the rehydrated MgAl hydrotalcite. A report demonstrated the XRD patterns of MgAl hydrotalcites synthesised with different Mg/Al atomic ratios between 0.5 and 3.5 (Figure 4). The catalysts with the Mg/Al atomic ratios of 0.5 and 1.5 were the least developed. The lower the Mg/Al atomic ratio, the more the peaks shifted towards higher values, attributing to a decreased *d*-spacing between the hydroxide layers, resulting in reduced distance between layers of MgAl hydrotalcite as the Al content was elevated [16].

The XRD peaks on the (003) plane were applied in the Scherrer equation to calculate the crystallite size of the MgAl hydrotalcites. Specific surface areas (S_{BET}) of the MgAl hydrotalcites were determined via the BET plot. Park et al. found that different preparation methods of MgAl hydrotalcite significantly impacted the crystallite size and S_{BET}. The MgAl hydrotalcite prepared via co-precipitation (HT_P) demonstrated the smallest crystallite size and the highest S_{BET} compared to the urea (HT_U) and simple (HT_S) techniques (Table 1). Yu et al. [17] reported that the crystallite size of the synthesised (HT_A) and rehydrated MgAl (HT_R) hydrotalcites could be calculated as the catalysts prepared through the co-precipitation method but under different conditions retained their LDH structure. Nonetheless, the calcined MgAl (HT_C) hydrotalcite

did not produce results for crystallite as the structure of the catalyst was destroyed during the calcination process.

Kang et al. [16] concluded that as the Mg/Al atomic ratio decreased, the S_{BET} increased even at the Mg/Al ratio of 1.0 (Figure 4). Nonetheless, based on the XRD characterisation, the 1.0 sample exhibited lower S_{BET} due to the unsuccessful formation of layered structures. Additionally, the catalyst produced with the Mg/Al ratio of 1.5 demonstrated the most significant S_{BET} and the smallest crystallite size. Consequently, the crystallite size was strongly affected by the preparation method as the growth of the hydrotalcite layers and the degree of layer stacking differed greatly depending on the preparation method. Resultantly, the surfaces of the active sites had different exposures to reactants, resulting in varying catalytic activities of the MgAl hydrotalcites [14].

Upare et al. [18] reported XRD patterns for all the samples with rehydrated Mg/Al ratios from 1.0 to 5.0 (Figure 5). Based on the XRD characterisation, an increase of Mg/Al ratio was slightly shifted to a lower angle on the (003) plane at 2θ of 11.4° corresponding to the interlayer anion. This observation indicating that the interlayer spacing and unit cell parameter increased with Mg/Al ratio of the rehydrated hydrotalcite [18]. Additionally, the crystallite size increases from 7.9 to 10.3 nm as the rehydrated hydrotalcite with Mg/Al ratio increases from 1.0 to 3.0. Conversely, the crystallite size decreases from 10.3 to 6.8 nm as Mg/Al ratio decreases from 3.0 to 5.0.

Apart from XRD and BET analysis, SEM analysis also can be employed to confirm the structure of MgAl hydrotalcites and to prove the crystallite size calculated from the XRD analysis. The characteristic layered structures of the synthesised MgAl hydrotalcites were composed of platelet-like particles that agglomerated in different ways depending on the preparation method, as shown in Figure 6. In particular, the HT_P MgAl hydrotalcite with the smallest crystallite size exhibited a sand-rose morphology (Figure 6(a)) [14]. Kang et al. [16] observed a similar sand-rose morphology, indicating that the co-precipitation method successfully produced the layered MgAl hydrotalcite structure (Figure 7). The findings might be due to the surfaces being easily exposed to reactants, which strongly affected the catalytic activity of the catalysts [14]. Consequently, Park et al. reported that MgAl hydrotalcites prepared according to the co-precipitation procedure could be expected to exhibit superior activity over other hydrotalcite catalysts in base-catalysed reactions [14].

Catalytic reaction in the isomerization of glucose to fructose

Glucose isomerisation was employed as a model reaction to explore the catalytic activity of the synthesised MgAl hydrotalcites. The isomerisation of glucose into fructose is a critical step in biomass conversion technologies [19]. Generally, the isomerisation of glucose into fructose was conducted in a batch-type glass reactor with glucose as the reactant, MgAl hydrotalcite as the catalyst, and dimethylformamide. The reaction was conducted at 100°C for 3 h. After the reaction was completed, the reactor was cooled in an ice bath, followed by filtrating the resultant solution to separate the catalyst. Lastly, the filtrate was analysed with HPLC equipped with a UV-Vis detector. Table 2 tabulates the catalytic activity of the synthesised MgAl hydrotalcite as a solid base catalyst in the isomerisation of glucose into fructose, as reported by Park et al., Yu et al., and Kang et al. [14, 16, 17]. According to Park et al. [14], the MgAl hydrotalcite prepared by co-precipitation produced the highest fructose yield at 25% compared to the other methods. Moreover, since the method fabricated the smallest crystallite size with abundant surface base sites, numerous researchers utilised MgAl

hydrotalcite catalyst prepared with the co-precipitation technique to convert glucose into fructose [14].

Yu et al. [17] found that the highest fructose yield (30%) was obtained when the rehydrated MgAl hydrotalcite catalyst was employed. The results were due to the abundant and selective surface base sites for glucose isomerisation were produced during the rehydration process. Meanwhile, Kang et al. [16] studied the effects of Mg/Al with different ratios on the catalytic activity of MgAl hydrotalcite. They reported that the MgAl hydrotalcite with an Mg/Al ratio of 1.5 produced the highest fructose yield (42%). The increased catalytic activity of the MgAl hydrotalcite during the isomerisation of glucose into fructose was assumed to be due to the small crystallite size obtained by co-precipitation of Mg/Al with the molar ratio of 1.5. Theoretically, the larger the surfaces of the MgAl hydrotalcite exposed to the reactants, the catalyst would exhibit a better catalytic activity.

A report demonstrated by Upare et al. on glucose isomerization, 1-butanol was used as the solvent. It is noted to be very effective in preventing the formation of humin based on their previous study [18]. The uniqueness of 1-butanol as a solvent for glucose isomerization showed that there is no leaching of Mg ions from the hydrotalcite catalyst compared to other solvents such as water, ethanol and dimethylformamide [18]. Notably, the rehydrated MgAl hydrotalcite catalyst with Mg/Al ratio of 2.0 is the excellent catalyst for the isomerization of glucose into fructose with the highest percent yield (51%). The fructose yield increased from Mg/Al ratio of 1.0 to 2.0, however, it decreased from Mg/Al ration of 2.0 to 5.0. These results showed that the high rehydrated Mg/Al ratio were not favourable in the formation of fructose [18].

Apart from using the combination of 1-butanol and hydrotalcite catalyst in glucose isomerisation, ethanol is one of the solvent used in this reaction. Yabuhita et al. found that the use of ethanol enhance the fructose yield and thus, obtained 50% yield which is quite higher compared to other results (Table 2). Furthermore, the removal of ethanol after the reaction is much simpler as its boiling point is quite low than water [20]. By having Mg/Al molar ratio of 3, Yabushita et al. [20] successfully acquired the formation of fructose within a short time.

Conclusion

Based on the comprehensive literature review, it could be concluded that the preparation method of MgAl hydrotalcite strongly influenced the growth and stacking of its layers and the type of anions intercalated during the formation of the layered structure. The unique characteristics of the MgAl hydrotalcites led to varied crystallite sizes and morphologies. The co-precipitation method was more favourable than the urea and simple methods to fabricate MgAl hydrotalcites with surfaces that consist of numerous basic sites. Furthermore, different Mg/Al molar ratios also affected the formation and catalytic activity of the synthesised MgAl hydrotalcite. The catalytic activity of the synthesised MgAl hydrotalcite was observed in the isomerisation of glucose into fructose. The MgAl hydrotalcite prepared via co-precipitation produced the highest fructose yield as its small crystallite size and sand-rose morphology result in significant exposure of its surface active sites to the reactants.

Abstract

Polymelamine is a new class of polymer that possess electrocatalytic behavior in dopamine (DA) detection. Our previous studies have successfully replaced the conventional acidic electrolyte to deep eutectic solvent (DES) has open the opportunity for a greener solvent in used. Herein we report the optimization process of melamine electropolymerize in DES- reline. Various electrochemical techniques have been employed to studies the ideal parameters. The optimum potential window, scan rate, and number of scan cycles were recorded as -0.20 V – 1.60 V, 50 mV s^{-1} and five scan cycles, respectively. Cyclic voltammetry (CV) was employed in the electropolymerization of melamine to optimize the redox behavior of polymelamine film on electrode surface. The growing of polymer film which indicated by the increased of reduction current can be well-controlled by the slow scan rate and optimum scan cycles which leads to strong adhesion and uniform morphology. Amperometry sensing on DA was performed to study and compare the sensitivity and limit of detection for the polymers synthesized in varied parameters. A brief discussion on the principal polymerization factors that would affecting the electrocatalytic behavior of melamine is included.

Keywords: deep eutectic solvent, electropolymerization, melamine, optimization

Abstrak

Polimelamin adalah kelas polimer baharu yang mempunyai tingkah laku elektromangkin dalam pengesanan dopamin (DA). Kajian yang dilaporkan terdahulu menujukkan kerjayaan penggantian elektrolit berasid konvensional kepada pelarut eutektik (DES). Kerjayaan ini membuka peluang untuk pelarut yang lebih mesra alam digunakan. Dengan ini, kami melaporkan proses pengoptimum elektropolimerisasi melamin dalam DES-relin. Pelbagai teknik elektrokimia telah digunakan untuk mengkaji parameter yang terbaik. Julat keupayaan, kadar imbasan dan bilangan kitaran imbasan yang terbaik dicatat pada -0.20 V – 1.60 V, 50 mVs^{-1} dan lima kitaran imbasan. Siklik voltametri (CV) telah digunakan dalam elektropolimerisasi melamin untuk mengoptimumkan tingkah laku elektropemangkinan lapisan polimelamin pada permukaan elektrod. Pertumbuhan lapisan polimer yang ditunjukkan dalam penainkkan arus penurunan boleh dikawal baik dengan kadar imbasan yang perlahan dan kitaran imbasan optimum untuk mencapai lekatan yang kuat dan morfologi yang seragam. Penderiaan amperometri pada DA telah dijalankan untuk mengkaji dan membandingkan kepekaan dan had pengesanan rendah untuk polimer yang disintesis dalam

parameter yang berbeza-beza. Perbincangan ringkas tentang faktor-faktor elektropolimerisasi yang mempengaruhi tingkah laku elektromangkin melamin telah disertakan.

Kata Kunci: pelarut eutektik dalam, elektropempolimeran, melamin, pengoptimuman

Introduction

Heretofore, the polymers such as polyisoprene, polystyrene, polythiophene, polyaniline, polypyrrole, formaldehyde resin and their by-products have been examined extensively as promising candidates in sensor development. A novel class of conducting polymer - polymelamine (PME) was proposed. PME is made from the nitrogen-rich melamine (1,3,5-Triazine-2,4,6-triamine) which is a heterocyclic organic compound. The synthesis methods of PME included chemical, electrochemical, photo-initiating, biocatalytic, and plasma polymerization. Among all, electropolymerization is commonly employed due to its advantages in facile engineer the morphology, thickness, density, and growing rate of the polymer. PME can be synthesized easily using electropolymerization technique by oxidize the amino groups found in melamine. In the discipline of electrochemistry, PME has been employed as a stable matrix to enhance the effective immobilization of nanomaterials on it. It is also employed as electrochemical sensor owing to the existence of numerous active groups such as nitrogen and amine. PME and its offshoots were soon utilized extensively in sensing of different neurotransmitters, pharmaceutic particles, and toxic heavy metals [1-3]. Moreover, PME composited with nanocarbon demonstrated high specificity and exhibited exceptional catalytic reaction over broad extent of molarity [4].

Deep eutectic solvent (DES) draws great attention lately owing to their solvation potential, conductivity, simple synthesis method, cost effective and many are biodegradable [5]. DES are commonly applied in two principal fields: metal processing (metal electropolishing, metal dissolution, metal deposition) and as synthesis solvent [6-8]. Reline (a Type III DES) was employed as stimulant and reducing mediator for polymerization of hydrophilic monomer at temperature close to ambient [9]. Reline and glyceline (a Type III DES) were proposed to substitute typical aqueous solution in free-radical polymerization of acrylamide [10]. The outcome shows the polymer synthesized has similar molecular mass compared to the polymer synthesized in aqueous solution. Moreover, polyaniline synthesized in DES demonstrated exceptional conductivity reported at 50 S cm^{-1} [11]. The polyaniline shows excellent reversibility to doping/dedoping mechanisms which indicated rapid charge transfer. Furthermore, Type I DES has effectively utilized as a cationic catalyst for epoxy resin curing [12].

Despite that, DES being the synthesis solvent particularly in the formation of polymers are rarely examined in terms of polymerization parameters. Conventionally, electropolymerization of melamine was conducted in acidic electrolyte [1]. Acidic electrolyte with pH less than two is the key for the growth and establishment of radical cations that required in rate-limiting step during the electropolymerization of melamine. In accordance with our published work, we have successfully superseded the conventional acidic electrolyte with DES. PME synthesized in DES manifests excellent sensitivity, specificity, and stability [13]. In this work, we focus on the optimization of polymerization parameters, and discuss the effect of these parameters in polymerization of melamine. Reline is selected as study target due to the enlightenment of the novel perception asserted that chloride ion (Cl^-) is the vital factor for PME formation [14]. Reline is a mixture of choline chloride and urea in 1:2 ratio, urea molecules offer plentiful positive hydrogen bonding spot to adopt the Cl^- negative ion into their polar matrix [15]. PME synthesized in reline is then applied in electrochemical qualification and quantification of dopamine (DA).

Materials and Methods

Materials

Melamine monomer, choline chloride, ethylene glycol, urea, glycerol, dopamine (DA), potassium dihydrogen

phosphate (KH_2PO_4) and potassium hydrogen phosphate (K_2HPO_4) were purchased from Sigma Aldrich. Ultra-pure deionized (DI) water with a resistance of 18.3 MΩcm (Merck Synergy) was used in all sample preparations. All the chemical reagents were of analytical grade and were used without further purification.

Instrumentation

The surface morphology of the bare and modified sensor was studied by using Horizontal Attenuated Total Reflectance-infrared spectroscopy (HATR-IR, PerkinElmer, Inc). All electrochemical experiments were carried out by Autolab potentiostat/galvanostat PGSTAT-302N with an ordinary three electrodes system, containing glassy carbon electrode (GCE) (ALS-Japan, diameter = 3.0 mm, surface area = 0.071 cm^2) as working electrode, a platinum braid wire (BASi, diameter = 1.0 mm, surface area = 0.008 cm^2) as counter electrode and sodium chloride (KCl) saturated Ag/AgCl (BASi) as the reference electrode. All the potential readings were referred to Ag/AgCl unless stated elsewhere. A pseudo reference electrode (Ag wire, BASi, diameter = 1.0 mm, surface area = 0.008 cm^2) was employed for electrochemical polymerization of polymer in DES or mixtures. The referred reading of the pseudo wire with respect to the Ag/AgCl electrode was at + 90 mV. Amperometry analysis of DA was conducted at constant potential (0.20 V) in PBS (0.10 M, pH 7.0).

Preparation of deep eutectic solvent

Type III DES - reline was prepared by mixing choline chloride into urea, in 1:2 molar ratio. The mixture was heat under oil bath with control temperature from 55ºC to 60ºC until a clear solution was obtained. Reline was then set aside to cool down to ambient temperature prior served as supporting electrolyte for the electropolymerization of melamine.

Preparation of 0.10 mM melamine(reline) solution

A 10.0 mM of melamine was prepared by mixing 5.0 mg of melamine into 4.0 mL reline followed by ultrasonication for 30 minutes until a homogeneous solution is achieved. The as-prepared melamine solution was named as melamine(reline).

Synthesis of PME(reline)/GCE

GCE was gently polished with 0.05 µM alumina slurry and then rinsed with DI water and ethanol a few times until a clean mirror-like surface was obtained. A clean GCE was then immersed into melamine(reline) solution and CV was scanned from the studied potential window at various scan rates for different number of cycles as part of the optimization studies. The fabricated PME(reline)/GCE was gently rinsed with DI to wash off the monomer residue and then set to dry in ambient condition before used.

Preparation of phosphate buffer solution

Phosphate buffer solution (PBS) was used as supporting electrolyte in amperometry sensing of DA. 27.2 g of KH_2PO_4 and 34.8 g of K_2HPO_4 were individually poured into 1.0 L volumetric flask and added with DI until meniscus line forming solution A (0.20 M) and B (0.20 M), respectively. PBS (0.10 M, pH 7.0) was prepared by mixing 39.0 mL solution A and 61.0 mL solution B follow diluted with DI to 200 mL. The pH value of the buffer solution was confirmed with pH meter (model pH 700, Eutech Instruments).

Preparation of DA stock solution

1000 µM of DA stock solution was prepared by adding 0.015 g DA into 100 mL volumetric flask and added DI until meniscus. DA solution was freshly prepared daily and kept in refrigerator at 4ºC before used for not more than 12 hours. A layer of aluminum foil was used to cover the stock solution to avoid contact with light.

Results and Discussion

Optimization of potential window for melamine electropolymerization

To understand the effect of applied potential window on the melamine electropolymerization process, repeated CV cycling tests were carried out on melamine dissolved in reline. To begin with the potential window investigation, parameters of melamine concentration, scan rate, scan cycles, and temperature were fixed at 10.0 mM, 50 mV s^{-1}, five scan cycles and 25°C, respectively. Figure 1 shows the

electropolymerization of melamine at fixed starting potential (-0.20 V) and ended with varied potentials: 1.20 V, 1.40 V, 1.60 V, and 1.80 V. The electropolymerization behavior of melamine in reline was different from the conventional electrolyte - H_2SO_4 as in previous literature [14]. In conventional electrolyte, a cathodic peak at around + 0.85 V was noticed owing to the coupling among the melamine molecules and carbonyl groups (C=O and/or C-O) from the DES instead of head-to-head linking of amine groups betwixt the melamine molecules [13]. Figure 1(c) illustrated an anodic peak at 1.20 V was observed for the electropolymerization of melamine from -0.20 to 1.60 V. The anodic peak was due to functionalization of melamine monomers with carbonyl groups (C=O) attributed from the reline and forming an electroactive PME functionalized DES. Likewise, an anodic peak at about 1.20 V was observed in Figure 1(b) for applied potential window -0.20 - 1.40 V, indicating the formation of PME. However, it noticed that the peak current was lower as compared to the electropolymerization of melamine at -0.20 to 1.60 V, indicating the limit of charge depository of polymer formed at -0.20 - 1.40 V. Noted that in Figure 1(a) and Figure 1(d), no anodic peak was observed with the applied potential. This is probably due to a narrow potential window restricts the charge depository ability of monomer during polymerization, while a wide potential window will lead to overoxidation of polymer, causing breakage of polymer chain [16]. From these, it was concluded that potential range from -0.20 V to 1.60 V is well suited to carry out the melamine electropolymerization for the PME formation.

To further verify how the tuning of potential window affecting the performance of PME in dopamine (DA) sensing, all the PME/GCE electrodes synthesized in varied potential window were further tested in two aspects: sensitivity and limit of detection (LOD). In amperometry setting, DA is oxidised at potential 0.20 V [13]. Therefore, amperometry was scanning at fixed potential (0.20 V) with additional of DA with concentration ranging from 100 - 1200 μM in PBS (0.10 M, pH 7.0) as shown in Figure 2. Sensitivity and LOD were then calculated based on the amperometric results and summarized in Figure 3 and Table 1. Naming of PME was based on the maximum applied potential e.g., PME synthesized in reline with potential window applied at -0.20 - 1.20 V is named as PME(reline +1.20 V). Based on Figure 2, it was noticed that the amperometry result of PME(reline +1.60 V) recorded the highest current response as compared to the other PME. Figure 3(A) and (B) illustrated the calculated sensing sensitivity and LOD of DA at PME(reline), respectively. Noted that the sensing of DA at PME(reline +1.60 V) recorded the highest sensitivity and lowest LOD recorded at 0.044 $\mu A\ \mu M^{-1}\ cm^{-2}$ and 0.198 μM, respectively which are in line with amperometry result shown in Figure 2. The sensitivity line graph of over-potential showed increment from +1.20 V and reached maximum at +1.60 V. At the same time, LOD obey the opposite relationship and reaching the minimum LOD at +1.60 V. In case, further widen the potential window of PME(reline) to +1.80 V, the electrode sensing capability has reduced drastically where the LOD did not showed any improvement and has been increased 10-fold recorded at 2.070 μM compared to +1.60 V. The result justified the optimized potential window for electropolymerization of melamine is -0.20 V to +1.60 V.

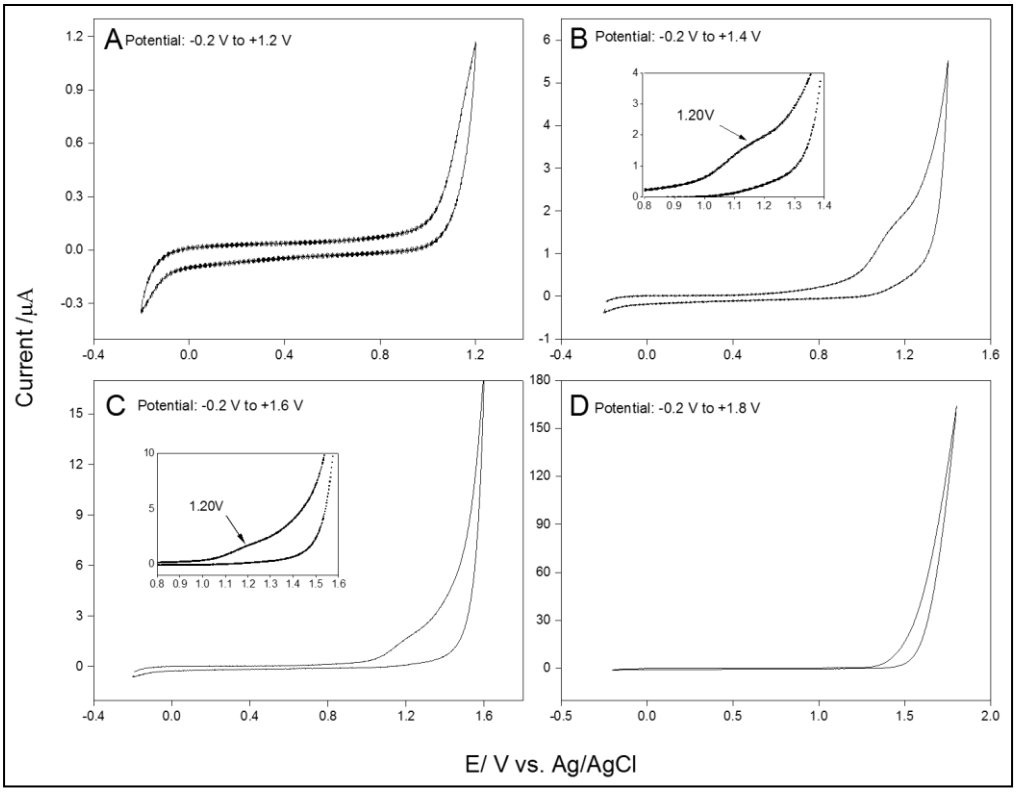

Figure 1. Electropolymerization of melamine (10.0 mM) in reline scanning with varied potential window a) -0.20 to 1.20 V, b) -0.20 to 1.40 V, c) -0.20 to 1.60 V, and d) -0.20 to 1.80 V at 50 mV s^{-1} with five scan cycles

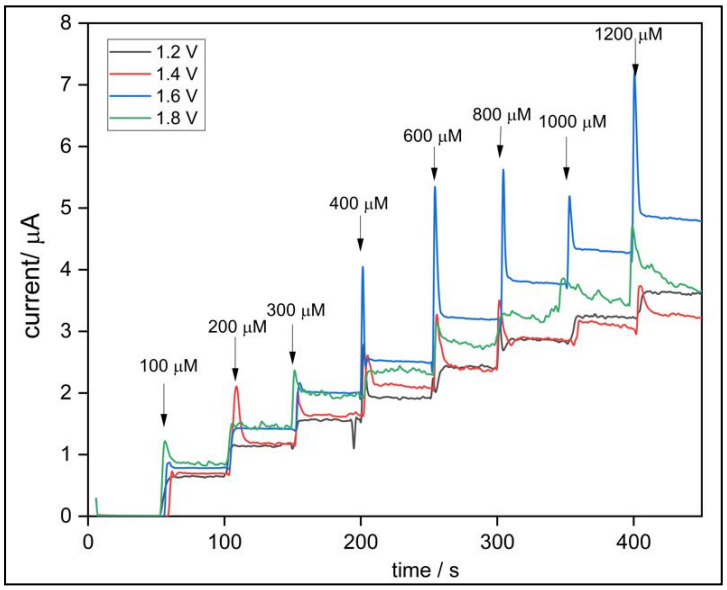

Figure 2. Amperometry results of PME synthesized in different potential window. All the amperometry test were scanned at a fixed potential (0.20 V) with additional of DA with concentration ranging from 100 - 1200 μM in PBS (0.10 M, pH 7.0)

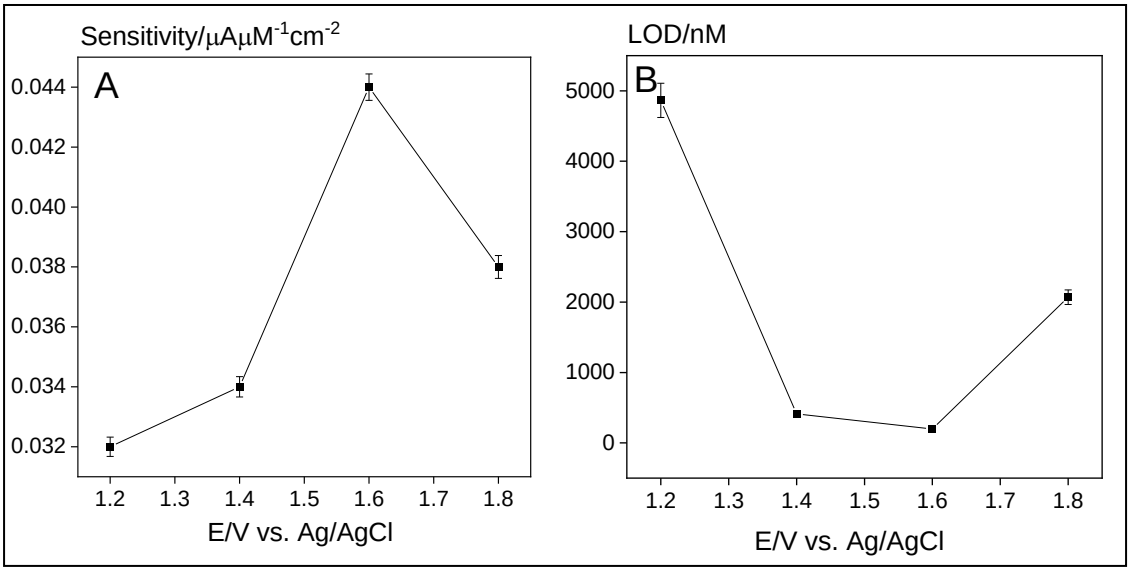

Figure 3. Graphs of (a) sensitivity and (b) LOD results versus varied potential window applied for electropolymerization of melamine in reline.

Table 1. Optimization studies for electropolymerization of melamine in reline, DA as model analyte; sensing with amperometry at 0.20 V vs Ag/AgCl: Effect of electropolymerization potential window, effect of scan rate and effect of scan cycles

Optimization of scan rate for melamine electropolymerization

Figure 4 illustrates the electropolymerization behavior of melamine in different scan rates. Scan rate determine the time taken to complete one polymerization cycle. In this study, the recorded voltammogram was not able to distinct any significant observation to relate the effect of scan rate on polymerization of melamine. Thus, these electrodes prepared at 10, 25, 50, 75, and 100 mV s^{-1} scan rates were analyzed using the amperometry technique to investigate the performance in DA sensing. Figure 5 displays the amperometry plot of PME whereas Figure 6 displays the calculated sensitivity and LOD based on the amperometry results obtained.

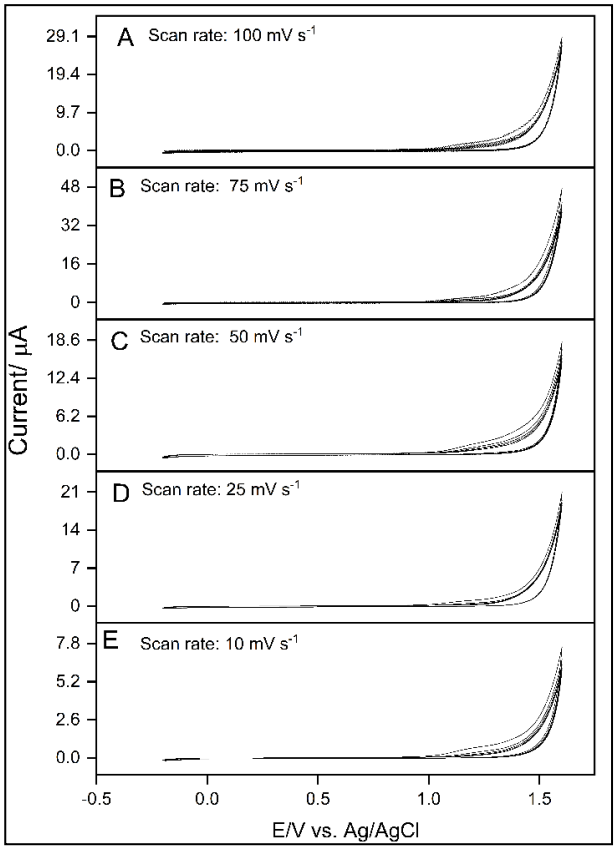

Figure 4. Electropolymerization of melamine (10.0 mM, -0.20- 1.60 V, five cycles) in reline scanning with varied scan rate (10, 25, 50, 75, and 100 mV s^{-1})

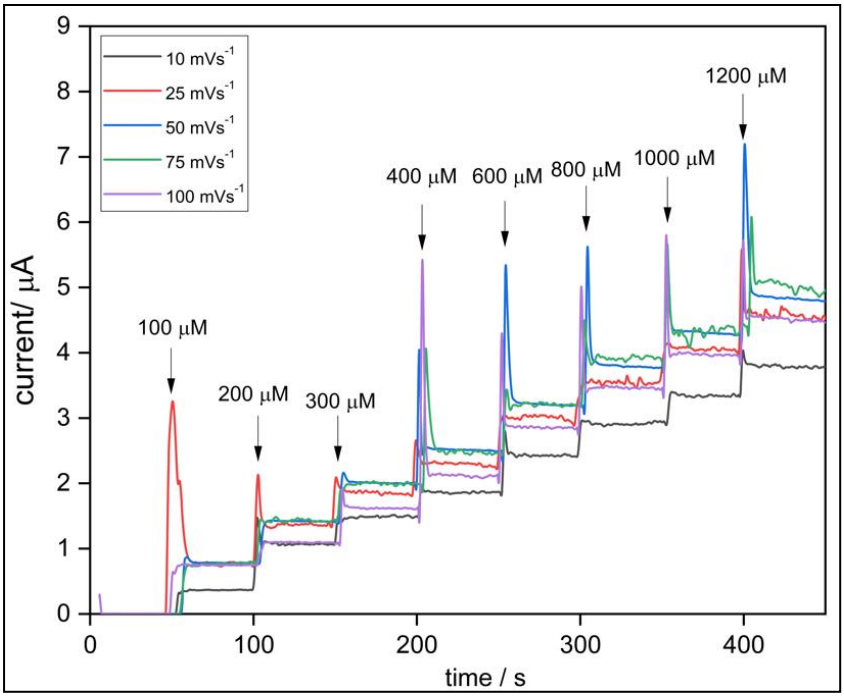

Figure 5. Amperometry results of PME synthesized in different scan rates. All the amperometry test were scanned at a fixed potential (0.20 V) with additional of DA with concentration ranging from 100 - 1200 μM in PBS (0.10 M, pH 7.0)

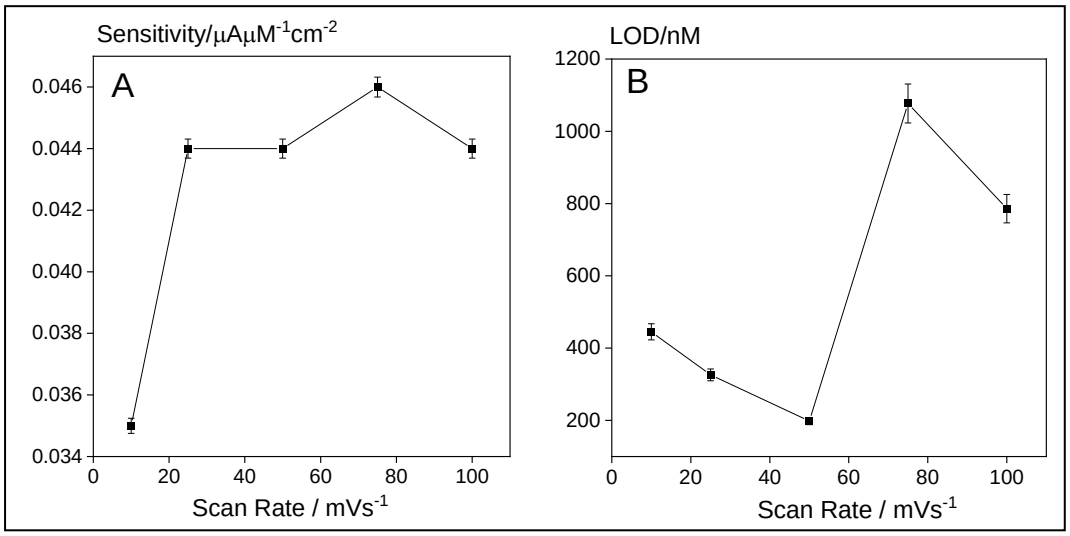

Figure 6. Graphs of (a) sensitivity and (b) LOD results versus varied scan rates applied for electropolymerization of melamine in reline

The result of amperometry sensing of DA at PME/GCE synthesized with varied scan rates are display in Figure 5. Based on Figure 5, the amperometry plots of PME(reline 75 mV s^{-1}) and PME(reline 50 mV s^{-1}) were very close to each other, unable to differentiate which scan rate gives the best outcome. Figure 6(a) and (b) show the fluttered of sensitivity and LOD of varied scan rates applied in electropolymerization of melamine (10.0 mM) in reline. The scan rate applied was varied from 10 to 100 mV s^{-1}. PME(reline) synthesized with 10 mV s^{-1} is named as PME(reline 10 mV s^{-1}) in accordance to the scan rate applied. As shown, the PME(reline 50 mV s^{-1}) was selected as the ideal scan rate where the sensitivity and LOD reported at 0.044 μA μM^{-1} cm^{-2} and 0.198 μM, respectively. In this case, PME(reline 75 mV s^{-1}) and PME(reline 25 mV s^{-1}) demonstrated the excellent sensitivity at 0.046 μA μM^{-1} cm^{-2} and 0.044 μA μM^{-1} cm^{-2}, respectively. However, both PME(reline 75 mV s^{-1}) and PME(reline 25 mV s^{-1}) showing much poorer sensing capability with LOD recorded at 1.077 μM and 0.326 μM, respectively as indicate in Table 1. It is noted that the change of polymerization scan rate affecting the LOD significantly. This is due to the low signal strength and high signal noise. Higher scan rate will result in branched polymer that have side chains growing out from the main chain. Branched polymer exhibits lower density and less packing where the analyte would be easily to move into the polymer cavity during the electrocatalytic activity, thus inducing flux of analyte molecules or ions at the electrode-electrolyte interface which result in a great fluctuation (noise) [17]. Whereas lower scan rate develops linear polymer which are very dense and compact, resulting there would be almost no channel for analyte to approach the electrode and hence reduced the signal strength and increased the LOD.

Optimization of scan cycles on melamine electropolymerization

Scan cycles influences the polymer film thickness and sensing characteristics. The optimum scan cycle was investigated using constant conditions *i.e.*, 10.0 mM melamine in reline electrolyte at room temperature with CV scanned from -0.20 V - 1.60 V. The growing of polymer film was indicated from the increase of the reduction current. Figure 7 illustrates the electropolymerization behavior of melamine in different scan cycle. Different scan cycles lead to different thickness of polymer on the surface of GCE. Unfortunately, the voltammogram could not show any significant result to relate the effect of scan cycle on polymerization behaviour of melamine as scan cycle are served to control the thickness the polymer film. Therefore, amperometry was employed to study the effect of polymer thickness on its sensing properties. Figure 8 shows the electrocatalytic performance of PME synthesized in different scan cycles. Scan cycles of five shows the steady increase of current with the increase of DA concentration, it also demonstrates the highest current response among all. Based on Figure 9(a) and (b), the optimum polymeric film can be obtained in five scan cycles, due to the sharp enhancement of sensitivity that has been recorded. When the scan cycles are increased to ten, it caused a minor decreased on LOD, further increasing of scan cycles to 15 attributed to a steeply decrease in sensitivity and raising of LOD. Such phenomenon was presumably due to excess polymer deposited on the GCE surface which blocking the electron transfer that needed for the DA oxidation process. As deduced from the higher charge transferred during polymerization, thin polymer films are usually superior in sensing studies due to better conductivity and easier in accessing analyte. Hence, five scan cycles were used for film formation.

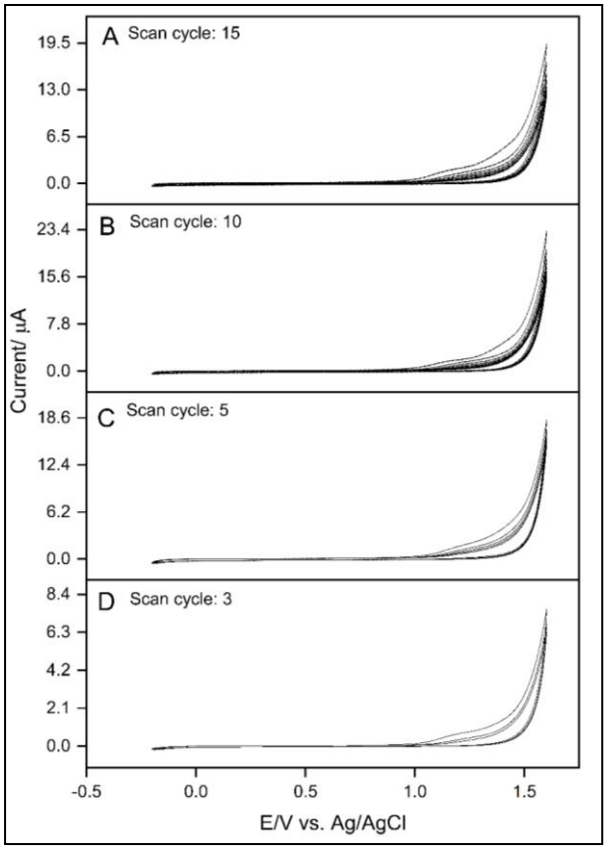

Figure 7. Electropolymerization of melamine (10.0 mM, -0.20- 1.60 V, 50 mV s^{-1}) in reline scanning with varied scan cycle (3, 5, 10 and 15)

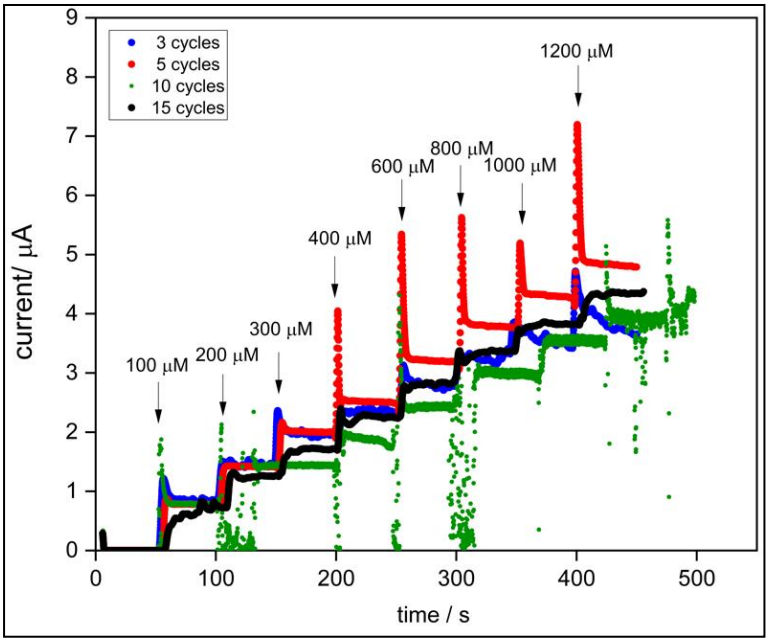

Figure 8. Amperometry results of PME synthesized in different scan cycles. All the amperometry test were scanned at a fixed potential (0.20 V) with additional of DA with concentration ranging from 100 - 1200 μM in PBS (0.10 M, pH 7.0)

Conclusion

Hereby reports the novel studies of optimization parameters for melamine electropolymerizes in DES, reline. Different parameters including potential window, scan rate, and number of scan cycles were manipulated in preparing PME in DES. Amperometry sensing on DA was conducted to compare the sensitivity and limit of detection for the PME prepared in different parameters. The optimum polymerization parameters for melamine were discovered as -0.20 V – 1.6 V, 50 mVs^{-1}, and five scan cycles, respectively. The effect of each parameter on the electrocatalytic behavior of PME has been clarified. With the successful optimization, PME(reline)/GCE with high sensitivity and low limit of detection recorded at 0.044 $\mu A\ \mu M^{-1}\ cm^{-2}$ and 0.198 μM has achieved. Proportionally, contemporary potential polymers can be construct by manipulating the parameters accordingly.

Abstract

One of the effective technologies in molecular recognition is based on the molecular imprinting process. In this work, the polymers were prepared by bulk polymerization, using methacrylic acid and ethylene glycol dimethacrylate as the functional monomer and crosslinking agent, respectively. The polymers were characterized by Fourier transform infrared spectroscopy, scanning electron microscopy and surface area and porosity analyses. Several parameters influencing the adsorption efficiency of Tryptophan (Tryp) such as adsorbent dosage, contact time, pH of sample solution as well as selectivity and reproducibility study, have been evaluated. The Tryptophan-imprinted polymer (Tryp-IP) showed significantly higher removal efficiency and selective binding capacity towards Tryp compared to non-imprinted polymer (NIP). The adsorption isotherm demonstrated that the Tryp-IP followed Langmuir isotherm model, indicating the Tryp-IP owning the homogenous surface type of adsorbent. In contrast, the NIP fit with the Redlich-Peterson model, indicating that mechanism adsorption is a mixed type. The kinetic study revealed that pseudo-second order was the appropriate kinetic model for Tryp-IP and the adsorption kinetic of NIP appeared to fit with pseudo-first order.

Keywords: molecularly imprinted polymer, tryptophan, adsorption study

Abstrak

Salah satu teknologi yang efektif dalam pengecaman molekul adalah berdasarkan proses pencetakan molekul. Dalam kajian ini, polimer telah disediakan melalui pempolimeran pukal, masing-masing menggunakan asid metakrilik dan etilena glikol dimetakrilat sebagai monomer berfungsi dan agen tautsilang. Polimer dicirikan oleh spektroskopi inframerah transformasi Fourier, pengimbasan mikroskop elektron dan analisis luas permukaan dan keliangan. Beberapa parameter yang mempengaruhi kecekapan penjerapan Triptofan (Tryp) seperti dos penjerap, masa sentuhan, pH larutan sampel serta kajian selektiviti dan kebolehulangan telah dinilai. Polimer tercetak-

Triptofan (Tryp-IP) menunjukkan kecekapan penyingkiran dan kapasiti pengikatan yang lebih tinggi terhadap Tryp berbanding polimer tidak dicetak (NIP). Isoterma penjerapan menunjukkan bahawa Tryp-IP mematuhi model isoterma Langmuir, ini menunjukkan Tryp-IP memiliki jenis penjerap permukaan homogen. Sebaliknya, NIP mematuhi model Redlich-Peterson, menunjukkan mekanisme penjerapan adalah jenis campuran. Kajian kinetik mendedahkan bahawa tertib pseudo-kedua adalah model kinetik yang sesuai untuk Tryp-IP dan kinetik penjerapan NIP kelihatan lebih sesuai dengan tertib pseudo-pertama.

Kata kunci: polimer tercetak molekul, triptofan, kajian penjerapan

Introduction

Tryptophan (Tryp) is one of the essential amino acids that is necessary for normal growth and it also acts as a precursor for several bioactive compounds such as nicotinamide (vitamin B6), serotonin, melatonin, tryptamine, kynurenine, and xanthurenic acids [1]. Tryp cannot be synthesized in the human body. However, it can be supplied via our dietary intake such as high protein food and fiber rich food like banana, soy, egg and rice. Even though the Tryp in the human body is relatively low, its potency is very significant. It is one of the amino acids capable of passing through the blood- brain barrier, which makes it very important for protein synthesis in our body [2]. Previous studies have shown that Tryp deficiency in the body can affect mood or cause depressive symptoms, whereas low serotonin levels contribute to increased anxiety and depression [3]. Since Tryp acts as a precursor for serotonin synthesis, the level of serotonin depends on the concentration of Tryp in the body [4]. From this point of view, it is crucial to determine the level of Tryp in the body to monitor this condition. At present, many technologies have been applied for the determination of Tryp, such as electrochemical sensors [5], high-performance liquid chromatography (HPLC) [6], solid-phase extraction-liquid chromatographic-tandem mass spectrometric (XLC-MS/MS) [7] and tandem mass spectrometer [8]. These techniques are very selective and precise; however, they often require pre-treatment steps, expensive and complicated instruments, skilled operators and a lot more time [9]. For these reasons, attention has been focused on the adsorption method due to its low cost and ease of operation. The latest development of adsorbent material for the determination and removal of Tryp/ Tryp derivatives such as polymeric resin [10], gold nanoparticles [11] and activated carbon [12], has shown outstanding results for the adsorptive capacity of Tryp.

In recent years, the low-cost adsorbent materials fabricated from molecular imprinting technology have attracted much attention due to the high selectivity and simple preparation method, which gives the technology a broad range of applications. Molecularly imprinted polymer (MIP) is an adsorbent from the imprinting technique with specific binding sites, shape and size towards the imprinted analyte called template. The molecular imprinting technique is a process that involves the polymerization reaction of functional monomers with the template molecule, thus allowing the formation of polymer networks to possess binding sites complementary with the template molecule [13]. MIP has several advantages which include low cost, ease of preparation, high stability and high selectivity and affinity. In addition, MIP is an insoluble substance with high durability under extreme pH conditions, organic solvents and high temperatures [14]. In general, many researchers favored the non-covalent approach due to the straightforward procedure, easy template removal as well as the fact that imprinted polymer can be used in various applications because most of the biomolecular interaction were non-covalent bond [15]. During pre-polymerization, functional monomers and template interaction are formed by self-assembly *via* non-covalent interactions, such as hydrogen bond, ionic interaction, hydrophobic interaction, and Van der Waals interaction [16]. Therefore, the present work highlights the application of MIP as a versatile material for selective determination of Tryp molecule. Tryptophan-imprinted polymer designated as Tryp-IP was prepared by bulk polymerization. Figure 1 shows a schematic for the formation of MIP for Tryp *via* the imprinting technique. The process involves methacrylic acid (MAA), ethylene glycol dimethacrylate (EGDMA) and azobisisobutyronitrile (AIBN) as the functional monomer, cross-linker and initiator, respectively. Once

the polymerization is complete, the removal of the template from the polymer matrix, leaves the cavities that are ideally complementary in terms of size, shape, and function to the template analyte. The corresponding non-imprinted polymer (NIP) was synthesized as a control sample.

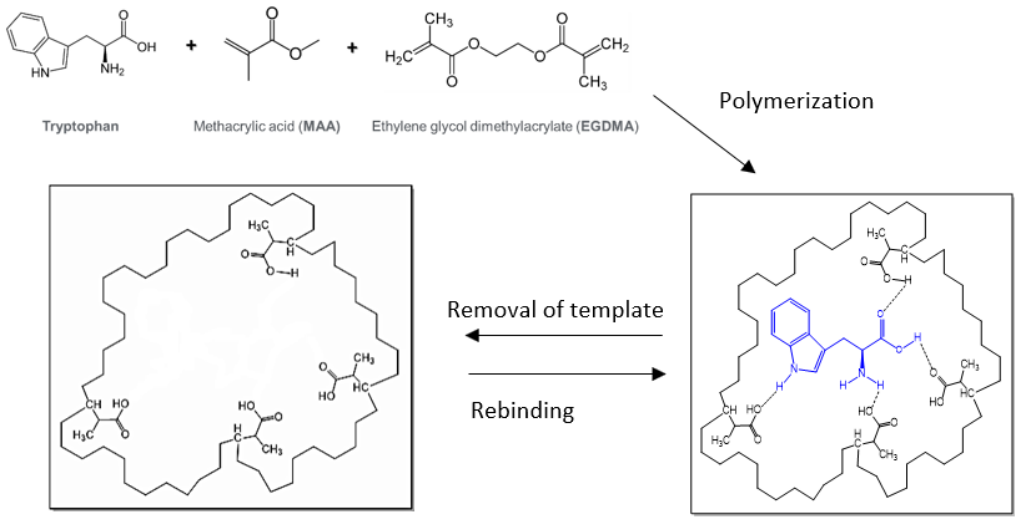

Figure 1. Schematic of the molecular imprinting process for Tryp

Materials and Methods

Materials

Tryptophan (Tryp), kynurenine (Kyn), tyrosine (Tyr), phenylalanine (Phe), methacrylic acid (MAA), ethylene glycol dimethacrylate (EGDMA), and azobisisobutyronitrile (AIBN) were purchased from Sigma Aldrich, Germany whereas methanol, acetic acid, sodium hydroxide (NaOH), hydrochloric acid (HCl) were supplied by R&M Chemicals, UK.

Preparation of Tryp-imprinted polymer

The preparation of Tryp-IP was carried out by the bulk polymerization method [17, 18]. Initially, Tryptophan (Tryp, 1 mmol) was dissolved in water/methanol (1:3 v/v). Then the functional monomer (MAA, 10 mmol), cross-linker (EGDMA, 30 mmol) and initiator; (AIBN) were added into the glass tube to allow the polymerization process to occur. Then, the mixture was stirred until homogeneous and purged with nitrogen gas before being placed in an oil bath at 60 °C for 48 hours. Upon completion of the polymerization reaction, the polymers obtained were crushed, ground, and sieved. The polymers were treated with methanol and acetic acid in a 9:1 v/v ratio by Soxhlet extraction to remove the template molecules. The obtained polymers were stored at room temperature for further characterization. Finally, the non-imprinted polymer (NIP) as a control sample was prepared using the same method but in the absence of the template.

Characterization of the polymers

The polymers were characterized by attenuated total reflection-Fourier transform infrared spectroscopy (ATR-FTIR). The spectra were recorded from 500 cm^{-1} to 4000 cm^{-1}. Then, the surface morphology of polymers was observed by Scanning Electron Microscopy (SEM). Each polymer was mounted on the stubs and coated with gold for protection from the electron beam. Next, the determination of the specific surface area, pore volume and pore diameter were performed by porosity analyzer using Bruner-Emmett-Teller (BET) and Barrett-Joyner-Halenda (BJH) technique.

Adsorption studies

The adsorption studies were conducted by batch rebinding experiment, which was performed in an aqueous medium [19]. First, 1 ppm of Tryp solution was prepared and mixed with a different mass of Tryp-IP (1, 3, 5, 7, 9 mg) while maintaining other parameters at optimal conditions. After the adsorption process, the Tryp solution was analyzed using a UV-Vis spectrometer to determine the remaining Tryp molecule by observing its final concentration. Then, the percentage removal and adsorption capacity of Tryp-IP towards Tryp was calculated using equations (1) and (2), respectively [20]:

$$\% \text{ removal} = \frac{C_i - C_f}{C_i} \times 100 \quad (1)$$

$$Q_e = \frac{(C_i - C_f)V}{W} \quad (2)$$

In the equations above, C_i and C_f are initial and final concentrations (mg/L) of Tryp solutions, respectively, Q_e (mg/g) is the quantity of total adsorption of Tryp molecules, V (L) is the volume of the solution and W (g) is the weight of polymers.

The interaction and adsorption mechanism of Tryp-IP and Tryp were further studied by fitting equilibrium data into the isotherm models. The adsorption equilibrium data obtained were fitted into Langmuir, Freundlich and Redlich-Peterson isotherm models. Langmuir isotherm is often associated with adsorption on the surface of homogeneous sites within the adsorbent and occurs in a monolayer pattern. Nevertheless, Freundlich isotherms apply to adsorption processes that occur on heterogeneous surfaces. Redlich-Peterson isotherm is a three-parameter isotherm which combines Langmuir and Freundlich isotherms. The Langmuir, Freundlich and Redlich-Peterson equation can be written in the following linear form as stated in equations (3), (4) and (5), respectively [21].

$$\frac{C_e}{Q_e} = \frac{1}{BQ_o} + \frac{C_e}{B} \quad (3)$$

$$\ln Q_e = \ln K_F + \frac{1}{n} \ln C_e \quad (4)$$

$$\ln \frac{C_e}{Q_e} = \beta \ln C_e - \ln A \quad (5)$$

In equations (3), (4) and (5), Q_e is the equilibrium adsorption capacity (mg/g), C_e is the equilibrium concentration of adsorbents at equilibrium (mg/L), and Q_o is the maximum adsorption capacity of the adsorbents (mg/g). B (L/mg) is the Langmuir adsorption constant, while K_F (mg/g) is the Freundlich adsorption equilibrium constants indicating the sorption capacity and 1/n represents the intensity of the adsorption. Meanwhile, A (Lg^{-1}) is Redlich-Peterson isotherm constant and β is the exponent that lies between 0 and 1. The favorability of the Langmuir isotherm was expressed by a dimensionless constant called the separation factor (RL), as shown in equation (6).

$$RL = \frac{1}{1 + B(C_e)} \quad (6)$$

where RL values indicate the adsorption to be unfavorable when RL > 1, linear when RL = 1, favorable when 0 < RL< 1, and irreversible when RL = 0 [21].

Adsorption kinetic study

Adsorption kinetics was studied to determine the kinetic behavior and rate-controlling step for the adsorption process of Tryp-IP. The experiments were conducted using 1 ppm of Tryp solution mixed with 9 mg of Tryp-IP. The kinetics of Tryp uptake by Tryp-IP were analyzed using a UV-Vis spectrometer. The time was set at 0 to 180 min. Two adsorption kinetic models, namely pseudo-first-order and pseudo-second-order, were tested and fitted into the adsorption kinetic data. The pseudo-first and pseudo-second order equations can be expressed in equations (7) and (8), respectively,

$$\ln(q_e - q_t) = \ln q_e - k_1 t \quad (7)$$

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad (8)$$

where q_t and q_e (mg/g) represent adsorption capacities at time and equilibrium, respectively, while k_1 and k_2 represent rate constants at equilibrium [22]. Furthermore, the favorability of kinetic models was calculated by standard deviation formula, Δq (%) and relative error, RE (%) as in the following equations:

$$\Delta q(\%) = \sqrt{\frac{[(Q_{e,exp} - q_{e,cal})/Q_{e,exp}]^2}{N-1}} \times 100 \quad (9)$$

$$RE\ (\%) = \frac{|q_{e,cal} - Q_{e,exp}|}{Q_{e,exp}} \times 100 \quad (10)$$

where N is the amount of data points fitted to the plot, $Q_{e,exp}$ and $q_{e,cal}$ (mg/g) are the experimental and calculated adsorption capacities, respectively. A lower Δq (%) gives the desired fitness of polymer to the kinetic model [20].

Effect of pH study

1 ppm of Tryptophan solution was prepared, and the pH was adjusted in the range of 4, 5, 7, 9, 11 and 13, by adding diluted HCl and NaOH. The experiment was carried out by mixing each solution with 9 mg of Tryp-IP. An independent analyte solution was analyzed and the optimum pH for optimum adsorption was determined.

3

Effect of selectivity study

In the selectivity study, the molecular structural analogues of Tryptophan; kynurenine, tyrosine and phenylalanine were tested for the binding performance with Tryp-IP. Firstly, 1 ppm of analyte concentrations were prepared separately and mixed with 9 mg of Tryp-IP. Then, the solutions were analyzed using UV-Vis spectrometer. The distribution coefficient (kd) was calculated based on the equation 11.

$$k_d = \frac{(C_i - C_f)}{C_f}\left(\frac{V}{W}\right) \quad (11)$$

where k_d is the concentration ratio between two solutions, C_i and C_f are initial and final concentrations of each compound, respectively. V (L) is the volume of the solution and W (g) is the weight of polymers [23]. The adsorption capacity of the polymer increases as the value of k_d increases. Selectivity coefficient (k), which indicates the selectivity of Tryp over the competitive compounds was calculated based on the equation 12 below:

$$k = \frac{k_d(\text{Tryp})}{k_d(\text{Kyn/Tyr/Phe})} \quad (12)$$

Relative selectivity coefficient (k') was determined by comparing the ratio of Tryp-IP and NIP as equation 13 below:

$$k' = \frac{k\,(\text{Tryp-IP})}{k\,(\text{NIP})} \quad (13)$$

Reproducibility study

A reproducibility study was explored to evaluate the practical application of the prepared adsorbent. Firstly, 1 ppm of Tryp solution was mixed with nine sets of Tryp-IP (9 mg) at the optimal time taken. Then, each solution was evaluated by UV- Vis spectrometer and its adsorption capacity were calculated.

Results and Discussion

FTIR characterization

Figure 2 shows the FTIR spectra of Tryp, Tryp-IP before and after template removal and the NIP. From the Tryp spectrum in Figure 2(a), a peak at 3400 cm^{-1} and 3012 cm^{-1} were observed, indicating a peak for NH stretching from the indole group and alkene C-H stretching, respectively. The IR peaks obtained at 1654 cm^{-1} and 1575cm^{-1} show the COO- and NH asymmetric stretching vibrations, respectively [9]. Due to the high cross-linking agent, all polymers show similar vibration peaks with almost the same IR spectrum. Based on Figure 2(b), the IR broad peaks obtained around 3471 cm^{-1} – 3275 cm^{-1} show a strong interaction between the NH group of Tryp and the O-H group of the MAA monomer through hydrogen bonding [24]. The aromatic stretching of C-H appeared at 2985 cm^{-1} at a lower intensity indicating the presence of Tryp in the polymer. After removal of Tryp Figure 2(c), the IR spectrum showed the complete disappearance of Tryp characteristic. The intensity of C=O from MAA at 1724 cm^{-1} increased. In comparison with Figure 2(b), the C=O absorption peak shifted from 1716 cm^{-1} to 1724 cm^{-1}, indicating the rupture of the hydrogen bond. In Figure 2(d), the IR spectrum for NIP is expected to be similar to Tryp-IP after the template is removed, where the C-H stretching vibration of MAA appeared at 2985 cm^{-1}. The schematic from Figure 1 is used to confirm all the functional groups present in the polymers for the FTIR spectra.

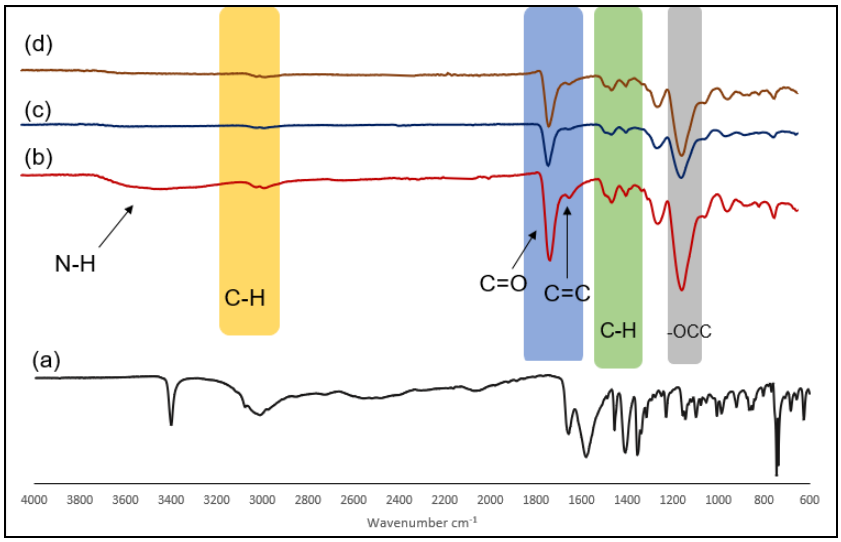

Figure 2. FTIR spectrum of (a) Tryp, (b) Tryp-IP before and (c) Tryp-IP after removal of the template and (d) NIP

SEM analysis

Figures 3(a) and 3(b) show the SEM micrographs for Tryp-IP and NIP, respectively. Bulky particles with the size in the range of a few microns is observed. This morphological feature is typical for polymers synthesized by the bulk polymerization approach. Furthermore, agglomeration is observed in Tryp-IP and NIP, and this is expected due to the high molar ratio of monomer to cross-linker (10:30) used in this study [24, 25]. Based on previous studies, bulk polymerization using the optimum molar ratio (4:20) can give a morphological image in heterogeneous irregular shapes and sizes due to crashing, grinding, and sieving processes [26]. Besides, the molar ratio of the cross-linker played a significant role in controlling the morphology of the polymer where it can form a rigid surface of the primary particles, which makes it difficult to agglomerate [27]. As in a previous study reported in the literature, the polymer morphology changes when the cross-linker ratio exceeds the optimum level within the polymer structure, resulting in the hard segment and a reduction in the polymer matrix binding sites [24].

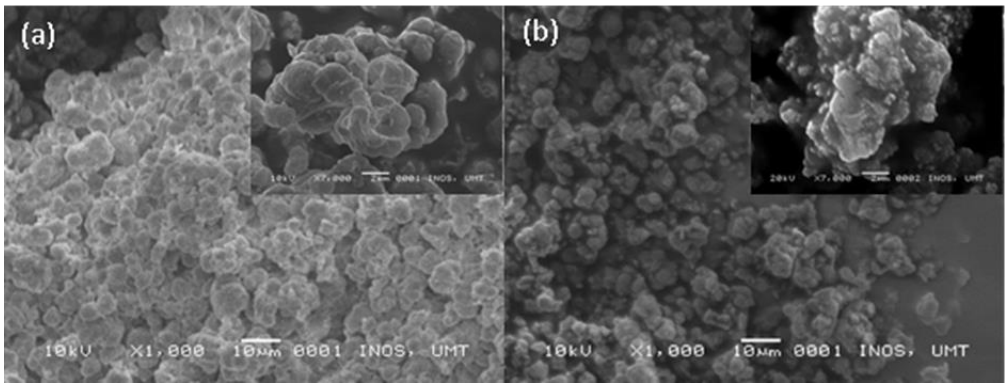

Figure 3. SEM micrograph of (a) Tryp-IP and (b) NIP

BET surface area analysis and porosity

BET analysis was carried out to determine the specific surface area and porosity properties of the Tryp-IP and NIP. Table 1 shows the results of surface area, pore volume and pore diameter of the polymers. The average pore diameters of Tryp-IP and NIP were in the range of 2–50 nm, indicating that both polymers have a mesoporous structure [20, 28]. However, Tryp-IP has larger a surface area and slightly larger total pore volume than the NIP. The increased surface area in Tryp-IP reflects the effect of the imprinting process, which occurred when the presence of the Tryp as a template during MIP synthesis resulted in the formation of pores or imprinted cavities [29, 30]. Based on previous studies, high molar ratios of monomers to the cross-linker resulted in non-specific interactions, while low ratios lead to inadequate functional sites [31]. Consequently, the agglomeration of the polymers particle resulted in the reduction of surface area and the number of active sites of polymers.

Table 1. BET surface area, pore volume and pore diameter

Polymer	Surface area ($m^2 g^{-1}$)	Pore volume ($cm^3 g^{-1}$)	Pore diameter (nm)
Tryp-IP	6.4519	0.022482	13.94
NIP	4.0351	0.016078	15.94

Adsorption isotherm study

The effect of the mass polymer was investigated to get the optimum mass for Tryp-IP. Based on Figure 4, it was observed that the percentage removal of Tryp increased with the increase of polymer mass. The maximum percentage removal achievable by Tryp-IP and NIP were 82% and 70%, respectively. An increase in polymer mass appears to increase the number of active sites and surface area for Tryp adsorption [32, 33]. Due to the absence of a template during the NIP synthesis, the non-specific cavities are formed, thus lower percentage removal of NIP than Tryp-IP. Based on Figure 4, the percentage removal increased until it reached the optimum level at 5 mg, indicating that all cavities were filled with Tryp molecules. However, a previous study agreed that a further increase in polymer mass could lead to adsorbent aggregation resulting in a decrease in the adsorption sites [34]. Hence, an increase in polymer mass does not increase the adsorption of Tryp.

Figure 5 is the isotherm models used in this study to fit the experimental data to predict the adsorption mechanism. Based on the isotherm parameter in Figures 5(a) and 5(b), the adsorption mechanism for Tryp-IP followed the Langmuir isotherm model and NIP followed the Redlich-Peterson isotherm which gave the highest R^2 value. The Langmuir isotherm was described as monolayer adsorption of Tryp onto Tryp-IP. The possible way for monolayer adsorption is for the adsorption to take place on the homogenous surface of the polymer matrix [35]. The similar observation was reported by the adsorption of D-Tryp onto polymer matrix [36]. To further strengthen the important features of the Langmuir isotherm model, the dimensionless constant separation factor (RL) was calculated [37]. RL values were found in the range of 0.017-0.009, which confirms adsorption of Tryp onto Tryp-IP was good. For the NIP, the data was fitted to the Redlich-Peterson model which, incorporates the features of both Langmuir and Freundlich isotherm. This can be applied as a homogeneous and heterogeneous system due to its versatility [38]. The parameters calculated for the three isotherms are tabulated in Table 2. From the data obtained, the maximum adsorption capacity for Tryp onto Tryp-IP was found to be 0.98 mg/g, which was seven times lower than the NIP (7.325 mg/g). The similar finding was reported by Hasanah et.al, which might be due to the non-specific recognition sites in NIP and therefore, made it swells better in polar solvent [39].

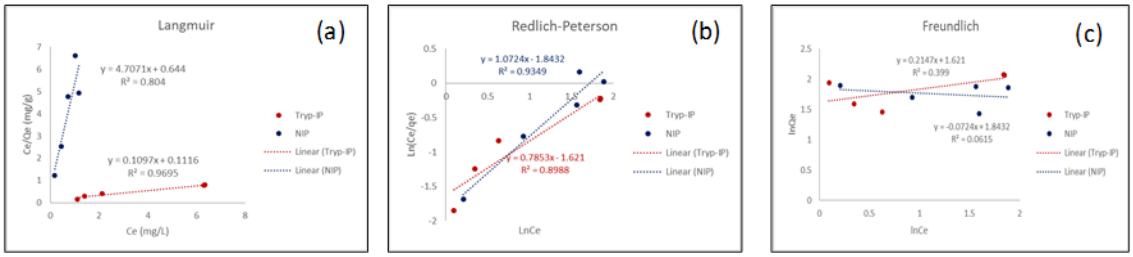

Figure 5. Adsorption isotherms of Tryp-IP and NIP using models (a) Langmuir (b) Redlich-Peterson (c) Freundlich

Table 2. Isotherm parameter for adsorption of Tryp by Tryp-IP and NIP

Polymer	Langmuir			Redlich-Peterson			Freundlich		
	Q_o	B	R^2	ß	A	R^2	1/n	K_F	R^2
Tryp-IP	0.98	9.116	0.9695	0.7853	5.058	0.8988	0.2147	5.058	0.399
NIP	7.325	0.212	0.804	1.0724	6.3167	0.9349	-0.0724	6.3167	0.0615

Adsorption kinetic study

The effect of contact time on the binding capacity of polymers is important to evaluate the binding efficiency in adsorption studies. It has been observed that the adsorption of Tryp onto the polymer surface increases with prolonging the contact time up to achieve equilibrium [40]. In Figure 6, initially, the adsorption rate of Tryp onto the polymeric surface was accelerating due to the abundant number of empty adsorption sites that can be accessed and less mass transfer resistance which allowed the active sites to capture the target analyte. However, with the progress of time, the number of active sites decreases, the imprinted cavities are gradually filled

with Tryp and the mass transfer resistance of Tryp to the active sites increases. Thus, the adsorption rate decreases and the removal percentage decreases slowly [41]. Finally, the adsorption equilibrium was reached within 120 min for Tryp-IP and 150 min for NIP. There is no change in the percentage removal if the time is prolonged because the polymer binding sites have been occupied with the Tryp. Therefore, it could be observed that Tryp-IP exhibited slightly higher percentage removal and faster mass transfer than the NIP, which could be attributed to the imprinting effect of Tryp [35, 42].

The adsorption mechanism was further evaluated by two of the most widely used kinetic models which is pseudo-first order kinetics, and pseudo-second order kinetic models. The results shown in Table 3 indicates that the R^2 value of Tryp-IP is most fitted with pseudo-second order (R^2 =0.9698) whereas the R^2 value for pseudo-first order is 0.2195. In the pseudo-second-order model, the theoretical and experimental adsorption capacity values were in good agreement. Therefore, the pseudo-second-order adsorption mechanism is predominant and the rate-limiting step at the surface involving a chemisorption process between Tryp and cavities of Tryp-IP [38].

Moreover, the values of Δq and RE were found to be low compared to pseudo-first order which means the accuracy and validity of the kinetic model were better equipped with pseudo second order. However, NIP appeared to be more suitable with pseudo-first order with the highest R^2 value (0.9107). It was expected that the rate of adsorption is proportional to the number of unused sites and the rate-limiting step was physisorption [39]. As in the case of Tryp-IP where Δq and RE values of NIP were exceedingly low for pseudo-first-order compared to pseudo-second order, these values indicate the accuracy of this kinetic model. Furthermore, the adsorption capacity Q_e (Table 3) for Tryp-IP (10.0336) was lower than NIP (11.3958). This result is due to the absence of specific recognition sites in the NIP, thus leading to the physical adsorption and random interaction of the Tryp molecule with the functional group of MAA in the polymer chain [43].

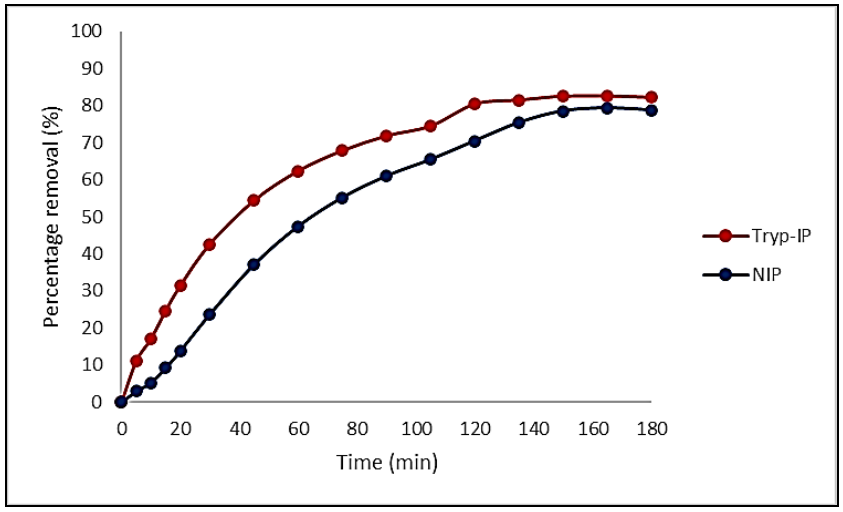

Figure 6. Effect of contact time on adsorption Tryp by Tryp-IP and NIP

Table 3. Kinetic parameter for adsorption of Tryp by Tryp-IP and NIP

Polymer	Model	Kinetic Parameters					
		y = mx + c	Q_e (mg/g)	Q_e (mg/g)	Δq (%)	RE (%)	R^2
Tryp-IP	Pseudo-first-order	y= -0.0223x +1.909	10.0336	6.746	8.464	32.78	0.2196
	Pseudo-second-order	y= 8.0813x +2.902		12.3001	5.826	22.56	0.9698
NIP	Pseudo-first-order	y= -0.017x +2.478	11.3958	11.9174	1.18	4.58	0.9107
	Pseudo-second-order	y= 0.0353x +7.9307		28.3286	38.37	149	0.3772

Effect pH study

The pH of the adsorption medium is the most critical parameter influencing the adsorption capacity [29]. In this analysis, a pH of 4-13 has been selected. Figure 7 shows that the highest percentage removal was obtained when the pH is in acidic condition and the percentage removal decreases as the pH increases (base condition). This condition might be due to the interaction of hydrogen bonding between the surface of the carboxylic group of MAA and the functional group of Tryp. As shown in Figure 7, the highest percentage removal of Tryp appeared when the pH became acidic. This observation occurred as a result of the zwitterionic Tryp and the large electronegativity of the oxygen atom of the carbonyl group in the polymers [43]. However, when the pH value becomes basic, Tryp exists as an anion and diffuses very slowly into the polymer surface [44]. Therefore, pH 5 was chosen as the optimal pH throughout this study.

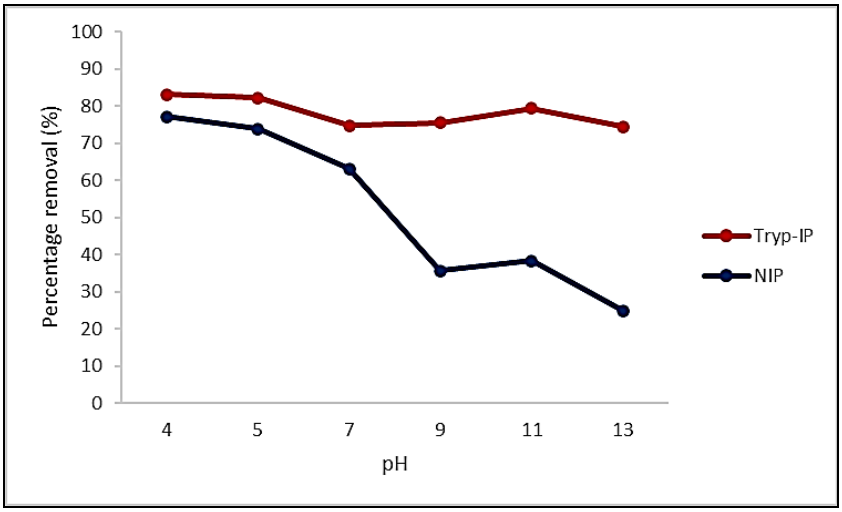

Figure 7. Effect of pH on adsorption Tryp by Tryp-IP and NIP

Effect of selectivity study

To study the selectivity of Tryp-IP and NIP, the recognition of Tryp was compared with tyrosine, phenylalanine and kynurenine as potential interferences. Table 4 shows the k_d values of each molecule in the Tryp-IP and the NIP. According to the Table 4, Tryp has higher k_d values compared to the other molecules in the Tryp-IP, which means that high specific recognition ability for Tryp is associated with a unique complementary form of the binding sites [42]. In contrast with the NIP, tyrosine gave a higher k_d value compared to Tryp. This is due to the non-specific

cavities existing in the NIP. Furthermore, the k values indicate that the polymer has selective behavior for the template in the presence of other molecules. The larger the k values, the higher the selectivity of the polymer towards the template compared to the other molecule [23]. For the Tryp-IP, the k values are higher than for the NIP, which means that Tryp-IP has selective behavior for Tryp as calculated in Equation 12. In order to show the efficiency of Tryp-IP for selective separation of Tryp against NIP, the k' values were calculated according to Equation 13. The larger the k' values the more selective is the Tryp-IP against NIP for the template toward the other molecules [41]. It can be concluded that the Try-IP has greater molecular recognition towards its template molecule.

Table 4. Selectivity study constant for Tryp-IP and NIP

	Tryp-IP		**NIP**		**k'**
	k_d	K	k_d	k	
Tryptophan	1.5751	-	1.2175	-	-
Kynurenine	0.7495	2.1015	0.8407	1.4482	1.451112
Tyrosine	0.5309	3.958	1.3346	0.9123	4.338485
Phenylalanine	0.8392	4.7168	0.7567	1.609	2.93151

Effect of the reproducibility study

The reproducibility performance of the Tryp-IP was evaluated by comparing the adsorption capacity for each adsorption process of Tryp-IP. The result in Figure 8 revealed that the percentage removal of Tryp did not show a significant change (80% to 83%) for each repeated usage. The Tryp-IP can be used at least nine times while maintaining its percentage removal of more than 80%, reflecting the excellent precision and reproducibility of the proposed polymer. Therefore, Tryp-IP showed good stability and could maintain its adsorption capacity at a constant value.

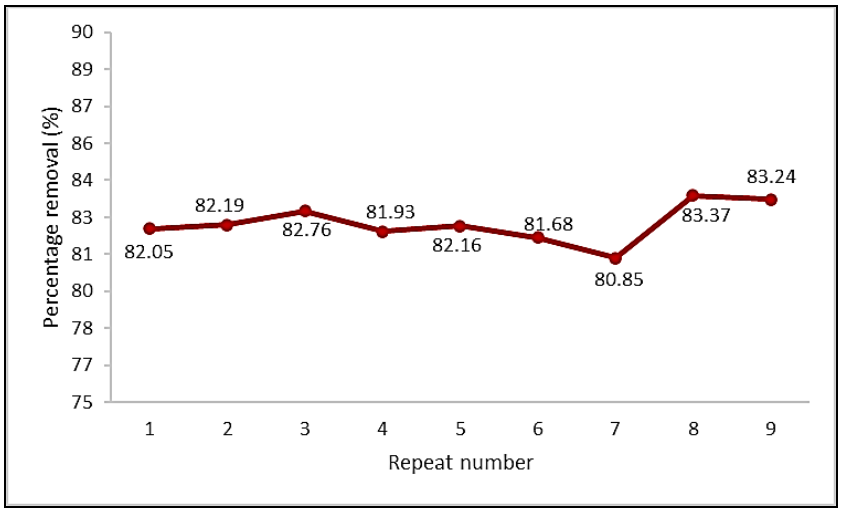

Figure 8. Effect of reproducibility of Tryp-IP

Conclusion

In this study, Tryp-IP and NIP were successfully synthesized through bulk polymerization and used as an adsorbent for tryptophan detection. FTIR, SEM, and BET were used to analyze the physical and chemical characterizations, which revealed evidence of chemical interaction, surface morphology, and cavities of the polymer matrix; all of which are responsible for the binding ability of the polymer. Hence, the adsorption studies have revealed that Tryp-IP has a greater removal percentage, selectivity, and stability than the NIP.

Abstract

Acne is a common skin disorder usually treated using antibiotics and drugs. However, until today, dermatologists struggle to treat acne resistance towards topical treatment over a long period. One of the solutions is using natural bioactive compounds from plant extracts. In this work, *Swietenia macrophylla* seeds oil, rich in active compounds, was used to inhibit acne-causing bacteria, i.e., *Propionibacterium acnes*, *Staphylococcus aureus*, and *Staphylococcus epidermidis*. The seed powder sample was extracted using the Soxhlet extraction method in three different solvents for six hours and ten cycles. The seed extracts were analysed using a gas chromatography-mass spectrophotometer (GC-MS), and a disc diffusion assay was performed to analyse the antibacterial activities. The heavy metal analysis was determined by inductively coupled plasma atomic emission spectroscopy (ICP-OES). The results show that bioactive compound yields are 37-72%. Eugenol and isoeugenol compounds are the main constituents in the oil extracts with 98% and 97% quality. The compounds also demonstrated inhibitory activities towards all tested bacteria, with inhibition zones between 11 and 22 mm on 30 µg tetracycline discs. These compounds without isolation work also showed inhibitory activity against all bacteria tested with inhibition zones ranging from 11 to 21 mm.

Abstrak

Jerawat adalah penyakit kulit biasa dan selalunya dirawat menggunakan antibiotik dan ubat-ubatan. Namun, sehingga hari ini, pakar dermatologi masih belum dapat merawat ketahanan jerawat terhadap rawatan permukaan dalam jangka masa panjang. Salah satu penyelesaiannya adalah menggunakan sebatian bioaktif semula jadi dari ekstrak tumbuhan. Dalam kajian ini, minyak biji *Swietenia macrophylla* yang kaya dengan sebatian aktif, digunakan untuk merencat bakteria penyebab jerawat iaitu *Propionibacterium acnes*, *Staphylococcus aureus*, dan *Staphylococcus epidermidis*. Sampel serbuk biji diekstrak menggunakan kaedah pengekstrakan Soxhlet dalam tiga jenis pelarut berbeza selama enam jam dan sepuluh kitaran. Analisis hasil ekstrak dijalankan menggunakan kromatografi gas-spektrofotometer jisim (GC-MS) dan asai cakera resapan dilakukan untuk menganalisis aktiviti antibakteria. Analisis logam berat pula ditentukan melalui spektrometri pancaran optikal-plasma gandingan

aruhan (ICP-OES). Hasil kajian menunjukkan bahawa hasil sebatian bioaktif ialah 37-72%. Sebatian eugenol dan isoeugenol merupakan sebatian utama dalam sampel ekstrak minyak dengan kualiti 98% dan 97%. Sebatian tanpa kerja pengasingan ini juga menunjukkan aktiviti perencatan terhadap semua bakteria yang diuji dengan zon perencatan berjulat antara 11 hingga 21 mm.

Introduction

IntroductionAcne is a specific skin disease in dermatology. The skin problem occurs in pre-pubertal individuals, teenagers, and adults. It usually occurs in 14 to 17 years old girls and 16 to 19 years old boys. Those affected would experience distressing self-esteem and social relationships due to the inflammatory lesions and scarring effects [1]. Several factors that trigger acne include genetics, gender, youth, stress, and smoking habit [2]. The proliferation of bacteria such as *Propionibacterium acnes* in clogged pores causes the problem to worsen, especially when the body releases enzymes to break down the sebum, causing inflamed pores [3]. The main goal of acne treatment is to control the existing acne lesions, prevent permanent scarring, and reduce the disorder. According to Vora et al. [4], acne may be treated by topical and systemic therapies, such as antibiotics, comedolytic agents, and anti-inflammatory drugs such as clindamycin, salicylic acid, and isotretinoin.

The use of natural products or non-drug treatments is preferable and acceptable due to organic awareness of remedial solutions. Moreover, natural products, especially skincare, are safer than synthetic products [5]. Even though various herbal products such as orange peel, neem, jojoba oil, and turmeric are used for acne treatment, the research on natural medication continues due to the tolerance resistance of *P. acnes* towards the commercially available antibiotics [6-7]. *Swietenia macrophylla* is a common plant species that grows wildly in Malaysia. It is known as the “sky fruit” or tunjuk langit, as the fruits seem to point upwards to the sky (Figure 1). *Swietenia macrophylla* is abundant in more than 40 countries, including Brazil, Bolivia, Mexico, Guatemala, Peru, and other central American countries [8]. In Malaysia, the locals usually consume the *S. macrophylla* seeds to treat high blood pressure, diabetes, increase blood circulation, and relieve body pain [9]. The *S. macrophylla* seeds are also widely used in healthcare and skincare products [10]. Due to the numerous pharmacological activities of *S. macrophylla* extract, *including* antimicrobial, anti-inflammatory, antioxidant, antidiabetic, antifungal, and antimalaria [11], the *S. macrophylla* extract is suitable to be explored and utilised in an acne treatment regime.

Figure 1. Photo image of *Swietenia macrophylla tree* and seeds (insert)

Hence, this study explored the properties of seed extract as the novel ingredient for acne treatment. The Soxhlet extraction method was performed to investigate the extraction yield in three different extraction solvent systems (methanol, ethyl acetate, and methanol: ethyl acetate mixture). The bioactivities of the extracts were analysed using a gas chromatography-mass spectrophotometer (GC-MS), and the heavy metals elements were determined using the inductive coupled plasma optical emission spectrometry (ICP-OES). A biochemical test and the disc diffusion assay method were conducted to determine the antibacterial activity against *P. acnes, Staphylococcus aureus, and Staphylococcus epidermidis*.

Materials and Methods

Material and reagents

Tetracycline (30 µg) was purchased from Sigma Chemicals (St. Louis, MO, USA), Mueller Hinton agar (MHA), Mueller Hinton broth, nutrient agar (NA) and nutrient broth used for the determination of antibacterial activity were purchased from Merck (M) Sdn. Bhd. and Thermo Fisher Scientific (M) Sdn. Bhd. All chemicals and solvents used in the experiment were analytical grades with above 98% purity. The reagents were supplied by the Chemistry Laboratory 2 and 4, UiTM Perlis Branch. The methanol, ethyl acetate, and 1:1 ratio of methanol: ethyl acetate mixtures were prepared and used to extract the *S. macrophylla* seeds sample. *P. acnes*, *S. aureus*, and *S. epidermidis* were obtained from the Biology Laboratory, UiTM Perlis Branch.

Preparation of *Swietenia macrophylla* samples extract

The *S. macrophylla* seeds were collected from the trees in Jitra, Kedah. The seeds were washed with tap water to remove dust and other inert materials. The cleaned samples were air-dried for two days. Then, the samples were ground into powder using an electrical blender. About 5.0 g of powdered seed sample was mixed with 150 mL of extraction solvent (methanol, ethyl acetate, and methanol-ethyl acetate mixture) and extracted using the Soxhlet apparatus for 6 h. The filtrate was then concentrated using a rotary evaporator to remove the solvent, and the yield percentage was expressed in w/w% and stored in a vacuum desiccator for further analysis. The yield percentage was calculated using the following equation:

$$\% \text{ yield} = [M_1 - M_o] \times 100 \quad (1)$$

where M_1 = mass of sample (g) and M_o = mass of the extract (g)

The chemical properties of SME

The chemical properties of SME were analysed using a GC-MS (Model Agilent 6890 equipped with 5MS, 30 m × 0.25 mm i.d. capillary column coated with 0.25 µm film and coupled with Agilent Chemstation software of NIST/Wiley Library). A volume of 0.1 mL samples extracts was derivatised with 100 µL N, O-Bis(trimethylsilyl)trifluoroacetamide (BSTFA) for 30 min in a sealed 2 mL vial. Then 0.1 µL of derivatised samples were analysed by the GC-MS, and the data was recorded, according to Hashim et al. [11].

The elemental analysis was determined using the ICP-OES (Model Thermo Scientific ICAP6000 Series). The multi-element of the standard solution was prepared from a 10-ppm stock solution in different concentrations at 0.01 ppm, 0.1 ppm, 1.0 ppm, and 10 ppm. Approximately 0.5 g of sample was digested with 8 mL of 65% nitric acid and 2 mL of concentrated hydrogen peroxide in microwave digestion. The sample was treated in the microwave digester for 15 min at 180 °C of 500 W. The treated sample mixture was cooled and diluted to 10 times concentration with distilled water prior to ICP-OES analysis.

The antibacterial analysis

The MHA and NA media were prepared according to the manufacturer's instructions. Approximately 38.0 and 28.0 g of the MHA and NA powders were weighed to prepare 1000 mL agar and poured into conical flasks. The powder was dissolved in distilled water and continuously stirred until homogenised. The agar solution was sterilised using an automatic autoclave at 121 °C for 15 min. The agar was cooled to 45 to 50 °C before being poured into sterile Petri dishes. These agars were stored upside down in a chiller of 4 to 8 °C before being used.

The bacteria were subcultured by the streaking method. The inoculation loop was sterilised and cooled for a few seconds before dipping into the bacterial solution and streaked in a zigzag motion on the agar. This method was repeated three times for each bacterium. The inoculating loop was sterilised each time before subculturing the bacteria. The agar plates of *S. aureus* and *S. epidermidis* were incubated at 37 °C for 18 to 24 h in an inverted position [12].

The *P. acnes* was subcultured using a different method since it is a facultative anaerobic. It grows best under limited oxygen (0-20%), and the growth rate was reduced at high oxygen concentration [14]. The cultured plate was incubated under anaerobic

conditions [13], i.e., inside a candle jar to provide a suitable condition for the *P. acnes* to grow at 37 °C for 72 h [15]. The biochemical tests involved were the catalase, the methyl red/Voges-Proskauer (MR-VP), and Gram staining to identify the desired bacterial interaction activities.

The catalase test was performed according to Habib et al. [16], whereby *S. aureus* and *S. epidermidis* were streaked onto MHA, and *P. acnes* was streaked onto NA to obtain bacterial colonies. The plates were incubated for 24 h and 72 h, respectively. Each bacterial colony was mixed with 2 to 3 drops of 3% hydrogen peroxide, where the formation of bubbles indicated positive results.

The methyl red (MR) and Voges-Proskauer (VP) test utilised the MR-VP broth. The MR-VP broth was prepared according to the manufacturer's recommendation. About 17g of broth powder was weighed to prepare 1000 mL MR-VP broth and sterilised at 121 °C for 15 min. The MR-VP broth was then incubated at 37 °C for 24 h and 48 h, respectively, for the VP and MR tests. The VP and MR test method. Approximately 1 mL of MR-VP broth was poured into test tubes. The VP test involved the addition of each bacterial colony, 0.6 mL of 5% α naphthol, and 0.2 mL of 40% of potassium hydroxide to test tubes. Meanwhile, the MR test involved the addition of five drops of methyl red to test tubes containing bacterial colonies. Then, the test tubes were shaken gently and left undisturbed for 10 to 15 min. The colour changes from yellow to red of the sample showed a positive result.

The Gram staining test method was performed according to Shinkafi and Ndanusa [17]. A loopful of bacteria was heat-fixed onto a slide. A drop of crystal violet, followed by the decolouriser, iodine, and safranin, was added onto the bacteria on the slide for 1 min and was washed off with distilled water. The slide was blotted to dry before being observed under the light microscope at 100× magnifications and recorded.

The disc diffusion assay method to test antibacterial activities was performed according to Park et al. [14]. Approximately 100 µL of each bacterial suspension was used and spread on MHA using a sterile cotton swab (for *S. aureus and S. epidermidis*) and NA (for *P. acnes*). Each disc impregnated with antibiotics was gently pressed down to ensure that the disc was completely in contact with the agar surface and did not fall when inverted. The streptomycin antibiotic disc was used as a positive control, while the extraction solvent, i.e., methanol, ethyl acetate, and 1:1 ratio of methanol: ethyl acetate mixture, was used as the negative control. The experiment was done in triplicate for each bacterium. The plates were incubated at 37 °C for 24 h (*S. aureus* and *S. epidermidis*) and 37 °C for 72 h in a candle jar to retain the anaerobic condition for *P. acnes*. The antibacterial activity was measured based on the diameter of the inhibition growth zone.

Results and Discussion

The *S. macrophylla* seed was extracted using the Soxhlet extraction method in three different solvent systems; methanol aqueous, ethyl acetate, and 1:1 methanol-ethyl acetate mixture. Table 1 shows that the 1:1 ratio of methanol-ethyl acetate solvent mixture produces the highest percentage of crude oil extract (72.68%), followed by ethyl acetate (67.55%) and aqueous methanol (37.65%). All solvents used can extract the crude oil in 6 h extraction time. Do et al. mentioned that methanol solvent is generally more efficient in extracting lower molecular weight polyphenols [18]. In this experiment, the combination of methanol-ethyl acetate organic solvent facilitates a suitable extraction of all soluble compounds in both solvents. According to Nawaz et al., using a combination of polar and nonpolar solvents can increase the excellent quality of extraction yield from the bean and other legume seeds [19]. Furthermore, Che Sulaiman et al. reported that the extraction yield of organic samples is also dependent on the extraction times, extraction temperatures, and solvent ratios [20].

Table 1. Percentage Yield of Swietenia macrophylla Seed's Extract in a different solvent

Solvent Types	Mass of Dried Powder (g)	Mass of Oil Crude Extract (g)	% Yield
Methanol	5.07 ± 0.02	1.90 ± 0.45	37.65
Ethyl Acetate	5.04 ± 0.02	3.40 ± 0.18	67.55
Methanol: Ethyl Acetate	5.04 ± 0.03	3.67 ± 0.49	72.68

The phytochemical compounds in the *S. macrophylla* seed extract were analysed using GC-MS analysis. About 13 compounds were successfully identified in the methanol extract, 20 in the ethyl acetate extract, and 12 in the 1:1 methanol-ethyl acetate mixture as terpenoids, flavonoids, and limonoids. The compounds obtained strongly depended on the nature of extracting solvent due to different antioxidant compounds that vary their chemical characteristics and polarities. The most extracted compounds were reported in ethyl acetate, methanol, and 1:1 methanol-ethyl mixture due to the semipolar-polar compounds [21]. The number of extracted compounds in the 1:1 methanol-ethyl acetate extract is less than ethyl acetate alone because the elution strength of ethyl acetate decreased due to the polarisation effect of methanol. The extraction process yielded seven compounds in methanol extract, five compounds in ethyl acetate extract, and two compounds in the 1:1 methanol-ethyl acetate mixture, with more than 80% quality compared to the GC-MS reference library software (Table 2). In Table 2 show that silane methoxytrimethyl-, disiloxane hexamethyl, and 2,2,2-trifluoro-N-(trimethylsilyl)- are the major bioactive compound present in *S. macrophylla* seed extract, with the under peak percentage area of more than 23.57%. A previous study by Azhari et al. [22] stated that several compounds of limonoids such as phenol, 2-methoxy-4-(1-propenyl)-, and eugenol were also found in *S. macrophylla seed* extract using the maceration method. In this work, compounds such as phenol, 2-methoxy-4-(1-propenyl)-, (E)-(isoeugenol), silane, [2-methoxy-4-(1-propenyl) phenoxy] trimethyl- (isoeugenol), and eugenol are present in the sample. As reported in previous works, these compounds possess effective antifungal and antibacterial activities [23-25]. According to Sharma et al. [26], phytocompounds present in chloroform and methanol seed extracts are responsible for the varied antioxidant and antimicrobial activities.

The concentration of arsenic (As), lead (Pb), cadmium (Cd), nickel (Ni), mercury (Hg), and copper (Cu) in *S. macrophylla* seed powder was analysed using ICP-OES. Table 3 shows the result of heavy metal concentration in the crude oil extract sample. Only low concentrations of mercury are detected in the sample, i.e., 0.080 ppm. The result revealed that the *S. macrophylla* seed powder is low in heavy metal content. Hence, it is considered a safe ingredient in medication or cosmetic products. According to the U.S. Food and Drug Administration (USFDA) limits regulation, the accepted concentration of mercury must be less than 1 ppm (1 mg/kg), i.e., safe to be used as new constituents in products [31].

The images of catalase test (CT), Voges Proskauer (VP), and Gram staining test (GST) of Gram-positive bacteria (*S. aureus, S. epidermidis*, and *P. acnes* [facultative anaerobic bacteria]), are shown in Figures 2 - 4. Figure 2 shows a positive CT result, whereby bubbles are observed at 10 min observation. The finding is similar to the study by Mustafa [30], Kallstrom et al. [31], and Cauich-Sanchez et al. [32]. The catalase acts as a catalyst in breaking down the hydrogen peroxide into water and oxygen to form an oxygen bubble produced by the bacteria. The VP test was conducted to measure the production of acetyl methyl carbinol, as shown in Figure 3. *S. aureus* and *P. acnes* show positive results, where the color of the solution change to red. In contrast, the colour of the *S. epidermidis* solution remains unchanged. This result

is similar to Shinkafi and Ndanusa [17], whereby the colour change from light yellow to slightly red in the *S. aureus* and *P. acnes* tests indicated positive results. Whereas the colour of the solution in the *S. epidermidis* tube did not change, indicating a negative result. Further validation analysis for *S. aureus*, *S. epidermidis*, and *P. acnes* were carried out using the methyl red (MR) test (Figure 4). The unchanged colour of the MR solution of *S. aureus* and *P. acnes* indicates positive results. On the contrary, the colour of the *S. epidermidis* solution changed from light yellow to red. The researcher also stated that *S. aureus* and *P. acnes* showed negative results when the colour of the MR solution remained unchanged. This is contradictory to *S. epidermidis*, which showed positive results when the light-yellow solution slightly changed to red. The purpose of the MR test is to determine the ability of the bacteria to oxidise glucose and produce a high concentration of acidic products.

Table 2. Phytocompounds in SME in different extraction solvents by using GC-MS

Retention Time (min)	**Area (%)**	**Name of Compound**	**Bioactivity**	**Solvent**
1.300	45.76	Silane, methoxytrimethyl-	NR	Methanol

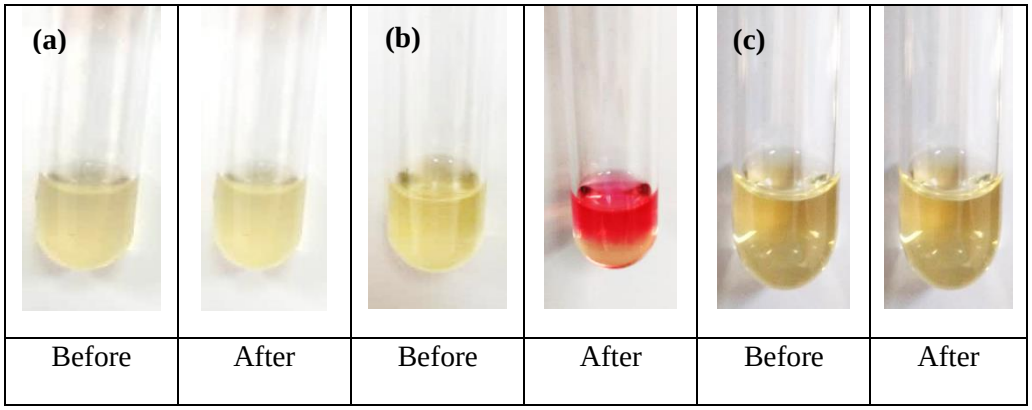

Figure 4. Photo images of methyl red (MR) test of (a) *S. aureus*, (b) *S. epidermidis*, and (c) *P. acnes*

The Gram-staining analysis was performed to determine the Gram-positive and Gram-negative bacteria based on the bacterial cell wall colour using an Olympus CKX53 inverted microscope (Figure 5). The Gram-positive bacteria, i.e., *S. aureus*, *S. epidermidis*, and *P. acnes*, were observed in this analysis. The results showed that the bacteria appear violet with aggregated grape-like clusters under 100× magnification [16]. In contrast, the *P. acnes* is visualised as violet with a rod-like bacillus structure [33], as shown in Figure 5(c). According to Panawala [34], the bacteria appear violet under the microscope due to the thick peptidoglycan cell wall and teichoic acid composition.

The inhibition zones of the three bacteria species were determined using the disc diffusion assay method, as shown in Figure 6 and Table 4. The disc assay method is a rapid determination of antibacterial activity by measuring the diameter of the inhibition zone that resulted from the diffusion of the phytochemical compound into the medium surrounding the disc [35]. Table 4 shows the inhibition zone category and bacterial inhibition zone in 30-disc tetracycline concentration (µg/disc).

The inhibition of bacteria towards the sample extract was expressed as susceptible, intermediate, and resistant according to international standards (ISO 20776-1). Susceptible is when the bacteria are inhibited *in vitro* by a drug concentration with high therapeutic properties. Meanwhile, intermediate is when the bacteria are inhibited in vitro by a drug with uncertain therapeutic effects. For resistance, the bacteria are inhibited in vitro by a drug with a high chance of therapeutic failure [36].

Figure 6 shows *P. acnes* is minimally inhibited in the methanol and 1:1methanol-ethyl acetate extracts. In comparison, the inhibition zone of the *S. aureus* is more prominent than in tetracycline (antibiotic control). Table 4 shows the results of the inhibition zone of the bacteria tested. *S. aureus* is susceptible in methanol and 1:1 methanol-ethyl acetate extracts, as the zone of inhibition more than 19.00 ± 0.00 mm, while *S. epidermidis* is resistant towards ethyl acetate and 1:1 methanol-ethyl acetate extracts at 13.00 ± 1.00 mm and 13.00 ± 2.31, respectively.

Meanwhile, *P. acnes* exhibits resistant, intermediate, and susceptible properties in 1:1 methanol-ethyl acetate, methanol, and ethyl acetate extract respectively. Aditi and Hossain [37] reported that *S. aureus* acquired resistance easily, a good bio-indicator model for surveillance studies of antimicrobial resistance [38]. *S. aureus* and *P. acnes* in ethyl acetate extraction solvent showed a more significant inhibition zone but slightly lower inhibition of *S. epidermidis*. In a nutshell, for antibacterial activity, all extracts showed a high therapeutic capability towards *S. aureus* and *P. acnes* but are less effective against *S. epidermidis*.

*R- resistant (≤14 mm), I- intermediate (15-18 mm), S-susceptible (≥19 mm) [9]
*The values were presented in mean ± SD, where n=3

Conclusion

The properties of *S. macrophylla* seeds in three different extraction solvents were successfully determined. Three new compounds, phenol, 2-methoxy-4-(1-propenyl)-, (E)-Eugenol; and silane, [2-methoxy-4-(1-propenyl) phenoxy] trimethyl, were successfully extracted from *S. macrophylla* seeds using ethyl acetate solvent. The highest extraction yield is obtained in the 1:1 methanol-ethyl acetate mixture (72.68%), followed by ethyl acetate (67.55%) and methanol (37.65%). From the disc diffusion assay, *S. epidermidis and P. aureus* are susceptible towards

methanol and 1:1 methanol-ethyl acetate extracts. In contrast, *P. acnes* is susceptible towards ethyl acetate extract. The result showed that *S. macrophylla* seeds extract is an effective ingredient for treating acne due to positive inhibition towards three acne-causing bacteria and is considerably low in heavy metal contents.

Acknowledgement

The authors are sincerely grateful to UiTM Perlis Branch, Arau Campus, to provide the research facilities. High appreciation also goes to the Frontier Applied Science and Technology research group (FAST) for completing this work.

Abstract

Biochemical methane potential (BMP) tests are extensively used in many studies related to anaerobic co-digestion (AcoD) to evaluate biogas production and determine the potential methane yield between various substrates at specific retention times and parameters. AcoD is a process of mixing two or more substrates in a digester that could help to improve the methane yield as compared to mono-digestion with the same substrates. This study evaluates the methane production efficiency via AcoD of food waste and thickened sludge by using the BMP tests. The substrates used for this study were wastes from non-dairy creamer, coffee, and mixed food waste with sludge. Additionally, thickened sludge as an inoculum was used for the BMP test. The samples characterisation was analysed according to standard and HACH methods. The thickened sludge was set up at a ratio of 1:1 as a control, while the food wastes sample with sludge was set up at a ratio of 1:2. The initial pH was adjusted in a range of 6.5-7. The BMP test setup was done using a 125mL serum bottle in triplicates for 31 days in an incubator at 37°C. The results showed that the highest methane production of the BMP was from thickened sludge itself which is 18.275 ± 3.3 mL CH_4/gVS, followed by non-dairy creamer waste with thickened sludge, mixed food waste with sludge and coffee waste with thickened sludge which are 17.865 ± 6.2 mL CH_4/gVS, 17.825 ± 0.05 mL CH_4/gVS and 14.797 ± 0.01 mL CH_4/gVS respectively. In conclusion, the pre-treatments process is highly recommended in order to improve biogas production.

Keywords: anaerobic co-digestion, biochemical methane potential, experimental methods, food wastes, methane production

Abstrak

Ujian potensi metana biokimia (BMP) digunakan secara meluas dalam banyak kajian berkaitan penghadaman bersama anaerobik (AcoD) untuk menilai pengeluaran biogas dan menentukan potensi hasil metana antara pelbagai substrat pada masa dan parameter pengekalan tertentu. AcoD merupakan suatu proses mencampurkan dua atau lebih substrat dalam pencerna yang boleh meningkatkan hasil metana berbanding mono-pencernaan dengan substrat yang sama. Kajian ini bertujuan menilai kecekapan pengeluaran metana oleh AcoD bagi sisa makanan dan enap cemar pekat menggunakan ujian BMP. Substrat yang digunakan

untuk kajian ini ialah sisa daripada krimer bukan tenusu, kopi, dan sisa makanan yang bercampur dengan enap cemar. Enap cemar pekat digunakan untuk ujian BMP sebagai inokulum. Pencirian sampel dianalisis mengikut kaedah standard dan HACH. Enap cemar yang menebal telah disediakan dalam nisbah 1:1 sebagai kawalan, manakala sampel sisa makanan dengan enap cemar disediakan dalam nisbah 1:2. Nilai pH awal diselaraskan dalam julat 6.5–7. Persediaan ujian BMP dilakukan menggunakan botol serum 125mL sebanyak tiga kali ganda selama 31 hari dalam inkubator pada suhu 37^{o}C. Hasil kajian menunjukkan bahawa pengeluaran metana BMP tertinggi adalah daripada enap cemar pekat itu sendiri, iaitu 18.275 ± 3.3 mL CH_4/gVS, diikuti sisa krimer bukan tenusu dengan enap cemar pekat, sisa makanan bercampur dengan enap cemar, dan sisa kopi dengan enap cemar pekat, masing-masing 17.865 ± 6.2 mL CH_4/gVS, 17.825 ± 0.05 mL CH_4/gVS, dan 14.797 ± 0.01 mL CH_4/gVS. Kesimpulannya, proses pra-rawatan amat disyorkan untuk meningkatkan pengeluaran biogas.

Kata kunci: pencernaan bersama anaerob, potensi metana biokimia, kaedah eksperimen, sisa makanan, penghasilan metana

Introduction

The amount of sewage sludge is continuously increasing as a surplus of the wastewater treatment process due to increased population. The higher percentage of households connected to the main wastewater treatment plants (WWTPs) also contributes to the higher production of sewage sludge [1, 2]. Nevertheless, improper handling and untreated sewage sludge may lead to environmental impacts and public health problems. This is because sewage sludge is characterised by its high concentrations of solids and organic matter, with the presence of nutrients, organic and inorganic pollutants and pathogens that create odour problems. Nowadays, there are several alternative techniques which are applied for sewage sludge disposal, such as incineration, landfills, compost, recycling, and anaerobic digestion (AD). AD is a proven technology and one of the most feasible techniques applied for the treatment of sewage sludge in many countries due to its lower operational cost, reduced chemical oxygen demand (COD), decreased pollutants discharged into the environment, and production of energy-rich biogas [3, 4, 5].

Besides that, anaerobic digestion (AD) is also known as the most efficient process for the treatment of municipal solid waste and wastewater sludge [6, 7]. In general, anaerobic digestion (AD) is the process in which organic waste such as bio-waste, animal manure, sludge, crops, and other biomasses are biologically degraded in the absence of oxygen and converted into a form of biogas and other organic compounds as end products [6, 7]. The food waste also can be characterised by its high percentage of biodegradability, moisture content around (> 70%), volatile solids (> 95%), with numerous amounts of lipids [8] that will enhance the AD performance. Other than that, the methane gas obtained from the AD process can be used to generate electricity and for heating purposes. Sewage sludge is characterised by its high concentration of solids and organic matter, with the presence of nutrients, organic and inorganic pollutants, and pathogens. According to Appels et al., [6], fuels can be produced by using sewage sludge. It can also be used as an inoculum in the anaerobic digestion process by considering its characteristics. Thus, anaerobic co-digestion (AcoD) is the process of mixing two or more substrates in a digester that could improve methane production from 25% to 400% as compared to the mono-digestion [9-13] of the same substrates [14,15].

Non-dairy creamer (NDC) and coffee are from the food and beverages industry. However, the NDC contains no lactose. It is a substitute product for milk or cream in the form of a liquid or powder which produces high water dissolved fat emulsion that is made up from vegetable oil (30% hydrogenated coconut or palm oil) for the purpose of reducing the amount of milk or replacing the milk powder in oatmeal, baked goods, coffee and others [16]. Huang et al.,[17] stated that NDC is made up of 60-65% glucose or corn syrup, 2-5% sodium caseinate, stabilisers, and emulsifiers [18], and it contains about 1.2% of minerals, 8.5% of protein, 32.5% of fat, and the highest percentage is carbohydrate at 58%. The liquid waste and sewage sludge are the by-products of the NDC industry. The improper processing of the NDC wastewater will affect

the environment. The sewage sludge and wastewater from NDC contain high organic matter such as proteins, lipids, and carbohydrates [19-21] While the coffee processing effluent is highly acidic, has high chemical oxygen demand (COD), and also contains a high amount of organic matter and suspended solids [22-23], the foul odour and eutrophication occurs due to the dark brown colour of the effluent which was produced from the coffee processing plants due to the decomposition of lignin (humic acid, tannin) with different macromolecules such as caffeine and polyphenols (melanoidins). Cardenas et al., [24] cited that melanoidins consist of ligands (polysaccharides, tannins), which hardly degrade biologically [25]. Thus, AD is considered as an alternative method to treat both NDC and coffee waste.

In addition to that, AD can be applied experimentally via the biochemical methane potential (BMP) test by determining the biodegradability of waste biomass and wastewater and also the methane potentiality [26]. The BMP experimental test is usually suitable for small-scale (batch) analysis (lab-work) which is costly, and time-consuming, with analysis within 20 to >100 days [27] compared to the BMP theoretical test. Several parameters influence the determination of BMP experimental tests such as the inoculum-substrate ratio, pH, temperature, retention time, chemical oxygen demand (COD), total solids (TS), moisture content, volatile solids (VS), and others [28]. The objective of this study is to evaluate the methane production via anaerobic co-digestion of food waste and sludge by using the BMP experimental method.

Material and Methods

Sample collection

Substrate and inoculum

Food waste samples as substrates (coffee, non-dairy creamer waste and mixed food waste) were obtained from the food manufacturing industry and the IWK sludge (thickened) was used as inoculum. All food wastes and thickened sludge were supplied by Indah Water Konsortium Sdn. Bhd (IWK), whose WWTP plant is located at IWK Sewage Treatment Plant, Kuala Lumpur. Then, the collected samples were degassed or pre-incubated to deplete the residual biodegradable organic material present in them [29]. Table 1 presents the setup of substrates used for this study.

Table 1. Substrates for BMP, and S/I ratio

Inoculum & Substrates	Label	Substrate/inoculum Ratio, S/I
Thickened sludge (inoculum)	IWK Sludge	1:1
Non-dairy creamer waste + inoculum	Co-digestion 1	1:2
Coffee waste + inoculum	Co-digestion 2	1:2
Mixed food wastes + inoculum	Co-digestion 3	1:2

Analytical method

Sample characterization

The characterisations of the substrate (food waste) and inoculum (thickened sludge) conducted for this study are the moisture content, Volatile Matter, pH, temperature, Total Solid (TS) and Volatile Solid (VS), chemical oxygen demand (COD), alkalinity and volatile fatty acid (VFA). Thus, all these parameters were measured according to the Standard Methods [30] except for the alkalinity and VFA, which used the HACH method. About 200mL of the sample was placed in a 500 mL beaker. The pH meter was calibrated first at pH 4, 7 and 10, and then the pH of the samples was measured by using the pH meter (Orion Star A111 pH meter). In order to do that, moisture and TS were determined by drying the samples at 105 $^{\circ}$C overnight and for 4 hours at a constant weight [30]. While the previous sample from the moisture content and TS was heated by furnace at 550 $^{\circ}$C for 2 hours and 15 minutes to measure the volatile matter and VS. Chemical oxygen demand (COD) was performed by using and preparing the high

range COD standard reagents (200-15000 mg/L), blank, and samples. Each sample was diluted by 1:10 time's dilution, and about 2.0 mL of the sample was filled into the high range COD reagent vial. Thus, the samples were placed into the COD reactor within 2 hours at 150 °C. Then, the readings of the COD were analysed by using the spectrophotometer.

However, for alkalinity, the digital titration cartridge, sulfuric acid 1.600±0.008 N was used (based on the HACH method procedure). About 10mL of the sample volume was titrated with a digital titration cartridge, and the titration was stopped at a pH 4.5. Then, the counter (at the digital titrator) showed the digits for the first endpoint, and the digits were multiplied with the digit multiplier (x10) for samples in the range of 1000-4000 (mg/L as $CaCO_3$). Thus, the exact volume (mg $CaCO_3$/L) total alkalinity was recorded. Lastly, for the VFA test method, about 0.5 mL of deionized water and samples (the filtrate or supernatant) were placed separately on a sample cell. An amount 1.5 mL of ethylene glycol was added to each sample cell, and then it was swirled, followed by adding 0.2 mL of 19.2N sulfuric acid. Then, the sample cell was boiled for 3 minutes. The sample cell was immersed into cool water at 25 °C (until the cells feel cold). 0.5 mL of Hydroxylamine hydrochloride solution, 2.0 mL of 4.5N sodium hydroxide standard solution, 10 mL of ferric chloride sulfuric acid solution, and 10 mL of deionized water was added to each sample cell and the cell was inverted to mix. 10 mL of the blank solution and prepared sample were transferred to a clean sample cell. The sample cell was inserted into the cell holder and the results were shown in mg/L HOAC.

Sample preparation

BMP experimental test

The BMP experimental test was performed in 125 mL serum bottles for the AD process [31] with a working volume of 70% and 30% remaining for the gas production as shown in Figure 1 [32]. Food waste samples such as coffee and non-dairy creamer were used as a substrate, while the IWK sludge (thickened sludge) was an inoculum. The initial pH was adjusted at a range of 6.5-7. After mixing and adding the samples into the serum bottle, the nitrogen gas was purged immediately in the headspace of the bottles for 3 minutes to remove the presence of air, which creates an anaerobic condition in the system [33], prior to sealing the serum bottles. All serum bottles were placed into an incubator at 37 °C, which is the optimum temperature for microbial activities [34] within the retention period of 31 days [35]. Every batch of AD was set up according to a 1:1 ratio for control and a 1:2 ratio of food waste to sludge. The serum bottles were placed into a rotary shaker once a day for 15 minutes to ensure the mixtures were well shaken. All experiments were performed in triplicate. An inoculum filled with water, with no substrate added, was used as a blank assay for the background of the methane yield. The gas sample produced was abstracted from the serum bottle and was then analysed by Gas Chromatography (GC) Agilent 7890A (30m x 32 µm x 0.25 µm).

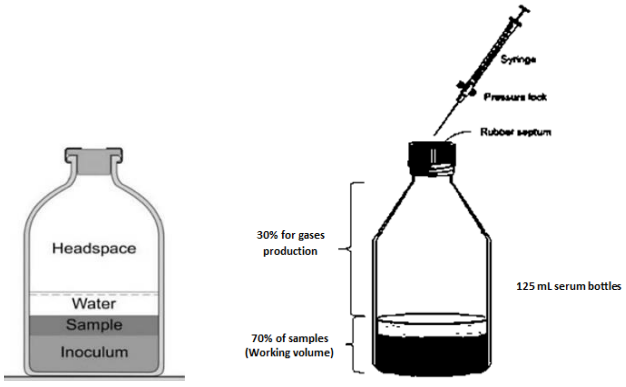

Figure 1. 125 mL of serum bottles set up [31]

Results and Discussion

Sample characterization

The results of the characterization of all samples are summarized in Table 2. The pH for non-dairy creamer waste (NDC), coffee waste, thickened sludge, and mixed food waste with sludge was in the range of slightly neutral to alkaline. The highest pH observed was in coffee waste. During the methanogenesis stages of AD, the methanogenic bacteria are highly sensitive to pH, so the optimum pH for methanogenic bacteria activities is within a range of 6.8-7.2 [36-37], as supported by Lusk [38]. The digester should be maintained at a pH near 7.0 to enhance biogas production, while a low pH would create the accumulation of volatile fatty acids (VFA) which results in the inhibition of the digestion process [39-40]. For a proximate analysis, the information on the moisture content (MC), volatile matter (VM) and others were obtained, which is important to determine the potentiality and suitability of the biomass [41]. From the results in Table 2, the MC for all raw samples is more than 90%, which shows that the water content of each sample was high, which means the raw materials have sufficient MC for anaerobic digestion, as the moisture content of the food waste in the substrate is between 95 - 97% from his study [42]. The volatile matter (VM) for all the samples was in the range of 66-80%. Thus, the fraction of VM for all the samples showed its potential to produce higher biogas production [43-44]. The thickened sludge and mixed food waste produced the higher chemical oxygen demands (COD) with 18790 ± 96.44, and 12,516 ± 92.38 mg/L respectively. According to Treagust [45], the COD of coffee wastewater reaches up to 50,000 mg/L. Toxic chemicals such as tannis, alkaloids (caffeine) and polyphenolics can be found in coffee wastewater in small amounts. The COD values measured the oxygen needed to oxidize all organic material present within substances [46]. The higher the COD values, the higher the potential of substances to produce methane.

The total solids (TS) of the substrates mainly started from < 7%. TS measures the suspended and dissolved solids in water. Coffee waste has the greater TS value, with 7.32%, compared to others. Volatile solids (VS), are described as the organic matter present in the wastewater which is important for AD performances that would enhance the higher production of methane. The VS value for food waste and sludge is at a range of 40-70%. Alkalinity is a very important parameter in the AD process. Alkalinity helps to avoid the failure of the digester and causes the inhibition of methanogenic bacteria activities by preventing the pH drop. The alkalinity of NDC, coffee waste, thickened sludge, and mixed food waste with sludge was 900 ± 1.48, 794.83 ± 1.56, 3012.5 ± 1.75 and 3337.5 ± 0.89 mg $CaCO_3$/L. Volatile fatty acid (VFA) is another option to justify the availability of the raw materials used in AD for the production of methane. Like other common factors of AD such as pH, alkalinity, and COD, the VFA gives information on the process status [47]. The hydraulic loading, temperature, and organic loading might affect the concentration of VFA. According to Yu et al. [48], the accumulation of VFA will interrupt the digester buffer capacity, leading to acidification and the failure of system performance by inhibiting the methanogenic bacteria activities. Thus, the VFA readings for all the samples were 6510 ± 25.39, 2410.33 ± 27.94, 211 ± 23.81, and 707.33 ± 57.66 mg/L which represents the NDC, coffee waste, thickened sludge, and mixed food waste with sludge. There are many studies on the effects of VFA content that might affect AD efficiency.

Table 2. The results of the characterization of samples

Parameters	Non-Dairy Creamer waste (NDC)	Coffee waste	Mixed Food waste with sludge	Thickened sludge
pH	7.46 ± 0.01	11.55 ± 0.08	7.07 ± 0.03	7.09 ± 0.03
Moisture Content (%)	99.34 ± 0.02	90.05 ± 0.03	95.53 ± 0.02	96.21 ± 0.01
Volatile Matter (%)	80.03 ± 1.82	73.59 ± 1.18	66.07 ± 2.08	68.97 ± 0.002
Chemical Oxygen Demands (mg/L)	8400 ± 52.92	7843.33 ± 32.15	12516.67 ± 92.38	18790 ± 96.44
Total Solid (%)	0.68 ± 0.18	7.32 ± 0.02	4.49 ± 0.03	4.11 ± 0.06
Volatile Solid (%)	70.84 ± 0.08	44.68 ± 0.002	67.11 ± 0.06	69.18 ± 0.001
Alkalinity (mg $CaCO_3$/L)	900 ± 1.48	794.83 ± 1.56	3337.5 ± 0.89	3012.5 ± 1.75
Volatile Fatty Acids, VFA (mg/L)	6510 ± 25.39	2410.33 ± 27.94	707.33 ± 57.66	211 ± 23.81

BMP experimental test

The BMP experimental test was performed in 125 mL serum bottles for the AD process [31] with a working volume of 70% and 30% remaining for the gas production as shown in Figure 1. Constant BMP experimental results were achieved for all samples after the retention time of 31 days for the anaerobic digestion process took place. The BMP assays are assumed to be finished when the daily production is less than 1% or when the cumulative graph shows a constant trend of methane production which indicates the organic substances are fully degraded. The microorganisms no longer have enough nutrients for digestion purposes. Figure 2 shows the methane production of co-digestion 1, co-digestion 2, co-digestion 3, and thickened sludge. The lag phase, which is the time of adaptation for inoculum to a new environment or medium, stopped around 7 days, in this study. According to the curves in Figure 2, it can be observed that the methane production was initially slow, but continuously increased at around 20 days. There was a constant production of methane from day 20 until day 31. Thus, it took almost 20 days for all the methane to be produced from the substrates. It can be seen that the highest methane production was from the thickened sludge which is 18.275 ± 3.3 mL CH_4/gVS, followed by the non-dairy creamer waste with sludge (co-digestion 1) that is 17.865 ± 6.2 mL CH_4/gVS and mixed food waste with sludge (co-digestion 3) at 17.825 ± 0.05 mL CH_4/gVS. While, the lowest methane production is from coffee waste with sludge (co-digestion 2) which is 14.797 ± 0.01 mL CH_4/gVS.

Co-digestion 2 shows the lowest production of methane compared to co-digestions 1 and 3. The coffee waste itself is characterized as lipids, cellulose, lignin-rich biomasses. Lignin (humic acid, tannin) has different macromolecules such as caffeine and polyphenols (melanoidins). Cardenas et al.,2009 [24] cited that, melanoidins consist of ligands (polysaccharides, tannins), which hardly degrade biologically [24]. The cellulose and lignin make the lignocellulosic biomass a great prospect for biogas production through AD. However, it is still considered difficult for it to be degraded and digested. Somehow, the study also highlighted that lower methane potentials of about 0.16 - 0.35 CH_4 m3/kg VS of food waste are rich-lignocellulosic fractions and have low lipids content, such as fruit and vegetable residues and brewery waste. Moreover, the coffee waste shows that the highest pH, which is 11.55 ± 0.08, is very alkaline. It will affect biogas productivity. As mentioned before, it has been proved that the optimum pH for methanogenic bacteria activities is within a range of 6.8-7.2, which will give a

significant effect on biogas yield [36-37]. Co-digestion 1 shows that the second-highest methane yield is 17.865 ± 6.2 mL CH_4/gVS. This is because NDC contains high organic matter with about 1.2% minerals, 8.5% protein, 32.5% fat, and the highest percentage is carbohydrates (58%) [18-21]. Protein and carbohydrate-rich substrates are considered to be easily degradable, and lipids have less of a hydrolysis rate [48]. Thus [42, 49], higher methane yields can be achieved from food wastes rich in lipids, such as easily degradable carbohydrates.

The reading of the methane yields for co-digestion 3 (mixed food waste with sludge) is slightly similar to co-digestion 1 which is 17.825 ± 0.05 mL CH_4/gVS. The COD of co-digestion 3, which is 12516.67 ± 92.38 mg/L, is higher compared to co-digestion 1 and co-digestion 2. However, the COD for the thickened sludge, which is 18790 ± 96.44 mg/L, shows the highest yield compared to the others. This shows that most of the organic matter is contained in both co-digestion 3 and the thickened sludge. It can be summarised from Figure 2, that the solely thickened sludge has the potential to produce a higher methane yield without adding any substrate. As we informed, the mixed food waste with sludge consists of coffee and non-dairy creamer waste. Thus, there is the mixing of protein, carbohydrates, and lipids with lignin groups of waste within it. These can act as a reason for the lower methane yield of co-digestion 3 compared to the inoculum which is solely thickened sludge. Therefore, the pre-treatment to the substrate is suggested either by biological, chemical, or thermal treatments to improve the substrate's potential in producing methane. This study has proven different substrates have different characteristics, as can be seen in the proximate analysis of the raw materials. Thus, pre-treatment approaches can be taken to enhance the efficiency of methane generation.

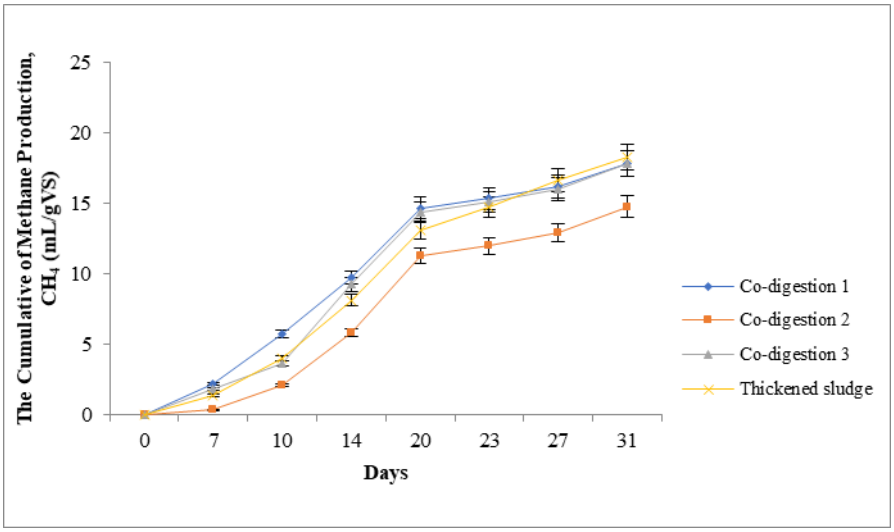

Figure 2. The cumulative BMP experimental test of methane production for co-digestions and inoculum

Conclusion

The NDC and coffee industry play an important role by providing good handling and processing wastewater management in order to achieve and maintain environmental stability. Nevertheless, the BMP experimental test results indicate that there is a potential for a single inoculum (thickened sludge), and the co-digestion of different wastes such as coffee waste, non-diary creamer waste, and the sample of mixed food waste with sludge would produce a methane yield within the 31 days of the AD process. However, it is also possible to inhibit the AD process if the nutrients are imbalanced. For further observation, an effective and environmentally friendly pre-

treatments process is highly recommended to improve biogas production.

Abstract

Recent works on many types of synergistic conducting polymers/tungsten disulfide (CP/WS_2) composites are thoroughly covered in this mini review. Data were gathered from over 60 scientific research papers from all over the world and published within the last decade (2012-2021). CPs are as versatile materials because of their remarkable advantages over other traditional materials. These advantages include wide and adjustable electrical conductivity, high mechanical flexibility, high capacitance, and low manufacturing cost. However, CPs do possess limitations in terms of stability, processability, and mechanical strength. As a result, CPs are frequently integrated with inorganic fillers such as metal sulfide. WS_2 has garnered significant attention among metal sulfides when combined with CPs, where it improves chemical/thermal stability and provide good processability to the CPs/WS_2 composites. Hydrothermal procedures and solvothermal techniques were all mentioned and discussed as relevant synthesis methods. As a result, hybridized CP/WS_2 composites have shown prospects in terms of functionality and applicability. Sensors, energy storage, and electrical applications are among the areas that experienced enhanced performance by using CP/WS_2. A brief discussion of the mechanisms underlying these successful applications is also included. This mini review is meant to provide readers with information on CP/WS_2 and, as a result, instill interest in new research topics.

Keywords: conducting polymer, tungsten disulfide, sensors, supercapacitors, photocatalyst

Abstrak

Terdapat banyak jenis komposit yang terdiri daripada konduktif polimer/tungsten disulfida (CP/WS_2) telah dibincangkan di dalam ulasan mini ini. Data yang telah dikumpulkan telah diperolehi dari lebih 60 penyelidikan saintifik dari seluruh dunia selama sepuluh tahun sebelumnya. CP merupakan bahan kimia yang serba boleh kerana mempunyai kelebihan yang luar biasa berbanding bahan tradisional yang lain, termasuk kekonduksian elektrik yang luas dan boleh laras, fleksibiliti mekanikal yang tiggi, kapasitans yang tinggi dan kos pembuatan yang rendah. Walau bagaimanapun, CPs mempunyai batasan dari segi kestabilan, kebolehkerjaan dan kekuatan mekanikal. Oleh itu, CP sering digunakan bersama dengan pengisi bukan organik seperti sulfida logam. Di antara sulfida logam, WS_2 telah mendapat perhatian yang signifikan jika digabungkan dengan CP kerana dapat meningkatkan kestabilan kimia/haba serta menambahbaik ciri-ciri pemprosesan dalam komposit CP/ WS_2. Antara kaedah sintesis yang relevan yang telah dibincangkan dalam kajian mini ini adalah proses hidrotermal dan teknik solvotermal.

Hasilnya, komposit CP/WS_2 yang dihibridisasi telah menunjukkan penningkatan dari segi fungsi dan kebolehgunaan. Penggunaan CP/WS_2 dalam bidang sensor, penyimpanan tenaga dan aplikasi elektrik dapat meningkatkan keupayaan mereka. Perbincangan ringkas mengenai mekanisme aplikasi yang berjaya turut disertakan. Akhir sekali, tujuan kajian mini ini adalah untuk memberi maklumat kepada pembaca mengenai CP/WS_2 dan menarik minat mereka untuk menghasilkan suatu kajian penyelidikan yang baharu.

Kata kunci: konduktif polimer, tungsten disulfida, pengesan, superkapasitor, fotomangkin

Introduction

Conducting polymers (CPs) are a unique class of materials with a π-conjugated system that corresponds to its electrical conductivity. The success of CPs as synthetic metals was discovered in the late seventies by Hideki Shirakawa and his team by accidental addition of excess halides in the reaction medium of polyacetylene. Since then, CPs were widely studied upon in terms of their significant properties such as large conducting mechanisms, electrical properties, adjustable electrochemical properties, and easy processing. Currently, the CPs family consists of polyacetylene (PA), polyaniline (PANI), polypyrrole (PPy), poly(phenylene vinylene) (PPV), poly(3,4-ethylene dioxythiophene) (PEDOT), polyfuran (PF), and other polythiophenes (PTh) and its' derivatives [1]. Due to their fascinating properties, CPs have received widespread attention from both the industrial community and researchers, especially in the study of supercapacitors, sensors, fuel cells, and photocatalysis for their wide range of applications. Figure 1 summarizes far-famed CPs that correspond to their applications.

Although CPs have become the interest of many communities, they still possess a few drawbacks such as high recycling instability [2], high defect sites from poor temperature tolerance [3], slow exchange of ions [4], and inconsistent solubility [5]. Therefore, enormous effort has been undertaken to incorporate various types of filler such as carbon materials, polymers and inorganic compounds into the CPs' matrix to enhance its properties. Particularly, in recent decades, many attempts were made to produce CPs-inorganic hybrid materials, where the integration of inorganic fillers into CPs may enhance the stiffness, toughness, and dimension stability of the resulting hybrid materials [6]. Among the inorganic fillers, transition metal dichalcogenides (TMDC) were the most favored due to considerable bandgaps in the range of 1-2eV, which is applicable for sensing, nanoelectronics, and photonics [7]. Considering metal sulfides are a class of TMDC, it is an excellent candidate to improve the CPs' properties in terms of conductivity, thermal stability [8], capacitance activity, and cyclic stability[9]. This is because by supplying electrons or withdrawing electrons to or from the transition state of reaction, the transition metal retains a good source of electrons from the partially filled d-subshell. CPs eventually have more free-moving electrons obtained from metal sulfide and therefore exhibits better electrical conductivity. In a study reported by Ramesan 2013, it was found that when PPy and cadmium sulfide (CdS) were combined, the nanocomposite's alternating current conductivity was greater than pristine PPy. Meanwhile, the highest generated direct current electrical conductivity was obtained when a higher amount of CdS were added [10].

In addition, metal sulfide is outstanding because it generates excellent characteristics due to its two-dimensional (2D) structure that exhibits tunable band gaps in the visible to near-infrared spectrum [11] and exceptional physicochemical properties [12]. Among the metal sulfides, tungsten disulfide (WS_2) possesses considerable advantages too, which is comparable to other existing metal sulfides. Tungsten is a d-block element from period 6 and sulfur is a p-block element from period 3. Interestingly, the band-gap of WS_2 changed from an indirect band-gap of 1.4 eV to a direct band-gap of 20 eV when a 2D material was isolated by a simple mechanical exfoliation technique from the bulk material. Due to the wide bandgap, WS_2 is seen as an interesting material for many areas of application, especially in the industry of solid lubricant, lithium-ion

battery, catalytic degradation, and electronic devices. By considering the pros and cons of both CPs and WS_2, numerous synthetic approaches have been developed with different morphologies, structures, and properties to satisfy the demands of different applications. WS_2 has been investigated with several types of CPs such as PANI, PPy and PEDOT. In the past decade, CP/ WS_2 composites have been found to have potential in several applications such as in supercapacitors, electronic components and sensors and actuators. However, a simple search in the SCOPUS database with a combined search string specifically on CPs and WS_2 only resulted in less than 50 papers, indicating that more extensive research is needed to cultivate and promote the CP/WS_2 binary composites. Therefore, this mini-review is an attempt to scrutinize the potential applications of CP/WS_2 composites and its benefits.

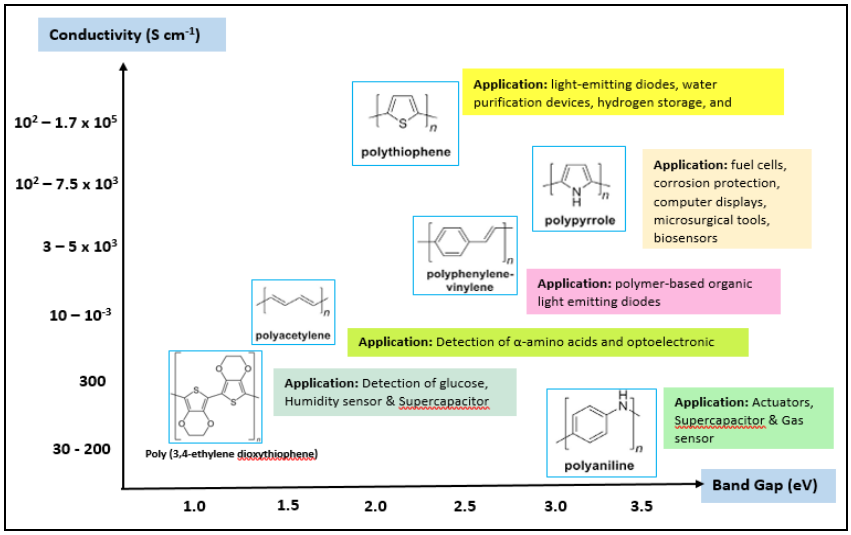

Figure 1. Various types of CPs assigned to a specific range of conductivity and band gap including their existing applications

Brief history of tungsten disulfide composites

Tungsten disulfide (WS_2) or also known as tungstenite is an inorganic compound which is composed of tungsten and sulfur with a molar mass of 247.98 g/mol. In the past, WS_2 has shown great potential for a high-temperature solid lubricant used in space as jotted in the National Aeronautics and Space Administration (NASA) record (History of Tungsten Disulfide (WS_2), 2018). The idea was initiated due to inefficient spacecraft mechanisms which cannot be inspected or maintained after launched. It was discovered that some parts of the spacecraft were not well-lubricated. On top of that, any satellite components that are subject to sliding wear must be properly lubricated to withstand the requirements of the mission. In that sense, WS_2 became the promising candidate due to its anti-friction properties that attributed by its crystal structure, which consists of hexagonal close-packed atomic tungsten layers sandwiched between two hexagonally closed atomic layers of sulfur. Weak Van der Waals forces that hold two adjacent sulfur layers allow them to slide for lubrication purposes [13]. Progressively, the success of WS_2 as a layered structure has expanded due to their interesting anisotropic behavior, great diversity in other physical properties and its advantages for various applications when added to base oil under specific laboratory test conditions. The composition of WS_2 with folded triple-layer of S-W-S sheets enables the atoms within each triple layer to be held by potential carbon-carbon bond. Each bond is clenched by weak Van der Waals interactions. This anisotropic nature of WS_2 therefore opens an opportunity to be

incorporated into different types of polymer matrices, resulting in high strength moduli and a good ability for shock absorption [14].

Synthesis method of WS_2

The synthesis of WS_2 composite usually involves multiple steps. Pristine WS_2 must be prepared prior to the integration with a specific CP. Then, WS_2 can be utilised to synthesise CP/WS_2 composite commonly via chemical oxidative method [15]. Every synthetic route for metal disulfide (MS_2) synthesis offers different outputs. The synthesised material can be tailored in order to develop various functions and applications for the metal sulfide [16]. For WS_2, every type of synthetic methods conducted possess several pros and cons depending on the processes involved. Hydrothermal and solvothermal syntheses are a few of the existing methods to synthesise WS_2 that have different synthetic route and its own significance.

Hydrothermal synthesis

Hydrothermal synthesis has been reported as an appealing method due to its simple procedure and productivity. Due to its advantages of low temperature, large-scale development and simple synthesis, it is an environmentally friendly technique for the preparation of various nanostructures [17]. In addition, hydrothermal method leads to the development of nanoscale products under supercritical pressure, which is cumbersome via classical routes. In this method, sodium thiosulfate and hydroxylamine sulfate are the important chemical ingredients. Hydroxylamine sulfate not only acts as the source of sulfur, but is also utilised as a strong acid to establish an acidic state for the nanoparticles that may form. Moreover, WS_2 can also be produced with a chrysanthemum-like nanostructure via hydrothermal synthesis. According to Tang et al. [18], the addition of pluronic and cetyltrimethyl ammonium bromide (CTAB) significantly affect the growth and final morphology of the WS_2. The resulted self assembled chrysanthemum-like nanostructures were grown prior to a fast nucleation of amorphous primary particles and slow aggregation of nanosheets [19]. Prominently, this method is interesting since large-scale metal sulfide composite can be achieved via this technique. However, this method is limited to aqueous precursors which might restrict the control over certain optimisations like temperature, reaction time, and type of solvent.

Solvothermal synthesis

Typically, solvothermal synthesis is a technique for preparing a variety of materials such as ceramics, polymers, metals and semiconductors. It might imitate the hydrothermal synthesis method but what differentiate both of them is the precursor type. Both hydrothermal and solvothermal synthesis use aqueous and non-aqueous precursor solution, respectively [20]. This method may adjust certain experimental parameters including temperature of reaction, time of reaction, type of solvent, type of surfactant, and type of precursor to ensure precise control of the size, distribution of shape and crystallinity of the nanostructure product. Focusing on WS_2, one step exfoliation-restacking technique is invalid to be employed even though WS_2 has similar chemical structure with MoS_2. The reason why this restacking technique makes the WS_2 layered nanocomposites difficult to obtain is because the precursor does not have optimum concentration. Hence, the solvothermal method is used to increase the amount of lithium introduced in WS_2 in order to improve processability [21].

Applications of conducting polymer/tungsten disulfide

The electrical properties of polymeric materials have piqued researchers' attention in the field of solid-state electronics. Generally, CPs by nature reveal poor electrical conductivity due to the absence of free moving electrons to enable the conduction process. However, when the CPs undergoes doping treatment with oxidizing or reducing agent, they can exhibit reasonable conductivity [22]. As a result of the presence of both the polymer and the filler material, a range of inorganic materials may be integrated into CPs with improved characteristics. Metal sulfide appears to be a superior alternative for making hybrid CP composites than metal oxide and other carbon derivatives. Metal sulfide is not only inexpensive and abundant in nature, but it also performs well in faradic redox reactions, making it useful in the fuel cell

business. When it comes to the WS_2 nanostructure, the weak Van der Waals interactions indicate that it is anisotropic, and it is well known for its high strength moduli and shock absorption capabilities [14]. However, WS_2 has a drawback in the form of short cycle stability, which causes the capacitance to rapidly degrade. As a result, including WS_2 into CP matrices might be a promising method to improve the stability and combine favourable physical properties of both organic and metallic components while retaining capacitance in a single composition [23].

Polyaniline/Tungsten Disulfide (PANI/WS_2)

Since PANI is one of the most promising CP with enhanced properties, researchers actively synthesize and analyze the PANI composites in numerous applications. A lot of papers were published on the preparation of conducting composites of PANI, such as PANI/TiO_2, PANI/ZrO_2, PANI/Fe_3O_4, PANI/MoO_3, PANI/zeolite, PANI/WO_3, PANI/MnO_2 and PANI/WS_2 from metal sulfide groups [24]–[31]. Despite many papers have been published regarding PANI composites, PANI/WS_2 are still lagging in terms of research and have limited source of information. Only a few reports were found using PANI/WS_2 in the fabrication of micro supercapacitor microrobots and its incorporation with chlorin e6 (Ce6) to give a triple-synergistic strategy in tumor treatment [32]. In a study by Stejskal et al. [33] PANI/WS_2 was fabricated through in situ polymerisation. The flake-like semiconducting particles of WS_2 were coated with a thin film of PANI during the oxidation of aniline. In addition, scanning electron microscopy (SEM) analysis of PANI/WS_2 revealed a porous nature and seems to be robust, where the WS_2 particles interlinked the PANI nanorods. This is probably due to the fact that, WS_2 naturally exists as a stack layered material, where the incorporation of PANI provides additional strength to the whole structure.

Humidity sensors

Humidity is another critical parameter that significantly affects the operation of electronic components in the determination of geographical distribution and the maximum intensity of precipitation, biosphere and surface hydrology. Measurements of humidity or moisture level in the human body could be beneficial in evaluating a variety of physiological and metabolic conditions. Since low humidity has adverse effects on human health, the existence of humidity sensor is important in interpreting the growth, repair and aging mechanisms to regulate internal body conditions [34]. Manjunatha et al. [31] reported on the preparation of PANI/WS_2 composite by in situ polymerisation technique and demonstrated an excellent humidity sensing compare to pure WS_2 as reported by Guo et al [35]. Typically, PANI/WS_2 exhibits enhanced humidity sensing properties due to its porous nature. The porous nature is of paramount interest for the adsorption of water molecules, which is also an important aspect in developing humidity sensors. Consequently, the agglomerated flower-like structure with highly microporous nature of PANI/WS_2 is assumed to have an important role in the humidity sensing behaviour of the composite. Typically, the water vapour could find its way through micropores of PANI/WS2 to react and give response in the sensing mechanism. Figure 2 shows a uniform distribution of WS_2 micro-sized sheets in the matrix of PANI from the observation of a field emission scanning electron microscope (FESEM) micrograph of the composite with magnification 12kx.

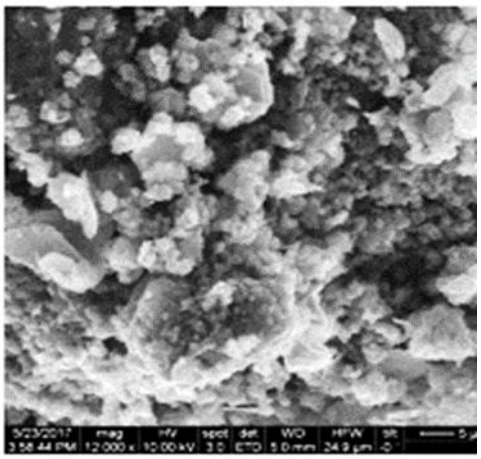

Figure 2. Field emission scanning electron micrograph of the PANI/WS_2 composite with 12000x magnification [31]

Ammonia gas sensor

The application of gas sensors in industries of environmental analysis, automotive, medical applications and indoor air quality controls have been developed for more than a decade ago due to the enforcement of the Occupational Safety and Health (OSHA) regulations against volatile hazardous gases [36]. Among the hazardous gases, ammonia (NH_3) has received major attention in the field of gas sensors due to its abundance in chemicals manufacturing industries and applied in diverse areas around the world [37]. Hybrid PANI/WS_2 composite promises a synergetic effect for NH_3 gas detection. The mechanism of NH_3 gas sensing by PANI/WS_2 can be proposed based on electron donation concept. Complementary to each other, PANI is a p-type conducting polymer with a linear conjugation of π−electronic system, while WS_2 is an n-type semiconductor whose band gap increases with the decrease in the number of stacked layers. The fact that NH_3 could donate electrons to the p-type PANI resulted in a decrease in the hole-transport concentration and next, deprotonation reaction caused the resistance of PANI to incline. Consequently, PANI/WS_2 showed high selectivity towards NH_3 gas with long term stability and repeatability [38]. The magnificent sensing capability of PANI/WS_2 sensor in humid environments and at room temperature makes it a suitable candidate for environmental monitoring devices [39].

Supercapacitor

Self-propelled supercapacitor device based on WS_2 nanoparticles-polyaniline/platinum (PANI/Pt) microrobot design opened a new insight that it can act as an on-demand reconfigurable device owing to its superior capacitance of 14000 μFcm^{-2} with energy density and power density of 0.07 $mWhm^{-2}$ and 120 mWm^{-2}, respectively [40]. Due to great capacitance result exerted by this microbot, it is expected to be proficient for on-demand construction and adjustment of the electronic devices. The fabrication of this autonomous WS_2NPs-PANI/Pt self-propelled microsupercapacitor for on-site electronics delivery in the circuit involved an electrodeposition process using cyclopore polycarbonate membrane as a template. WS_2NPs-PANI/Pt micromotors (μ-motor) fabrication process is shown in Figure 3.

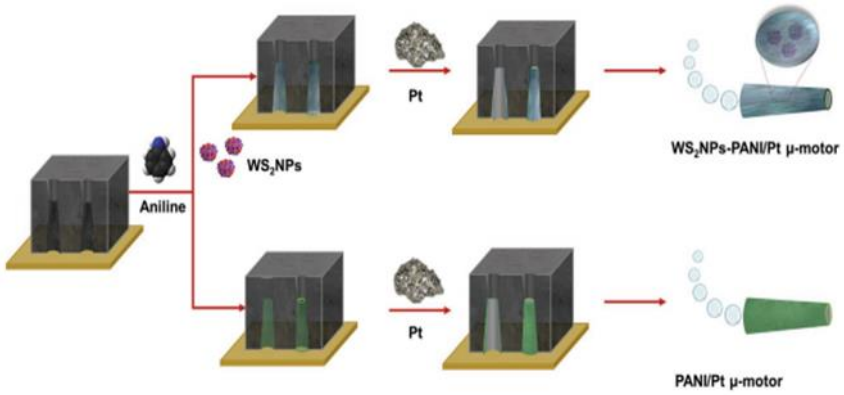

Figure 3. Schematic representation of WS_2NPs-PANI/Pt μ-motor fabrication process. Reproduced with permission from ACS [40].

Polypyrrole/Tungsten Disulfide (PPy/WS_2)

The integration between PPy and WS_2 nanocomposites exhibited a conductivity higher than the pristine WS_2 at ambient temperature [37]. In addition, WS_2 coated with PPy has benefit of wettability. In simple words, wettability is the ability of surface to reduce the surface tension of the liquid that is in contact with it and allow the liquid to spread over the surface and wet [41]. Wettability is important in adhesion as it provides quality for adhesive bonding and coating. Besides, synthesis of PPy/WS_2 can be steered by in-situ oxidative polymerization. The oxidation of pyrrole yields water-insoluble pyrrole oligomers that is further adsorbed on an immersed surfaces and continually grow the PPy chains. Typically, the process started with adsorption where the PPy patches are reinforced into chain colonies and are then grown slowly, resulting in uniform brush-like coating on the entire film [42] to the extent whenever the substance are still available, additional PPy globules will continuously be produced. The PPy globules are produced on hydrophilic PPy films or in surrounding aqueous phase and the globules stick to the film surface. In this context, the deposition of CPs are hydrophilic or hydrophobic surface dependent [43]. The product therefore generally consists of two phases which involve a thin polymer film deposited on the substrate and globular PPy. These two phases were demonstrated by the morphology analysis where, at a composition of 23.7 wt.% of PPy content, WS_2 flakes readily become coated with PPy. Furthermore, the appearance of additional PPy globules was due to the increment of the PPy content up to 38.3%. The idea of uniform PPy coating on WS_2 is due to the different hydrophobicity of pyrrole oligomers in conjunction to the fact that WS_2 is mildly hydrophilic [41].

Hydrogen evolution reaction

Hydrogen evolution reaction (HER) is basically a water splitting technology which found importance in energy storage based on hydrogen evolution. The combination of PPy and WS_2 seems to be a promising composite in the HER catalytic process due to the enhanced conductivity and wettable properties of this composite. Stejskal and co-workers [41] prepared PPy/WS_2 in various ratio of pyrrole monomer. The study revealed that excess of PPy globules would block the active edges of WS_2 in HER, despite of improved conductivity. However, a significant result was attained upon physical mixing of the PPy and WS_2 as a result of proton abundancy which was responsible for capacitive charging process in HER.

In Vivo drug release

Traditional drug delivery medications, such as oral administration and injections, tend to deliver greater drug concentrations than necessary, which may cause side effects in patients. Therefore, externally controlled drug delivery systems are of special relevance for study because they enable for drug delivery control from outside the body [44]–[46]. Particular interest on PPy functionalized WS_2 was paid by Hsiao and co-workers [47] since the composite possesses excellent synergistic properties to fine-tune the electrical properties to enable an electrically active nanocarrier system for an effective drug delivery to the target organ. The study revealed that a large quantity of anti-cancer drug, such as 5-fluorouracil (5-FC), be effectively delivered (90%) in the presence of electrical stimulation. They also successfully reported could that no toxic effect was evident in the electrical stimulation of PPy/WS_2.

Poly (3,4-ethylenedioxythiophene: Poly (Styrene Sulfonate)/Tungsten Disulfide (PEDOT: PSS/WS_2)

Poly(3,4-ethylenedioxythiophene): poly(styrene sulfonate)/tungsten disulfide, PEDOT:PSS/WS_2 is one of the ternary CPs composites as a potential material in thermoelectric applications due to its various benefits such as adjustable electrical conductivity and solution processability [49, 50]. PSS is a polymer surfactant, which enhances the dispersion and stability of PEDOT in water and other solvents [50]. PEDOT:PSS is well-known in the thermoelectric field for its excellent mechanical flexibility, low thermal conductivity, water solubility and processability [51]. As PEDOT:PSS went through a small treatment via direct vacuum filtration, the composite has been enhanced with high

electrical conductivity. Since then, research related with incorporation of inorganic nanostructures with PEDOT:PSS to enhance the thermoelectric performances has been expanding [49].

The introduction of PEDOT:PSS into WS_2 resulted in a composite that facilitated the charge carriers to move along the polymer chains, which effectively improved the charge transfer within the composite [52]. The fabrication technique was utilized due to the poor conductivity of WS_2, where the lateral transfer of electrons along the lamella structure of the WS_2 nanostructures were blocked, making the electron transfer inefficient. PEDOT:PSS also acts as spacers to avoid restacking of WS_2 and provide plenty of channels to enhance the charge transport. Moreover, synthesized the PEDOT:PSS/WS_2 thin film synthesized may easily be peeled off and transferred to another substrate, resulting in more potential applications. Therefore, stronger performing thermoelectric composite such as PEDOT:PSS/WS_2 carries better properties rather than the pristine PEDOT:PSS and pristine WS_2 [52].

Schottky diodes

In a study by Ortiz et al. [53], PEDOT:PSS/WS_2 Schottky nano-diode was constructed through hetero-junction of a hole transporting CP with an n-type semiconductor. In order to fabricate this composite, individual PEDOT:PSS was synthesized via electrospinning while the mono- and multi-layer WS_2 flakes were synthesized via chemical vapor deposition (CVD). These combination methods are developed from a previous research that implemented electrochemical polymerization techniques [54]. The previous experiment demonstrated poor device operation due to undesirable chemical reactions with the inorganic semiconductor. In terms of performance, the equations in standard thermionic emission model of a Schottky junction were used and from there it exerts an ideality parameter of 1.9 and a barrier height of 0.58 eV. Far from being ideal, the high ideality parameter measured value for this device may be contributed by the recombination of hole and electrons at the interface or the presence of interface states at the CP/WS_2 interface. Even so, upon large surface to volume ratio of the film, semiconductor carrier density is tunable via a back-gate bias and the reversible change of barrier height makes it potentially useful as a sensor [53].

Supercapacitor

In the organic semiconducting family, PEDOT has triggered worldwide interest owing to its development as pioneer for electronically conducting polymers (ECPs). However, the fact that PEDOT has outstanding electrochemical properties is still insufficient for it to meet the needs of practical applications. To overcome the problem, WS_2 has been incorporated into PEDOT to accelerate its applications in the fields of various devices, especially for the supercapacitors [55]. Nevertheless, to excel as high-performance supercapacitors, PEDOT/WS_2 may need to form a ternary composite with another compound. The combination of the three components in nanoscale creates a synergistic effect and higher potential in the faradaic processes Xia et al. [34]. For instance, a recent study in the electrical field by Liang et al. [56]reported that the use of poly(3,4-ethyleenedioxythiophene)-poly(ethylene glycol)-tungsten disulfide (PEDOT-PEG-WS_2) as ternary compounds exhibited good performance as a supercapacitor. PEDOT-PEG-WS_2 nanocomposite was prepared via electrochemical self-assembly of PEDOT and WS_2 nanosheets in the presence of PEG.

This ternary composite has resulted in a unique three-dimension interpenetrating porous network (3D-IPN) in nano-/micro scale. The addition of 5% PEG surfactant has effectively stabilized the WS_2 nanosheets that coexist with additional electrolytes. 3D-IPN materials has gained attention for its high-volume ions transport system and utilization of limited space that allows enhancement of energy storage capacity. Moreover, the 3D-IPN confined to metal-organic framework helps to build and verify automotive hydrogen storage systems that will allow hydrogen-fueled vehicle platforms to meet customer specifications. The optimization of PEDOT-PEG-WS_2 nanocomposite has been developed from the WS_2 contents and CV cycles adjustment. Based on their CV area and specific capacity of each sample, it was found that the as-prepared PEDOT-PEG-WS_2 nanocomposite has reached maximum specific capacity by adding 2.7% WS_2 in solution and 50 electrodeposition cycles.

Other than that, electrochemical properties of the engineered 3D IPN-PEDOT-PEG-WS_2 nanocomposite were recognized and compared with PEDOT-PEG [56].

Organic photovoltaic cells

OPV is an electrical device that converts light directly into electricity by photovoltaic cells, which combine physical and chemical phenomenon. The great characteristics such as low cost, light weight, flexible and scalability through roll-to-roll coating processes make OPV is great for green technology. The performance of OPV can be improved by a few ways including device structure optimization, conversion of light to suitable absorbance wavelengths and synthesis of new short band-gap polymers. PEDOT:PSS is familiar in hole-extraction layers (HEL) which works as buffer layers between the active layer and electrode. Recently, researchers have discovered that MoS_2 based OPVs utilizing PEDOT:PSS HEL, possesses better performance due to increased hole extraction and light absorption [57]. This finding has opened a venue for WS_2 to replace traditional MoS_2 as HEL in OPVs since it is structurally similar to MoS_2 with some expectation to enhance device performance equally or better. Surprisingly, a study by Lin and co-workers [58] exhibited excellent results of the OPV device performance through the implementation of an WS_2 HEL layer combined with the indium tin oxide (ITO) anode, PEDOT:PSS layer, poly (3-hexylthiophene) (P3HT) and phenyl-C61-butyric acid methyl ester (PCBM) [58]. In this study, WS_2 nanosheets were obtained by a simple ultra-sonication method and were uniformly spin coated on a ITO/glass as visualized in Figures 4 (a) and (b). Next, the hole-extraction efficiency of WS_2 was amplified by a UV-ozone treatment which at the same time empowered the OPV device.

In another study by Le and co-workers [59], the effect of WS_2 upon UVO treatment was investigated by introducing WS_2 into CP composites such as PEDOT:PSS, P3HT:PCBM and lithium fluoride/aluminum (LiF/Al) [59]. As expected, the change in work function of WS_2 due to UVO treatment enhanced its hole-extraction properties. The power conversion efficiency (PCE) of the OPV with WS_2/PEDOT:PSS was 3.07%, which is superior compared to the OPV with only PEDOT:PSS layer of 2.87%. Therefore, the study agreed on a deduction that high PCE resulted from the efficiency of charge separation and collection processes by WS_2/PEDOT:PSS.

Polyfluorene/ Tungsten Disulfide (PFO/ WS_2)

Polyfluorene (PFO) is an attractive material for display applications such as light source in organic light emitting diodes (LED) due to efficient blue light emission, good solubility and high mobility. Light absorption of PFO in the UV region falls

approximately at 380 nm. Beyond the desired blue emission at 425 nm, a green component close to 530 nm can either be attributed to intermolecular interactions or oxidation-induced keto defects that cause aggregates to form [60]. According to Luccio et al. [61], even though the energy emission is low, the removal of the inter-chain interaction enhanced the color purity and luminescence stability of PFO/WS_2. Considering WS_2, both fullerene-like nanoparticles (F-WS_2-NP) and nanotube (WS_2-NT) structures work differently. F-WS_2 is more into lubricating fluids, self-lubricating coatings and medical devices. Meanwhile, WS_2-NT is great at improving the mechanical properties of CP composites [61]. With respect to that, the addition of inorganic nanomaterial like WS_2 ensures color emission tunability. Not to mention, the exhibited optical and electrical properties of PFO/WS_2 depends on the number of WS_2 layer present [61]. The surface morphology of PFO has a smooth appearance at a glance as shown in Figure 5 (a). Meanwhile, SEM images of PFO/WS_2 nanocomposite films showed high dispersion of WS_2 nanotubes upon various WS_2 concentration from 10 wt.% to 50 wt.% as displayed in Figure 5 (b–d). It is observed that the dispersion of the WS_2-NT is quite homogeneous for all the concentrations investigated, even though some nanotube agglomerates remain. This finding suggests a further study is needed either on the purification of nanotubes or the preparation of the blend.

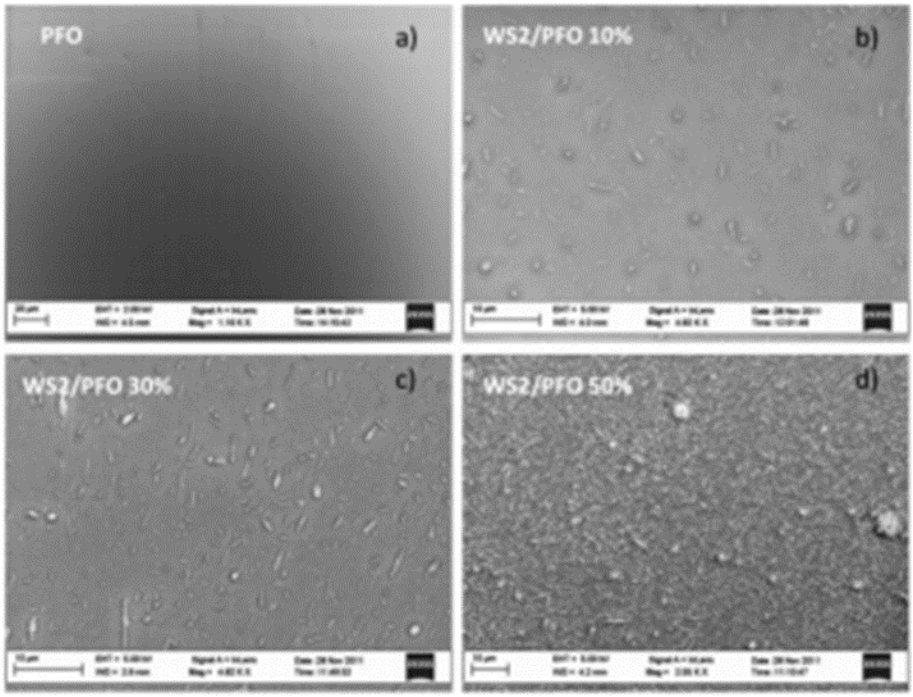

Figure 5. Scanning electron microscope images of a) bare PFO, and PFO/WS_2 nanocomposites at b) 10 wt.% c) 30 wt.% and d) 50 wt.% [61].

Organic light-emitting diode

An organic light-emitting diode (OLED) is a light emitting diode in which organic layers are responsible for light emission. The light emitted by OLED follows the basic principal of electroluminescence in which a material acts in response to the electrical field applied across it [62]. In context of CP/WS_2, PFO has recorded an investigation where PFO matrix and WS_2 nanotubes were combined to prepare PFO/WS_2 blends with various loadings of 10 wt.%, 30 wt.%, and 50 wt.%. The fabrication of these homogeneously dispersed PFO/WS_2 composites were influenced by two major steps including the WS_2 nanotube purification and the blend preparation. An optimization on the threshold

voltage has recorded the highest voltage of 4.7 V when 30% of WS_2 was integrated with PFO, and surprisingly the threshold voltage depreciated at 50% of WS_2 and recorded 4.1 V which was almost similar to pure PFO. Compared to pure PFO, the devices containing the nanocomposites has poor efficiency. This is because the electrical data exhibited that the PFO/WS_2 nanocomposite device of WS_2 showed fluctuated performances with increasing wt.%. Such unsynchronized data of threshold voltage and efficiency of the tailored material might be contributed by several factors such as unbalanced charges and electrode interfaces. It also could be due to the change of the device working point or total applied power [61]. Table 1 summarizes various CPs/WS_2 composites with its respective summary on desired applications and advantages.

Table 1. Summary of CP/WS_2 in various application and their significant advantages

Conducting Polymer/WS_2	**Application**	**Advantage**	**Remarks**	**Ref.**
PANI/WS_2	Dye sensitized solar cell (DSSC)	Higher conversion efficiency of WS_2 compare to platinum counter-electrode. Relatively cheaper cost compares to platinum.	Nano-sheets of WS_2 and nano-rods of PANI were used in the investigation.	[63]
	Supercapacitor	The higher composition of PANI in the WS_2 matrix has enhanced the supercapacitor performance.	Conductivity: 65.7 S/m; Specific capacitance: 441 at 0.5A/g.	[64]
	Supercapacitor	Exhibited excellent electrochemical properties and high frequency response.	High capacitance of 180 $\mu Fcm^{-}{}_2$ at 1_20 Hz. Potential use in energy storage device.	[65]
	Sensor	The sensor showed an excellent result under humid environment which can be utilized in the respiratory gases.	Ammonia sensor	[39]
PPy/WS_2	Drug release	Biocompatible Non-invasive electrically stimulating drug release system	5-fluorouracil (anticancer drug)	[47]
	Potential use in medium-frequency devices such as humidity and gas sensors.	Excellent operation in terms of AC conductivity and dielectric properties.	PPy with 40 wt% of WS_2 possessed highest conductivity of 5.081 x 10^{-3} S/cm.	[66]

Table 1 (cont'd). Summary of CP/WS_2 in various application and their significant advantages

Conducting Polymer/WS_2	**Application**	**Advantage**	**Remarks**	**Ref.**
PPy/WS_2	Humidity sensor	Excellent long term-stability.	Response/recovery = 5_2/58 s, respectively. Long term stability up to 60 days at 55 and 95% relative humidity.	[67]
PEDOT/WS_2	Electrochemical sensor	WS_2 has enhanced the denseness and smoothness of PEDOT morphology. The ternary composite of SWCNT/WS_2-PEDOT showed good linear response in the range of 0.00_2 – 0.9 μM with low LOD of 0.7 nM in the Vitamin B_2 detection.	The study involves molecularly imprinted polymer of WS_2-PEDOT in the presence of Vitamin B_2 as the template.	[68]
	Supercapacitor	The supercapacitor showed long-term stability up to 5000 cycles by retaining 83.3% of initial areal capacitance.	Hybrid material of ternary composites consist of PEDOT, MeOH, PEG and WS_2 were prepared using simple co-electrodeposition method.	[69]
	Schottky diode	Novel material of PEDOT/WS_2 used for the first time in nano-diodes. The perfect ambient tolerance of the diode makes it an ideal candidate for gas or light sensors.	The combination of PEDOT and WS_2 has resulted in rectification ratio of 1_2 and a turn-on voltage of 1.4 V.	[53]
	Miniature-supercapacitor	Simple and cost-effective fabrication of WS_2/PEDOT:PSS ternary composite. Improved flexibility in the miniaturized supercapacitor.	The WS_2/PEDOT:PSS supercapacitor recorded a high conductivity of 44 S/cm, high areal specific capacitance of 86 $mFcm^{-}{}_2$, and 107% capacitance retention after 5000 cycles.	[70]

Table 1 (cont'd). Summary of CP/WS_2 in various application and their significant advantages

Conducting Polymer/WS_2	**Application**	**Advantage**	**Remarks**	**Ref.**
Polythiophene/WS_2 (PTh/WS_2)	Functionally designed PTh/WS_2	Shown good magnetic effect which could find potential use in microwave absorbing materials.	Modified liquid phase oxidative polymerization that controls interface PTh-based layered material.	[71]
	Functionally designed coating method for Pth/WS_2	Electro-conductivity and mechanical properties of WS_2 has been enhanced via the tailor-made functionalization.	Potential use in drug release control.	[72]
PFO/WS_2	Organic Light Emitting Diodes	PFO with 30% of WS_2 showed a threshold voltage of 4.7 V when 30% of WS_2.	PFO/WS_2 has been tested for the first time as OLED and it opens the door for new avenues for this composite material.	[61]

Conclusion

A widespread overview of CP composites has been studied in the context of their properties and existing applications. WS_2-based CPs offer a very broad and promising field of research, not only due to its enhanced properties but also because of the chances to achieve multifunctional nano systems from the synergic effect between CP and WS_2. In this mini-review, CP/WS_2 composite showed the best performance as energy storage material followed by electronic components and sensors. CP/WS_2 is a great choice for energy storage since it shows high capacitive behaviour even in a micro-sized supercapacitor. As a matter of fact, this material composite deserves a place in electronic and biomedical industries. Based on the findings and limitation of this research, some improvement can be made on low energy emission by PFO/WS_2. As abovementioned, WS_2 nanotubes were not fully homogenous in the PFO matrix. Henceforth, future research might consider nanotube purification in the fabrication of PFO/WS_2. Besides, CP/WS_2 can also consider more formation of ternary compounds inspired from the PEDOT-PEG-WS_2 composite. This is because the initiative of using ternary compound can strengthen the connection between CP and inorganic filler, thus exhibiting remarkable performance in supercapacitors due to better electrons transport.

Abstract

A set of chiral multi-substituted pyrrolidine diastereomers containing β-amino ester moiety (**5a-c**) were successfully synthesized from 4-carbethoxy-3-hydroxy-2-oxo-5-phenyl-3-pyrroline (**1**). The key intermediate endocyclic β-enamino ester (**4**) was prepared by methylamination of precursor **1**, followed by acid-catalyzed reduction of **4** using sodium cyanoborohydride to obtain target products (**5**) with moderate diastereoselectivity. Other exploration on the reduction of **4** includes the use of sodium triacetoxyborohydride in acetic acid and catalytic hydrogenation which are subsequently compared with the aforementioned approach in terms of selectivity. Several plausible reaction mechanisms have been proposed based on experimental data.

Keywords: pyrrolidine; β-enamino ester; diastereoselective reduction; catalytic hydrogenation; sodium cyanoborohydride.

Abstrak

Satu set diastereomer pirolidin multi-penukarganti kiral yang mengandungi bahagian ester β-amino (**5a-c**) telah berjaya disintesis daripada 4-karbetoksi-3-hidroksi-2-okso-5-fenil-3-pirolin (**1**). Perantara utama, ester β-enamino endosiklik (**4**), telah disediakan melalui metilaminasi pendahulu **1.** Kemudian, penurunan bagi **4** yang dimangkinkan oleh asid menggunakan natrium sianoborohidrid menghasilkan produk sasaran **5** dengan diastereoselektiviti yang sederhana. Tatacara lain untuk menurunkan **4** termasuk penggunaan natrium triasetoksiborohidrid dalam asid asetik dan penghidrogenan mangkin telah dibandingkan dengan kaedah terdahulu dari sudut selektiviti. Di sini, kami menghuraikan beberapa mekanisme tindakbalas yang munasabah daripada hasil eksperimen ini.

Kata kunci: pirolidin; ester β-enamino; penurunan diastereoselektif; penghidrogenan mangkin; natrium sianoborohidrid.

Introduction

β-enamino esters **A** are recognized as versatile building blocks in the synthesis of various interesting alkaloids [1] including bi- and tricyclic heterocycles such as pyrrolopyrimidines [2], pyrroloquinolines [3], indoles [4], pyrrolizidines and indolizidines [5, 6] (Figure 1). The multifunctionality of these compounds resides in the simultaneous presence of a nitrogen atom, a carbon-carbon double bond, C=C (which when reduced, gives rise to one or two chiral centre(s) and enhances the nucleophilicity of the nitrogen via the localization of its lone pair electrons) and an ester group for further chain extension or ring closure [7, 8].

Owing to their role as key intermediates for synthesizing naturally occurring compounds (Figure 2), this class of functional group has been of crucial interest to researchers especially for the chemistry of its enantio- and diastereoselective reductions.

Excellent enantioselectivity of catalytic hydrogenation over palladium hydroxide, $Pd(OH)_2$ enables the preparation of (+)-calvine, an alkaloid piperidine isolated from coccinellid beetles of the genus *Calvia* [9]. Hydrogenations in the presence of 10% platinum on carbon (Pt/C) and 10% palladium on carbon (Pd/C) offers high diastereoselectivity to reduce β-enamino esters with exocyclic C=C in the asymmetrical syntheses of (+)-laburnine and (+)-tashiromine, respectively. While the ones with endocyclic double bond can be reduced using platinum dioxide-catalyzed hydrogenation with a large diastereomeric excess (d.e. = 90%) as described in the synthetic approach of constructing (-)-isoretronecanol [10, 11].

Apart from that, chemical reduction by sodium triacetoxyborohydride, $NaBH(OAc)_3$ in acetic acid provides greater diastereoselectivity for enamino esters with endocyclic C=C rather than their exocyclic and acyclic counterparts [10], while in the presence of magnesium iodide (MgI_2), near quantitative yield can be achieved [12]. Sodium cyanoborohydride, $NaBH_3CN$ is a versatile reducing agent known for its ability to yield diastereopure β-amino esters as mentioned in the preparation of (±)-lythrancepine (II) and (III) [8].

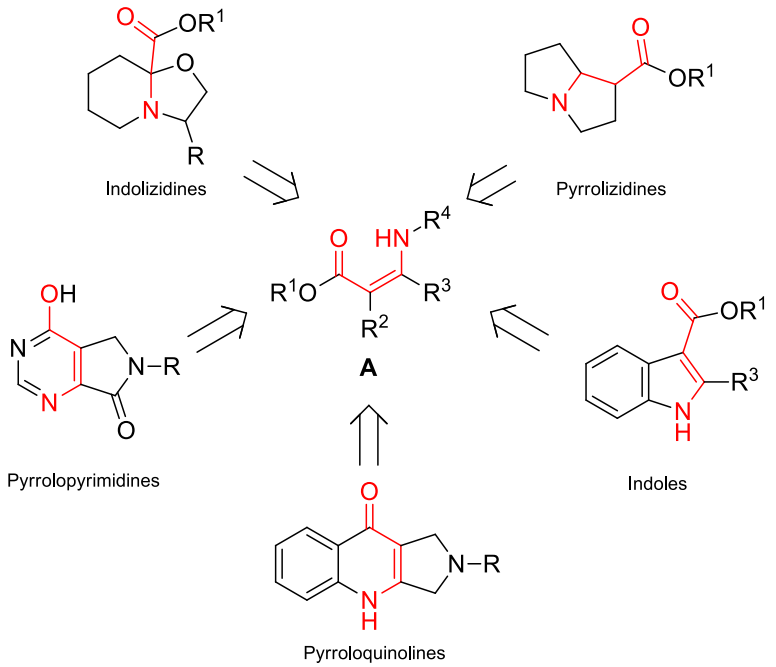

Figure 1. Bi- and tricyclic alkaloids derived from β-enamino esters

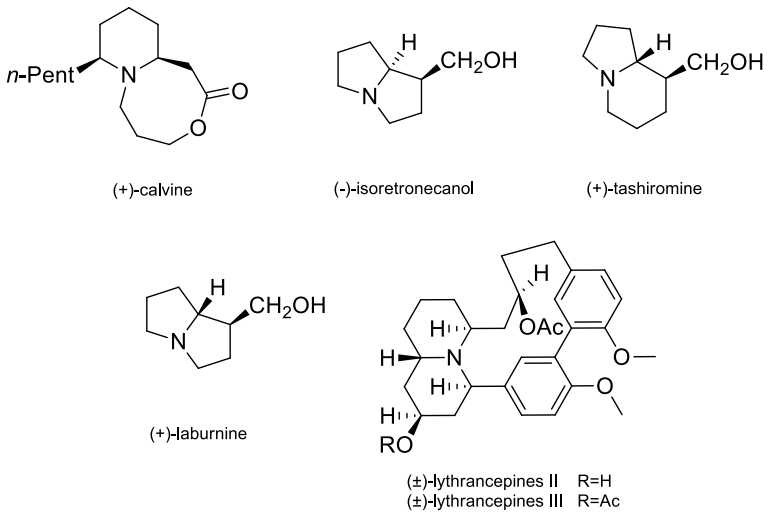

Figure 2. Naturally occurring compounds derived from selective reductions of β-enamino esters

Notably, some studies report that catalytic hydrogenations portray superior selectivity over chemical reductions when involving exocyclic and acyclic β-enamino esters [10, 13]. To our knowledge, there is yet any reported work that specifically discusses the chemistry behind the reduction of endocyclic β-enamino esters – i.e. comparison between the two approaches.

Ergo, in this short study, we describe an experiment to reduce β-enamino ester (**4**) containing endocyclic C=C. The procedures explored include hydrogenation with either 10% Pd/C or 20% $Pd(OH_2)$/C along with reduction using either $NaBH(OAc)_3$ in acetic acid or $NaBH_3CN$ in acidic medium. Different approaches are believed to have distinct stereochemical controls and effectiveness over the reduction protocols.

Materials and Methods

All reagents and solvents were supplied by R&M Chemicals, Merck KgaA and Acros Organics. The reactions were monitored by TLC on silica gel 60 F254 plates, Merck (layer thickness 0.25 mm) and visualized with UV light (254 and 365 nm) and $KMnO_4$ solution as the staining reagent. For product purification using column chromatography, Merck silica gel (230-400 mesh particle size) was used. Infrared spectra were recorded on Varian 3100 Excalibur Series FT-IR spectrometer in the range of 4000-400 cm^{-1}. ^{1}H-, ^{13}C- and 2D NMR spectra were captured on JEOL-400 (^{1}H 400 MHz, ^{13}C 101 MHz) NMR spectrometer.

Multicomponent reaction (MCR) to synthesize 4-carbethoxy-3-hydroxy-2-oxo-5-phenyl-3-pyrroline (1)

The method was adapted from literature [15]. Sodium diethyl oxalacetate (5.01 g, 24 mmol), benzaldehyde (2.4 mL, 24 mmol) and aqueous ammonia (8.0 mL, 119 mmol) were suspended in ethanol (70 mL) and refluxed. After an hour and 15 minutes, the reflux was stopped and once the mixture cooled down to room temperature, it was added to an ice bath. The mixture was acidified with concentrated HCl until it reached pH 2 while being constantly stirred. The resulting precipitate was filtered by suction and washed with distilled water. The solid was dried under vacuum overnight to give the product, 4-carbethoxy-3-hydroxy-2-oxo-5-phenyl-3-pyrroline, as a white solid (Yield: 2.67 g, 42%).

Analytical data: FT-IR (ATR) $\bar{\upsilon}$ (cm^{-1}) 3370 (O-H), 3311 (N-H), 2994 (C-H), 1689 (C=O); ^{1}H-NMR (400 MHz, CD_3OH) δ(ppm) 7.32-7.22 (m, 5H, ArH), 5.23 (s, 1H, ArC<u>H</u>NH), 4.10-4.01 (m, 2H, OCH_2), 1.06 (t, J = 7.1 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, CD_3OH) δ(ppm) 167.4 (C=<u>C</u>-OH), 163.5 (O-C=O), 155.0

(NHC=O), 137.4 (ArC-CH), 128.2 (ArCH), 127.9 (ArCH), 127.1 (ArCH), 114.0 (C=C-C=O), 60.1 (OCH_2), 57.3 (ArCHNH), 13.0 (CH_3).

Leuckart reaction to synthesize 3-amino-4-carboethoxy-2-oxo-5-phenyl-3-pyrroline (2)

The method was adapted from literature [2]. To a suspension of 4-carbethoxy-3-hydroxy-2-oxo-5-phenyl-3-pyrroline (**1**) (2.01 g, 8 mmol) in ethanol (40 mL), ammonium formate (1.03 g, 16 mmol) was added while stirring. After heating under reflux for 24 hours with TLC monitoring, the mixture was left to cool to room temperature. The solvent was evaporated under reduced pressure and the crude product was purified using column chromatography (petroleum ether/ethyl acetate: 2/1) to yield the product, 3-amino-4-carboethoxy-2-oxo-5-phenyl-3-pyrroline, as a white solid (Yield: 1.23 g, 62%).

Analytical data: TLC (Petreoleum ether/ethyl acetate : 2/1, R_f = 0.26); FT-IR (ATR) $\bar{\upsilon}$ (cm^{-1}) 3482 (N-H), 3385 (N-H), 3278 (N-H), 2965 (C-H), 1718 (conj. C=O), 1679 (C=O), 1625; ^{1}H-NMR (400 MHz, CD_3OH) δ(ppm) 7.28-7.19 (m, 5H, ArH), 5.16 (s, 1H, ArCHNH), 4.57 (s, 2H, NH_2), 4.06-3.99 (m, 2H, OCH_2), 1.07 (t, J = 7.1 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, DMSO-d_6) δ(ppm) 167.3 (O-C=O), 164.8 (NHC=O), 147.4 (C=C-NH_2), 140.3 (ArC-CH), 128.6 (ArCH), 128.0 (ArCH), 127.7 (ArCH), 103.3 (C=C-C=O), 59.3 (OCH_2), 57.8 (ArCHNH), 14.7 (CH_3).

Hydrogenation of 3-amino-4-carboethoxy-2-oxo-5-phenyl-3-pyrroline (2) over 10% Pd/C

This is our in-house method [19]. To a stirred solution of 3-amino-4-carboethoxy-2-oxo-5-phenyl-3-pyrroline (**2**) (0.50 g, 2.03 mmol) in acetic acid (50 mL), 10% Pd/C (0.30 g, 0.26 mmol) was added slowly. The reaction mixture was stirred vigorously under hydrogen atmosphere at 1 atm with TLC monitoring. After 22 hours, the reaction was stopped and the catalyst was filtered through Celite. The solvent was removed from the filtrate under reduced pressure to give a white solid. From TLC, FT-IR and NMR characterization experiments, it was concluded that the starting material **2** was recovered.

Analytical data: TLC (Petreoleum ether/ethyl acetate : 2/1, R_f = 0.26); FT-IR (ATR) $\bar{\upsilon}$ (cm^{-1}) 3482 (N-H), 3385 (N-H), 3278 (N-H), 2965 (C-H), 1718 (conj. C=O), 1679 (C=O), 1625; ^{1}H-NMR (400 MHz, DMSO-*d*6) δ(ppm) 9.10 (s, 2H, NH_2), 7.27-7.12 (m, 5H, ArH), 6.46 (s, 1H, NHC=O), 5.06 (s, 1H, ArCHNH), 3.91 (qt, J = 11.0, 3.5 Hz, 2H, OCH_2), 0.98 (t, J = 7.1 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, DMSO-d_6) δ(ppm) 167.3 (O-C=O), 164.8 (NHC=O), 147.4 (C=C-NH_2), 140.3 (ArC-CH), 128.6 (ArCH), 128.0 (ArCH), 127.7 (ArCH), 103.3 (C=C-C=O), 59.3 (OCH_2), 57.8 (ArCHNH), 14.7 (CH_3).

Synthesis of 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline (4)

The method was adapted from literature [2]. To a suspension of 4-carbethoxy-3-hydroxy-2-oxo-5-phenyl-3-pyrroline (**1**) (1.94 g, 8 mmol) in ethanol (40 mL), aqueous methylamine (40%) (1.4 mL, 16 mmol) was added while stirring. After heating under reflux for 24 hours with TLC monitoring, the mixture was left to cool to room temperature. After cooling in an ice bath, the resulting white crystals were filtered to give the product, 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline, as white crystals (Yield: 1.41 g, 69%).

Analytical data: TLC (Ethyl acetate, R_f = 0.83); FT-IR (ATR) $\bar{\upsilon}$ (cm^{-1}) 3351 (N-H), 2980 (C-H), 1698 (C=O), 1667 (C=O), 1633; ^{1}H-NMR (400 MHz, $CDCl_3$) δ(ppm) 7.30-7.20 (m, 5H, ArH), 6.48 (s, 1H, CH_3NH), 5.14 (s, 1H, ArCHNH), 4.04-3.93 (m, 2H, OCH_2), 3.34 (s, 3H, CH_3NH), 1.71 (s, 1H, CH_3NH), 1.03 (t, J = 7.1 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, $CDCl_3$) δ(ppm) 167.9 (O-C=O), 166.6 (NHC=O), 147.1 (C=C-$NHCH_3$), 138.9 (ArC-CH), 128.4 (ArCH), 128.1 (ArCH), 127.4 (ArCH), 104.8 (C=C-C=O), 59.5 (OCH_2), 57.9 (ArCHNH), 30.2 ($NHCH_3$), 14.1 (CH_3).

Hydrogenation of 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline (4) over 10% palladium on carbon (Pd/C)

This is our in-house method [19]. To a stirred solution of 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline (**4**) (0.50 g, 1.92 mmol) in acetic acid (10 mL), 10% Pd/C (0.20 g, 0.19 mmol) was added

slowly. The reaction mixture was stirred vigorously under hydrogen atmosphere at 1 atm with TLC monitoring. After 24 hours, the reaction was stopped and the catalyst was filtered through Celite. The solvent was removed from the filtrate under reduced pressure and the residue was purified by column chromatography (gradient elution) to yield the diastereomers of 4-carbethoxy-3-methylamino-2-oxo-5-phenylpyrrolidine as yellow oils; *cis-trans* **5a** (Yield: 51.9 mg, 10.3%), *all-trans* **5b** (Yield: 22.9 mg, 4.5%) and *all-cis* **5c** (Yield: 48.3 mg, 9.6%).

Analytical data: FT-IR (ATR) $\bar{\upsilon}$ (cm^{-1}) 3395 (N-H), 3200 (N-H), 2981 (C-H), 1698 (C=O), 1646 (C=O); *cis-trans* **5a**: TLC (Ethyl acetate, R_f = 0.53); ^{1}H-NMR (400 MHz, CD_3OH) δ(ppm) 7.38-7.28 (m, 5H, ArH), 4.98 (d, J = 4.8 Hz, 1H, H-5), 4.57 (s, 1H, $CH_3N\underline{H}$), 4.19-4.16 (dq, 2H, OCH_2), 3.60 (d, J = 8.4 Hz, 1H, H-3), 3.31 (m, 1H, H-4), 2.45 (s, 3H, $C\underline{H_3}NH$), 1.24 (t, J = 7.6 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, CD_3OH) δ(ppm) 176.0 (NHC=O), 171.1 (O-C=O), 140.4 (Ar$\underline{C}$-CH), 128.8 (ArCH), 128.1 (ArCH), 125.8 (ArCH), 61.4 (C-3), 60.8 (OCH_2), 58.0 (C-5), 53.9 (C-4), 34.0 ($NHCH_3$), 13.2 (CH_3). *all-trans* **5b**: TLC (Ethyl acetate, R_f = 0.13); ^{1}H-NMR (400 MHz, CD_3OH) δ(ppm) 7.40-7.31 (m, 5H, ArH), 4.73 (d, J = 8.2 Hz, 1H, H-5), 4.22-4.11 (m, 2H, OCH_2), 3.95 (d, J = 9.6 Hz, 1H, H-3), 3.01 (dd, J = 9.8, 8.5 Hz, H-4), 2.51 (s, 3H, $C\underline{H_3}NH$), 1.18 (t, J = 7.3 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, CD_3OH) δ(ppm) 175.6 (NHC=O), 173.4 (O-C=O), 140.0 (Ar$\underline{C}$-CH), 128.6 (ArCH), 128.3 (ArCH), 126.4 (ArCH), 62.7 (C-4), 61.4 (OCH_2), 58.2 (C-3), 55.4 (C-5), 32.2 ($NHCH_3$), 13.1 (CH_3). *all-cis* **5c**: TLC (Ethyl acetate, R_f = 0.31); ^{1}H-NMR (400 MHz, CD_3OH) δ(ppm) 7.38-7.29 (m, 5H, ArH), 5.11 (d, J = 6.4 Hz, 1H, H-5), 4.05 (d, J = 6.9 Hz, 1H, H-3), 3.86 (t, J = 6.9 Hz, 1H, H-4), 3.73-3.67 (m, 1H, OCH_2), 3.57-3.51 (m, 1H, OCH_2), 2.63 (s, 3H, $C\underline{H_3}NH$), 0.71 (t, J = 7.1 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, CD_3OH) δ(ppm) 174.6 (NHC=O), 169.4 (O-C=O), 136.6 (Ar$\underline{C}$-CH), 128.2 (ArCH), 126.3 (ArCH), 61.3 (C-3), 60.7 (OCH_2), 56.8 (C-5), 51.2 (C-4), 33.6 ($NHCH_3$), 12.5 (CH_3).

Hydrogenation of 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline (4) over 20% palladium hydroxide on carbon ($Pd(OH)_2$/C)

This method was adapted from our in-house method [19]. To a stirred solution of 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline (**4**) (0.50 g, 1.92 mmol) in acetic acid (10 mL), 20% $Pd(OH)_2$/C (0.13 g, 0.19 mmol) was added slowly. The reaction mixture was stirred vigorously under hydrogen atmosphere at 1 atm with TLC monitoring. After 24 hours, the reaction was stopped and the catalyst was filtered through Celite. The solvent was removed from the filtrate under reduced pressure and the residue was purified by column chromatography (gradient elution) to yield the diastereomers of 4-carbethoxy-3-methylamino-2-oxo-5-phenylpyrrolidine as yellow oils; *cis-trans* **5a** (Yield: 11.4 mg, 2.2%), *all-trans* **5b** (Yield: 0.7 mg, 0.1%) and *all-cis* **5c** (Yield: 10.3 mg, 2.0%).

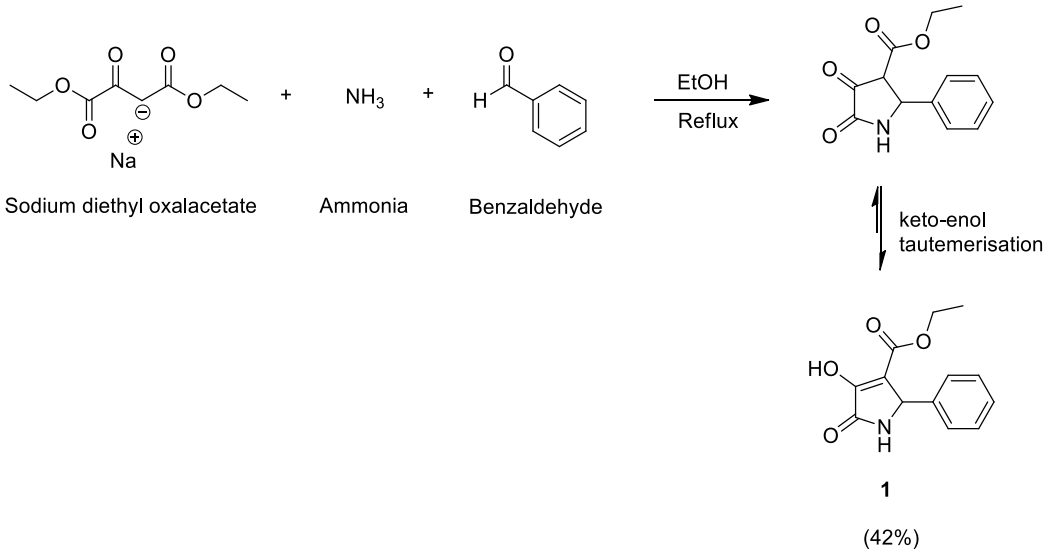
Reduction of 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrrolines (4) by sodium triacetoxyborohydride ($NaBH(OAc)_3$)

The method was adapted from literature [9]. A solution of $NaBH(OAc)_3$ was prepared by the addition of sodium borohydride ($NaBH_4$) (0.73 g, 19 mmol) to glacial acetic acid (5.6 mL, 96 mmol) at 0 °C and the mixture was stirred for 30 minutes at room temperature with some evolution of hydrogen gas. Then, 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline (**4**) (1.01 g, 4 mmol) in acetonitrile (25 mL) was transferred into the previous mixture. The resulting mixture was stirred vigorously for 48 hours before being neutralized by saturated Na_2CO_3 solution. Upon extraction by dichloromethane, the organic phase was washed with brine and dried over anhydrous $MgSO_4$. The solvent was removed from the organic phase *in vacuo* to give a white solid**.** From TLC, FT-IR and NMR characterization experiments, it was concluded that the starting material **4** was recovered.

Analytical data: TLC (Ethyl acetate, R_f = 0.79); FT-IR (ATR) $\bar{\upsilon}$ (cm^{-1}) 3351 (N-H), 2980 (C-H), 1698 (C=O), 1667 (C=O), 1633; ^{1}H-NMR (400 MHz, $CDCl_3$) δ(ppm) 7.30-7.21 (m, 5H, ArH), 6.43 (s, 1H, $CH_3N\underline{H}$), 5.14 (s, 1H, Ar$C\underline{H}$NH), 4.04-3.93 (m, 2H, OCH_2), 3.35 (s, 3H, $C\underline{H}_3NH$), 1.70 (s, 1H, $CH_3N\underline{H}$), 1.03 (t, J = 7.1 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, $CDCl_3$) δ(ppm) 167.9 (O-C=O), 166.6 (NHC=O), 147.1 (C=$\underline{C}$-$NHCH_3$), 138.9 (Ar$\underline{C}$-CH), 128.4 (ArCH), 128.1 (ArCH), 127.4 (ArCH), 104.8 (C=$\underline{C}$-C=O), 59.5 (OCH_2), 57.9 (ArCHNH), 30.2 ($NHCH_3$), 14.1 (CH_3).

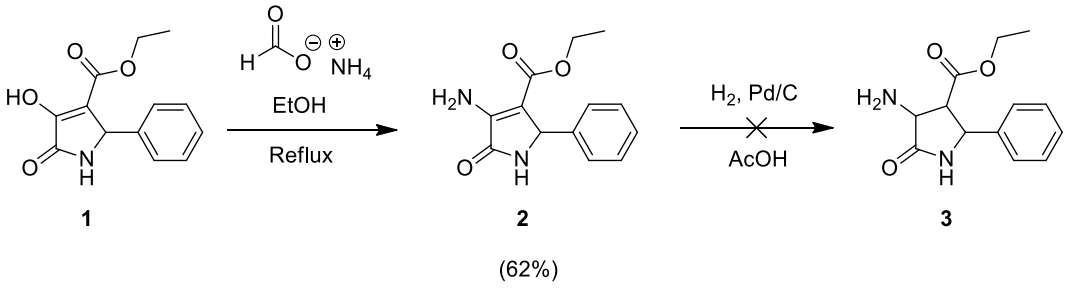
Reduction of 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline (4) by sodium cyanoborohydride ($NaBH_3CN$)

The method was adapted from literature [8]. Traces of bromocresol green was added to 4-carboethoxy-3-methylamino-2-oxo-5-phenyl-3-pyrroline (**4**) (1.00 g, 4 mmol) in methanol (20 mL) while stirring followed by $NaBH_3CN$ (0.97 g, 15 mmol). Dilute MeOH-HCl mixture was added dropwise until the colour of the reaction mixture turned yellow. More MeOH-HCl was added to the mixture periodically to maintain the yellow colour (pH ~4) with TLC monitoring. After 24 hours, the reaction was quenched by dropwise addition of 0.1 N NaOH solution (saturated with NaCl) until the mixture turned blue. The crude product was extracted by ethyl acetate and the organic phase was washed with brine and dried over anhydrous $MgSO_4$. The solvent was evaporated under vacuum and the residue was purified by column chromatography (gradient elution) to give the diastereomers of 4-carbethoxy-3-methylamino-2-oxo-5-phenylpyrrolidine; *all-trans* **5b** (Yield: 174.7 mg, 34.7%) and *all-cis* **5c** (Yield: 97.6 mg, 19.4%).



Analytical data: FT-IR (ATR) $\bar{\upsilon}$ (cm^{-1}) 3391 (N-H), 3306 (N-H), 2977 (C-H), 1718 (C=O), 1698 (C=O); *all-trans* **5b**: TLC (Ethyl acetate, R_f = 0.49); ^{1}H-NMR (400 MHz, $CDCl_3$) δ(ppm) 7.37-7.31 (m, 5H, ArH), 6.42 (s, 1H, $CH_3N\underline{H}$), 4.78 (d, J = 8.2 Hz, 1H, H-5), 4.18-4.16 (m, 2H, OCH_2), 3.84 (d, J = 9.6 Hz, 1H, H-3), 3.06 (t, J = 8.9 Hz, 1H, H-4), 2.16 (s, 3H, $C\underline{H}_3NH$), 1.20 (t, J = 7.1 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, $CDCl_3$) δ(ppm) 173.9 (NHC=O), 171.7 (O-C=O), 139.5 (Ar$\underline{C}$-CH), 129.0 (ArCH), 128.7 (ArCH), 126.5 (ArCH), 63.6 (C-3), 61.7 (OCH_2), 57.9 (C-5), 55.9 (C-4), 31.1 ($NHCH_3$), 14.1 (CH_3). *all-cis* **5c**: TLC (Ethyl acetate, R_f = 0.26); ^{1}H-NMR (400 MHz, $CDCl_3$) δ(ppm) 7.33-7.29 (m, 3H, ArH), 7.18-7.16 (m, 2H, ArH), 6.64 (s, 1H, $CH_3N\underline{H}$), 5.00 (d, J = 9.6 Hz, 1H, H-5), 4.10 (d, J = 9.1 Hz, 1H, H-3), 3.81-3.76 (m, 1H, H-4), 3.73-3.61 (m, 2H, OCH_2), 2.15 (s, 3H, $C\underline{H}_3NH$), 0.93 (t, J = 7.3 Hz, 3H, CH_3); ^{13}C-NMR (101 MHz, $CDCl_3$) δ(ppm) 175.3 (NHC=O), 169.7 (O-C=O), 137.7 (Ar$\underline{C}$-CH), 128.8 (ArCH), 127.2 (ArCH), 126.9 (ArCH), 61.2 (C-4), 59.4 (C-3), 57.6 (C-5), 52.1 (OCH_2), 31.1 ($NHCH_3$), 13.8 (CH_3).

Results and Discussion



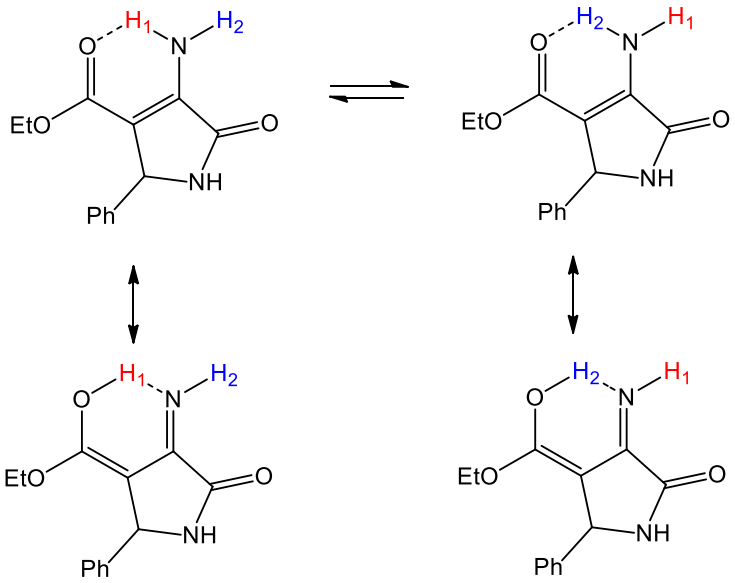
4-carbethoxy-3-hydroxy-2-oxo-5-phenyl-3-pyrroline (**1**) were prepared through one-pot multicomponent reaction (MCR) by refluxing equimolar sodium diethyl oxalacetate and benzaldehyde with excess aqueous ammonia in ethanol as developed by Metten et. al. (Scheme 1) [15]. The product was more stable in the enol rather than the keto form, consistent with previous findings [16-19]. The moderate yield was compromised for the ease of the purification process and overall facile procedure.

Afterwards, treatment of **1** with ammonium formate gave enamino ester **2** with a good yield via Leuckart reaction (Scheme 2) [2,3]. Hydrogenation of **2** in the presence of 10% Pd/C in acetic acid for 22 hours was ineffective, recovering the starting material. To our best knowledge, there is yet to be a report on a successful reduction of primary enamino esters such as **2**. Wang and co-workers described that the enamino group has to be protected prior to the hydrogenation to gain successful conversions [20]. Other works of literature suggested that there should be at least one substituent on the enamino functionality for the procedure to work [7-13]. Perhaps, the conjugated π system and alternating intramolecular hydrogen bonding form very stable 6-membered resonance structures (Figure 3) therefore preventing interaction with the metal catalyst.

However, methylamination of **1** in the presence of formic acid afforded secondary β-enamino ester (**4**), which was then reacted through four different reduction systems (Scheme 3).

Scheme 1. Synthesis of 4-carbethoxy-3-hydroxy-2-oxo-5-phenyl-3-pyrroline (**1**) via one-pot MCR

Scheme 2. Amination of **1** and the attempt to catalytically hydrogenate **2** over Pd/C



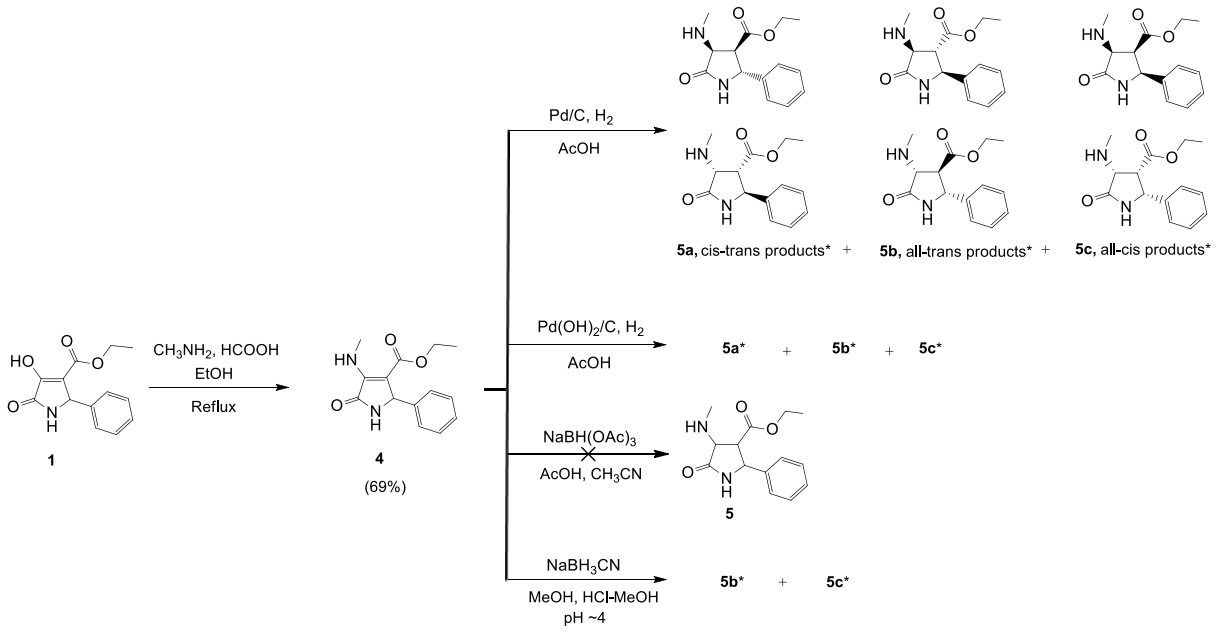


Figure 3. Intramolecular hydrogen bonding and the resonance structures of **2**.

* The absolute configuration was not determined. Thus, both possible enantiomers are displayed.

Scheme 3. Methylamination of **1** and various reduction protocols of **4**.

Pd/C hydrogenation of **4** displayed low diastereoselectivity (d.r. = 42 : 19 : 39) of three separable mixtures of β-amino ester diastereomers (**5a-c**) with low yields (4 to 10%) (Table 1). Hydrogenation of **5** in the presence of $Pd(OH)_2$ on charcoal was more diastereoselective (d.r. = 51 : 3 : 46) than Pd/C but afforded an even poorer yield (0.1 to 2.2%) of isomers (**5a-c**). Both catalytic processes involved the syn addition of hydrogens onto the double bond resulting in a nearly equivalent d.r. of **5a** (*cis-trans*) and **5c** (*all-cis*) products with a minor anti addition causing the formation of **5b** (*all-trans*) product, in agreement with one of our previous findings [17].

The treatment with sodium borohydride, $NaBH_4$ and acetic acid to form *in situ* sodium triacetoxyborohydride, $NaBH(OAc)_3$ failed to reduce compound **4**. On the other hand, reduction using sodium cyanoborohydride ($NaBH_3CN$) in acidic medium gained the mixture of **5b** and **5c** diastereomers, giving superior stereochemical control (d.r. = 64 : 36) than catalytic hydrogenations, with better yields. Deustch et. al. observed similar diastereomeric selectivities when reducing acyclic β-enamino ester derivatives by the same protocol [8].

Table 1. Stereoselective reduction of **4**

Reducing Agent	**Isolated Product Yield (%)***			**Diastereomeric ratio (d.r.)****
	5a	**5b**	**5c**	
Pd/C, H_2	10.3	4.5	9.6	42 : 19 : 39
$Pd(OH)_2$/C, H_2	2.2	0.1	2.0	51 : 3 : 46
$NaBH(OAc)_3$	-	-	-	-
$NaBH_3CN$	-	34.7	19.4	64 : 36

*Isolated yield of each diastereomeric product obtained after purification by column chromatography.
**Diasteremeric ratio (d.r.) was determined based on the isolated yield after column chromatography.

All resulting diastereomers were studied through nuclear magnetic resonance (NMR) experiments to assign their configurations. For instance, Nuclear Overhauser Effect Spectroscopy (NOESY) correlation between the hydrogen at C-4 (3.01 ppm) and aryl proton (7.35 ppm) in **5b** (*all-trans*) product confirmed that both the hydrogen and the phenyl ring are on the same side (Figure 4) whereby in **5c** (*all-cis*) product, the correlation between the hydrogens at C-4 (3.86 ppm) and C-5 (5.11 ppm) were observed, indicating their close proximities to each other. This claim is supported by the low proton NMR (^{1}H-NMR) chemical shift value of the hydrogen on C-4 of **5b** compared to that of **5c** due to the anisotropic effect of being near the phenyl ring. Moreover, **5b** diastereomer showed significantly higher values of $J_{4,5}$ coupling constant than **5c** (Table 2).

Alternatively, the assignment of *cis*-configuration between protons on C-4 and C-5 of **5c** isomer can be further proven by another anisotropy experienced by protons of its ester moiety indicated by their lower chemical shift values in comparison to those of **5a** (*cis-trans*) and **5b** diastereomers. On another note, the NOESY correlation between the hydrogen on C-4 (3.01 ppm) with methylamine proton (2.51 ppm) of **5b** led to the notion that the protons on C-3 and C-4 were *trans* to each other while for **5a**, its C-4 proton (3.35 ppm) correlated with the one on C-3 (3.60 ppm) thus they were assigned as *cis*.

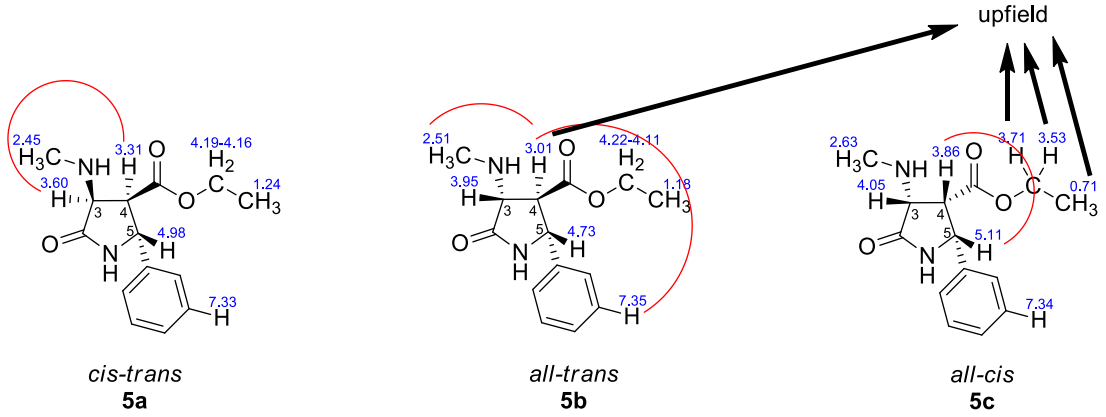
The mechanistic pathway that we proposed for these catalytic hydrogenations is displayed in Scheme 4. Syn addition of hydrogens on either side of the C=C of the enamino ester caused both the methylamine and ester groups to be on the same side. These structural changes

gave rise to steric clashes between the ester and phenyl ring that determined which conformer was more favourable. The steric strain in **5c** (ester and phenyl groups located near to each other) contributed to a slightly lower yield compared to the thermodynamic product **5a** (the groups were on opposite sides).

Anti addition of hydrogens by metal-catalysed hydrogenation was initiated by the formation of an enolate intermediate through the protonation of one of the prochiral centres which are C-3 in **5b**, the less hindered site (Scheme 4). The following step involved the addition of another hydrogen on C-4 selectively to form a stable conformer whereby the ester group and phenyl ring were situated on different planes (lower steric strain) thus resulting in the *trans*-position between the hydrogens on C-3 and C-4 [10].

$NaBH_3CN$ reduction began with a rate-determining step of acid protonation on C-4 of **4** from either side of the C=C of the enamino ester, thus forming respective iminium intermediates (Scheme 5) [21]. Then, an attack by cyanoborohydride from the less crowded site (away from the phenyl ring) restored the nitrogen lone pair electrons. The reagent selectively favoured the formation of **5b** over **5c** due to the greater strain between ester and phenyl groups in **5c**, consequently causing the latter to be less energetically stable.

The poor yield of $Pd(OH)_2$ hydrogenation compared to Pd/C and the unsuccessful reduction by $NaBH(OAc)_3$ can be explained by the bulkiness of the reagent structures causing severe steric hindrance that antagonized the reactions.



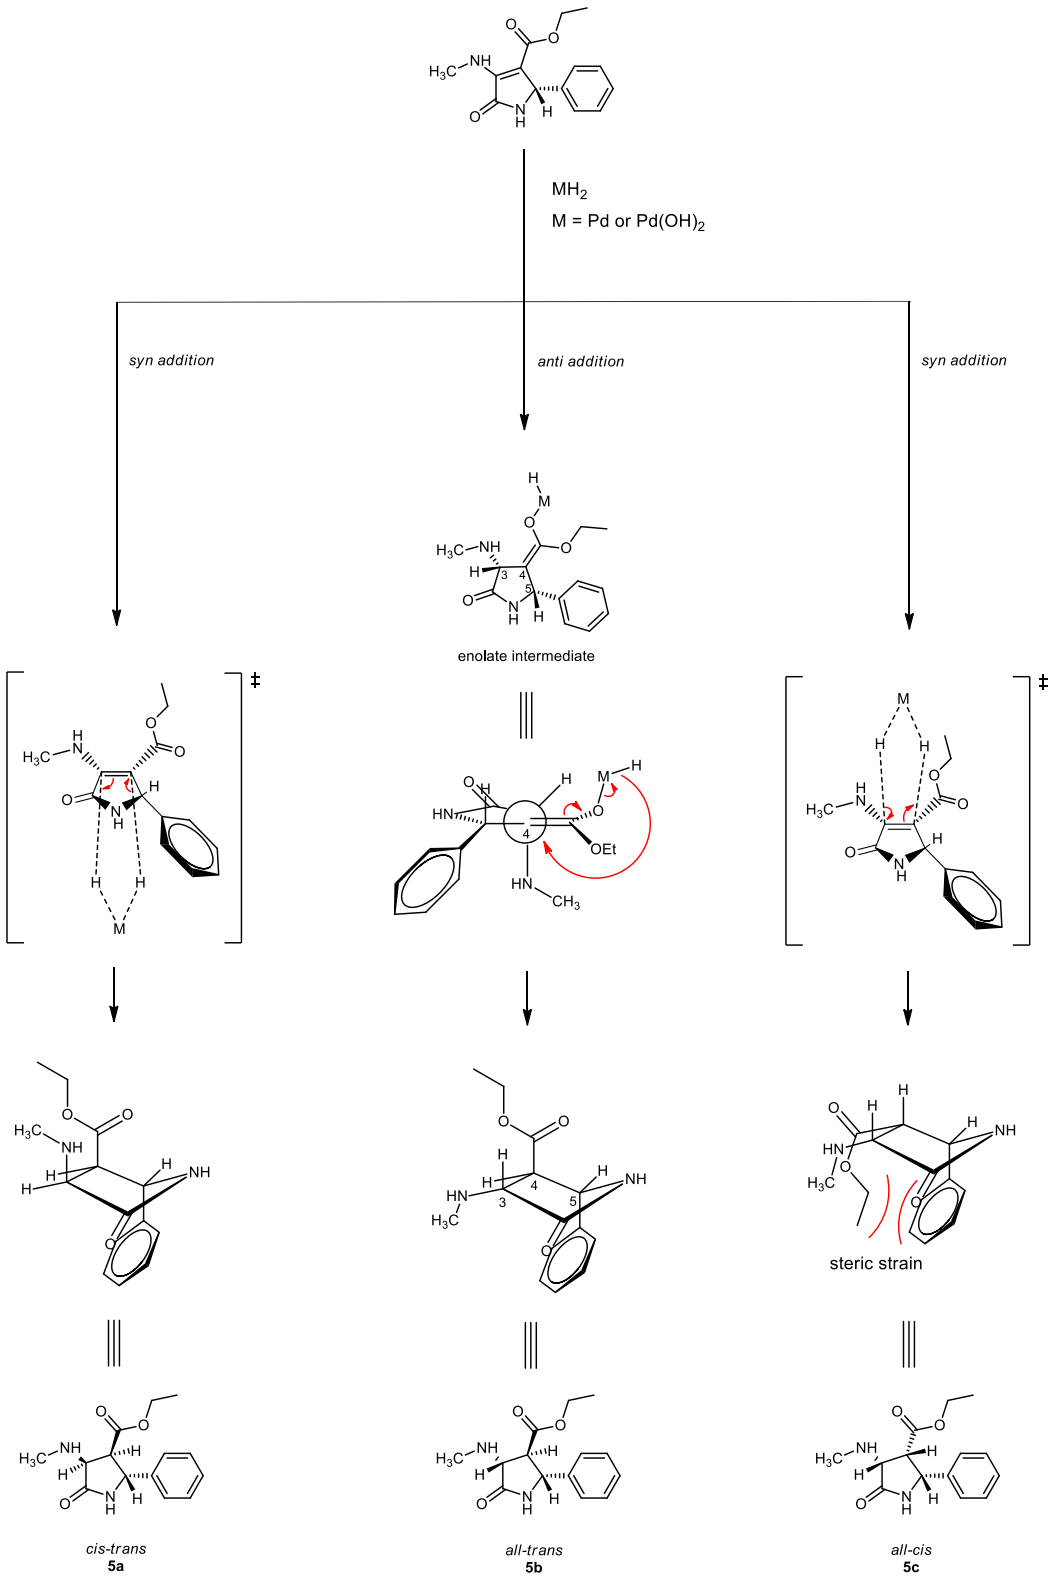


Figure 4. ^{1}H-NMR shift values and NOESY correlations of diastereomers **5a-c**

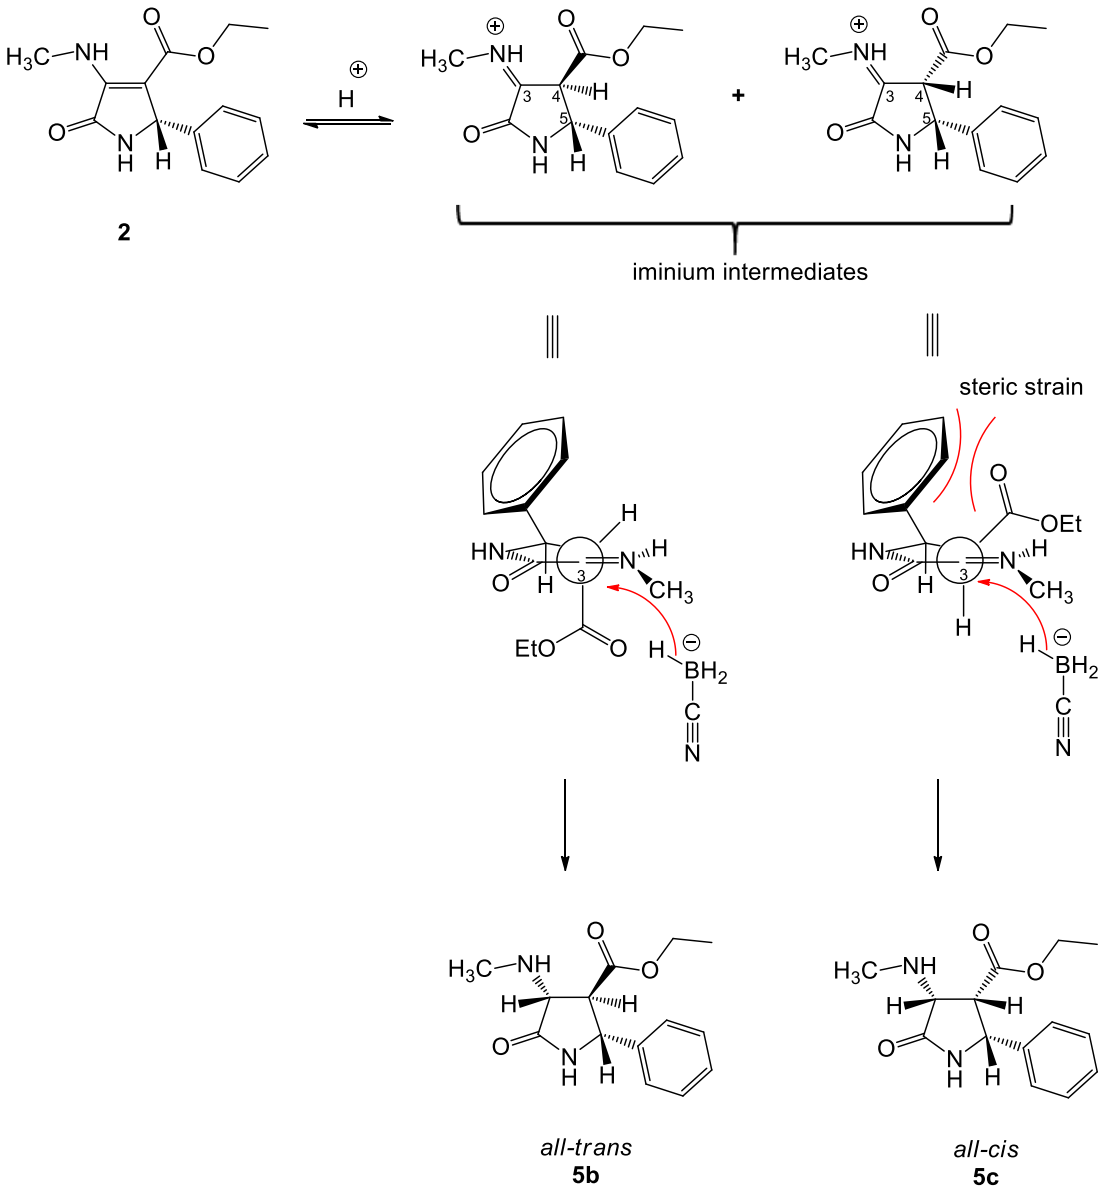

Table 2. Selected ^{1}H-NMR data for diastereomers **5a-c** in methanol-d_4

Compound	Shift value, δ (ppm)			Coupling constant, J (Hz)		
	H-3	H-4	H-5	H-3	H-4	H-5
5a	3.60	3.35	4.99	8.4	–*	4.8
5b	3.95	3.01	4.73	9.6	8.5	8.2
5c	4.05	3.86	5.11	6.9	6.9	6.4

*H-4 of **5a** showed a multiplet pattern

Scheme 4. Proposed mechanistic pathways for Pd and $Pd(OH)_2$ hydrogenation of **4**

Scheme 5. Plausible reaction mechanism for reduction of **4** by $NaBH_3CN$.

Conclusion

Overall, the stereochemical control for this class of functional group depends strongly on the position of the ester group in regards to the phenyl ring after the protonation/reduction steps i.e. if they are on the same plane, the lower the preference for the formation of said diastereomer. This brief experiment shows that endocyclic β-enamino ester (**4**) can be reduced with excellent diastereoselectivity by $NaBH_3CN$ (d.r. = 64 : 36), in addition to its moderate turnover percentage (54.1%). Hydrogenations on Pd and $Pd(OH)_2$ surfaces suffered from poor selectivities (d.r. = 42 : 19 : 39 and d.r. = 51 : 3 : 46, respectively) and yields (0.1 to 10.3%) with unexpected anti additions of hydrogens while $NaBH(OAc)_3$ reduction recovered the starting material. Nevertheless, we have successfully employed some of these reduction strategies to prepare chiral

cyclic β-amino ester with satisfying diastereomeric purity.

Abstract

Simple sample preparation was investigated and developed to selectively determine Cr(VI) in wastewater samples or effluents based on the liquid-liquid extraction principle using tetrabutylammonium hydrogensulfate (TBAHS) as the ion-pair reagent in an acidic medium. TBAHS was prepared in an organic solvent to improve the extraction efficiency. The extracted Cr(VI) in the organic phase endured the acid digestion, and its atomic absorption was measured at 357.9 nm. The influences of several working parameters, namely, organic solvents (methyl isobutyl ketone-MIBK, dichloromethane-DCM, and chloroform), pH values (lower than 1.0, 1.0, 2.0, and 3.0) in the aqueous phase, TBAHS concentrations in the organic solvent (0.02, 0.04, 0.05, and 0.06 mol L^{-1}), extraction duration (from 3 to 30 minutes), number of extraction cycles (single or repeated extraction), sample preservation duration at ambient temperature, and co-existence of Cr(III) in the sample matrices, were investigated to discover the optimized working parameters. The results showed that dichloromethane (DCM) was the most effective extraction solvent. The most favorable conditions for complex formation were determined as follows: a pH of around 1.0 to 3.0; 0.05 mol L^{-1} TBAHS prepared in DCM, triple extraction, and a shaking duration of 15 minutes for each extraction cycle. The calibration curve was linear in the range of 0.05, 0.10, 0.20, 0.40, 0.60, 0.90, 1.2, 1.5 and 2.0 mg L^{-1}, and the regression equation was $y = 0.1068x + 0.0012$ with $R^2 = 0.9994$, exhibiting goodness of linearity. The method detection and quantification limit values were estimated to be 0.012 mg L^{-1} and 0.04 mg L^{-1}, respectively. The repeatability (RSD_r = 0.71%) and reproducibility (RSD_R = 1.1%) were favorable according to the requirements presented in Appendix F of AOAC (2016) for analytical method validation. The proposed method was applied to real wastewater samples and spiked samples, showing very low Cr(VI) concentrations for most samples and proper recoveries (91.1-109%).

Keywords: Cr(VI), Cr(III), liquid-liquid extraction, TBAHS, dichloromethane, DCM, ion-pair reagent

Abstrak

Penyediaan sampel yang mudah telah dikaji dan dibangunkan bagi penentuan terpilih Cr(VI) di dalam air sisa atau efluen berdasarkan prinsip pengekstrakan cecair-cecair menggunakan tetrabutylammonium hidrogensulfat (TBAHS) sebagai reagen pasangan ion di dalam medium berasid. TBAHS telah disediakan dalam pelarut organik bagi tujuan meningkatkan keberkesanan pengekstrakan. Cr(VI) yang telah diekstrak di dalam fasa organik melalui penghadaman asid, dan serapan atom telah diukur pada 357.9 nm. Pengaruh parameter seperti pelarut organik (metil isobutil keton-MIBK, diklorometana-DCM, dan klorofom), nilai pH (dibawah 1.0, 1.0, 2.0 dan 3.0) di dalam fasa akues, kepekatan TBAHS di dalam pelarut organik (0.02, 0.04, 0.05, dan 0.06 mol L^{-1}), tempoh pengekstrakan (dari 3 hingga 30 minutes), bilangan kitaran pengekstrakan (pengekstrakan tunggal atau ulangan), tempoh pengawetan sampel pada suhu sekitar, dan kehadiran bersama Cr(III) dalam matrik sampel turut dikaji untuk penentuan parameter kerja yang optimum. Hasil kajian menunjukkan diklorometana (DCM) paling efektif sebagai pelarut pengekstrakan. Keadaan paling baik untuk penghasilan kompleks ditentukan seperti berikut: pH antara 1.0 hingga 3.0; 0.05 mol L^{-1} TBAHS disediakan dalam DCM, tiga kali pengekstrakan, dan masa goncangan ialah 15 minit bagi setiap kitaran pengekstrakan. Lengkung kalibrasi adalah linear pada julat 0.05 hingga 2.0 mg L^{-1}, dan persamaan regresi ialah $y = 0.1068x + 0.0012$ dan $R^2 = 0.9994$. Had pengesanan dan kuantifikasi telah dihitung masing-masing pada 0.012 mg L^{-1} and 0.04 mg L^{-1}. Kebolehulangan ($RSD_r = 0.71\%$) dan kebolehhasilan semula ($RSD_R = 1.1\%$) adalah baik berdasarkan keperluan yang dinyatakan dalam Appendix F of AOAC (2016) bagi validasi kaedah analisis. Kaedah yang dicadang ini telah digunapakai bagi analisis sampel air sisa sebenar dan sampel yang dipaku, ia menunjukkan kepekatan Cr(VI) yang rendah dan perolehan semula yang baik (91.1-109%).

Kata kunci: Cr(VI), Cr(III), pengekstrakan cecair-cecair, diklorometana, reagen pasangan ion

Introduction

Chromium (Cr) has been known as the non-essential and toxic element for human beings and animals despite existing in trace quantities [1, 2]. The emission of Cr into the environment is mainly derived from metallurgical, electroplating, pigments, etc. The two most common species of chromium are Cr(III) and Cr(VI), whereby Cr(VI) exhibits remarkably high toxicity due to its higher solubility and flexibility than Cr(III) [3, 4], 100 times more toxic than Cr(III). Many studies have indicated death risks from lung cancers during working and direct exposure to Cr(VI). Moreover, Cr(III) is considered an essential micro-nutrient and is responsible for blood glucose control and lipid metabolism in mammals. Because of their toxicity differences, the determination of total Cr concentrations did not provide enough reliable and accurate information to evaluate the toxicity potentials toward the environment. Additionally, the selective determination of Cr species has helped the scientists to recognize their origins and behaviors to find adequate solutions to remove these exposed pollutants from the environment. Modern instrumental methods using ICP-OES or ICP-MS coupled with liquid chromatography have met the requirements for direct analysis of Cr species in various sample matrix due to their selectivity and sensitivity [5, 6]. However, such methods are costly and not easily equipped in many laboratories. Therefore, another cheap, convenient, simple, and effective analytical method by using selective solvent or liquid-liquid extraction techniques (LLE) and measured on the Flame-Atomic Absorption Spectrometry (F-AAS) analysis, a common instrument for metal(loid)s quantification in various environmental laboratories, should be developed for Cr(VI) detection in complicated sample matrices such as wastewater.

For trace analysis of metal ions, solvent extraction has become a popular technique to serve the analyte enrichment and/or matrix removal purposes. Moreover, such techniques allow to easy control of the volumes of the aqueous and organic phases, which makes them possible to be coupled with any potentially suitable analytical methods for determining various metal ions. Typically, the volume of organic solvent used in the extraction is smaller than that of the sample volumes, resulting in higher enrichment factors and lower method limits of detection and quantification. At the industrial scale, solvent extraction has been utilized in chemical industries for the purification of chemical elements and/or for the separation and concentration of metals of interest [7, 8]. However, for the analytical

method development, the single application of organic solvents is usually faced with a lack of selectivity. Therefore, in order to enhance the selectivity of the LLE, complexing agents in organic solvents could be used. The separation of Cr(III) and Cr(VI) using ion-exchange and/or complex reagents in organic solvent have gained considerable interests among the scientists since the last few decades, e.g., zephyramine [9], bis(2-ethyl hexyl phosphoric acid) in benzene [10], diphenyl carbazide with isoamyl alcohol [11], and 4-methyl-3-pentene-2-one [12]. In 2009, Kalidhasan and Rajesh published the determination of Cr(VI) based on the LLE using tetrabutylammonium iodide (TBAI) as an ion-pair reagent in methyl isobutyl ketone (MIBK) used as the extraction solvent [8]. The ion-pair complex was back-extracted using ascorbic acid to convert Cr(VI) into free Cr(III) before spectrophotometric measurement for quantification purposes. The extraction of Cr(VI) using TBAB as the ion-pair reagent in dichloromethane was performed with 95% recovery [13].

As an emerging country with rapid development in industrialization and urbanization, Vietnam has been facing the risk of serious water pollution, as the heavy metals discharged from industrial activities have identified as a threat to public health and the safety of the ecosystem. Notably, the wastewater from the mechanical, electronic, dyeing, and tanning industries, etc., potentially has high concentrations of heavy metals, e.g., Cr, and in many cases, may exceed the permitted levels. In the present study, we employed the liquid-liquid extraction (LLE) using tetrabutylammonium sulfate (TBAHS) as the ion-pair reagent prepared in the extraction solvent of dichloromethane to separate Cr(VI) from the effluents into the organic phase before measuring the quantity using Flame Atomic Absorption Spectrometry (F-AAS). The preparation of TBAHS in the organic solvent instead of in water aimed to assist the chemical reaction between the analyte and the complexing agent, then to increase the extraction yield for quantification purposes. The parameters related to the LLE namely the concentrations of ion-pair reagent, extraction pH and solvents, reaction duration, numbers of extraction cycles (repeated extraction), and sample preservation as the co-existence of Cr(III), were evaluated to discover the optimized analytical conditions for real wastewater application. Moreover, in this current study, the ion-pair reagent was prepared in the extraction organic solvent instead of in the aqueous phase to increase the extraction efficiency, minimize the interferences of co-existing ions and substances, and improve the recovery of the proposed analytical method for quantification purposes.

Materials and Methods

Chemicals and reagents

All chemicals and reagents, including a stock solution of 1000 mg L^{-1} chromium (III), methyl isobutyl ketone (MIBK), dichloromethane (DCM), and chloroform, were of the analytical grade and purchased from Merck (Germany). A stock solution of 1000 mg L^{-1} chromium (VI) solution was prepared from potassium dichromate (≥ 99.9%, Merck, Germany). Working standard solutions of Cr(VI) were prepared daily by appropriate dilution of the 1000 mg L^{-1} stock solution using deionized water (DIW, Millipore, USA) before each use. Ion-pair reagents of 0.05 mol L^{-1} tetrabutylammonium hydrogensulfate (TBAHS) in extraction solvents namely dichloromethane (DCM), methyl isobutyl ketone (MIBK), and chloroform were prepared by dissolving 7.608 g of TBAHS in 500 mL of each of these solvents to obtain three different solutions used as the extraction solvent. Sulfuric acid of 1.0 mol L^{-1} was prepared by properly diluting the concentrated sulfuric acid in DIW. The Cr(VI) standard solution of 1.0 mg L^{-1} was prepared and used for evaluating the effects of various analytical parameters in the LLE, including types of organic solvents, pH index in the aqueous phase, ion-pair reagent concentrations in the extraction organic solvent, shaking duration per each extraction cycle, and the numbers of extraction cycles (single or repeated extraction). For the assessment of sample preservation at the ambient temperature, primarily due to the effects of Cr(III) co-existence, Cr(III) and Cr(VI) standard solutions were spiked into real wastewater samples to obtain the concentrations of both species at 1.0 mg L^{-1}.

Liquid-liquid extraction

The single factor experiment of the standard solution was used for optimizing the liquid-liquid extraction (LLE). The LLE was set up as follows: 1.00 mL of 10 mg L^{-1} Cr(VI) was added to 40 mL glass vial with a cap. The solution pH was adjusted to different investigated values, namely below 1.0, 1.0, 2.0, and 3.0 using 1.0 mol L^{-1} sulfuric acid and sodium hydroxide solutions. Then, 5.00 mL of TBAHS with various concentrations of 0.02, 0.04, 0.05, and 0.05 mol L^{-1} in the extraction organic solvents was added to the sample liquids to carry out the LLE. Three different organic solvents of methyl isobutyl ketone or MIBK, dichloromethane or DCM, and chloroform were investigated to discover the most suitable extraction solvent. The extraction was carried out by shaking the sample glass vial for a certain duration (3, 5, 10, 15, 20, 25, and 30 minutes). Single, double, and triple extractions were evaluated to find out the number of repeated extractions required for the highest recovery. All the organic phases were collected and transferred to another glass vial before being evaporated to the volume of around 1 mL by gentle heating at 60-70 ºC. Next, approximately 1 mL of concentrated nitric acid was added. The mixture was continued to heat until the volume observed was nearly 0.3-0.5 mL (do not heat to dry). Finally, the residue in the reaction vial was dissolved carefully in DIW and transferred to a 10-mL volumetric flask. The solution was filtered through a 0.45-µm membrane before measurement at 357.9 nm on an atomic absorption spectrometer.

Flame atomic absorption spectrometry for determining Cr(VI)

Cr(VI) determination after LLE was performed on a flame atomic absorption spectrometer (AA-6650 Shimadzu, Japan), equipped with a chromium hollow cathode lamp, an air-acetylene flame atomizer. The wavelength, lamp current, and spectral bandwidth used were 357.9 nm, 10 mA, and 0.5 nm, respectively. The burner height was 12 mm and the gas flow rate were 3.0 L min^{-1}. The background correction using a Deuterium lamp was applied for all measurements. The calibration curve was developed based on the linear relationship between the Cr(VI) standard concentrations (i.e., 0.05, 0.10, 0.20, 0.40, 0.60, 0.90, 1.2, 1.5 and 2.0 mg L^{-1}) prepared in 0.5% (v/v) nitric acid and the respective absorbance. The method limits of detection and quantification (MLD and MLQ) were determined by simultaneously analyzing 11 blank samples using the optimized LLE and F-AAS measurement. The estimated average concentration value ($\bar{x}$) and standard deviation (SD) were calculated to apply in the following relationships [14, 15]: MLD = $\bar{x}$ + 3SD and MLQ = 10/3*MLD. The repeatability and reproducibility were evaluated by calculating $\%RSD_r$ and $\%RSD_R$ for intra-day (six replicates, n = 6) and inter-day (three separate days). The trueness of the method was evaluated based on the recovery of the spiked samples.

Application of the proposed method to determine Cr(VI) in real effluent samples

A total number of 10 wastewater samples or effluents were randomly collected from several industrial parks around Ho Chi Minh City, based on ISO 5667-3:2003 [16] and ISO 5667-10:2020 [17]. The effluents were collected from the wastewater drain pipes of textile and electronics factories. The samples were contained in acid-washed polyethylene bottles, filtered through a 0.45-µm membrane (GE Whatman Membrane Filters, GF/F), and stored at freezing conditions (−10 ºC) until further analysis. These samples were analyzed by the proposed analytical method using the LLE procedure for the selective determination of Cr(VI). Besides, the Cr(VI) standard solution was spiked to these collected effluents to carry out the recovery test based on the real sample matrices, which aimed to assess the matrix effects on the analytes of interest.

Results and Discussion

Effects of extraction solvents

There are two possible ways for the extraction of Cr(VI from the aqueous phase to the organic phase. A common approach is the formation of an ion-pair complex in the aqueous phase, using an ion-pair reagent in water. The formed complex was extracted using a suitable organic solvent. However, the produced TBA^+–$HCrO_4^-$ ion-pair complex is less polar, and therefore poorly interactive with water. The molecule has a large molecular size, and thus is less stable in water, lowering extraction efficiency. Another

approach is to prepare the ion-pair reagent in organic solvents and carry out the LLE between aqueous and organic phases. In the present study, to enhance the extraction efficiency and minimize the interferences of co-existing ions and substances, the later approach was applied, i.e., the TBAHS was prepared in organic solvents, then used for LLE. The formation of an ion-pair complex could happen at the interface between the aqueous and organic phases (mostly in the aqueous phase) due to shaking effects. Such affects allow for the analyte of interest to be transferred into the organic solvent due to the stronger interaction formed by the ion-pair complex with organic solvents [8]. In the present study, three organic solvents were investigated for their potential use as extraction solvents, i.e., MIBK, DCM, and chloroform. The extraction yield (%) of Cr(VI) in the solvents (i.e., performing a single extraction within 10 minutes) is presented in Figure 1.

In descending order, the highest yield was obtained in DCM (97.4%), followed by chloroform (70.9%), and MIBK (26.9%). The differences in extraction yields could be due to the differences in the polarity of these solvents, of which MIBK has a relatively high polarity, and thus was less effective for extraction of Cr(VI). Meanwhile, DCM (polarity index of 3.1) and chloroform (polarity index of 4.1) are less polar than MIBK [18, 19], thus exhibiting higher extraction efficiency. Between DCM and chloroform, the former exhibited a better extraction efficiency, which may be due to the lower polarity and larger size of DCM molecules that allow for more favorable solvation for the ion-pair complex. The ion-pair complex is large in size, held by relatively weak electrostatic forces (Figure 3) but possesses enough stability to be effectively extracted to the organic phase [20]. Due to the large size of the formed complex, the organic solvents with larger molecule sizes may provide favorable conditions for better extraction yields than that of smaller molecule sizes under the same working parameters. Comparing between CCl_4 and $CHCl_3$ as the extraction solvent, CCl_4 with lower polarity was reported to perform higher extraction efficiency [21, 22]. Therefore, in this current study, an ion-pair reagent of TBAHS was prepared in DCM as a lower polar extraction solvent for further experiments and investigations to assure the highest extraction yield.

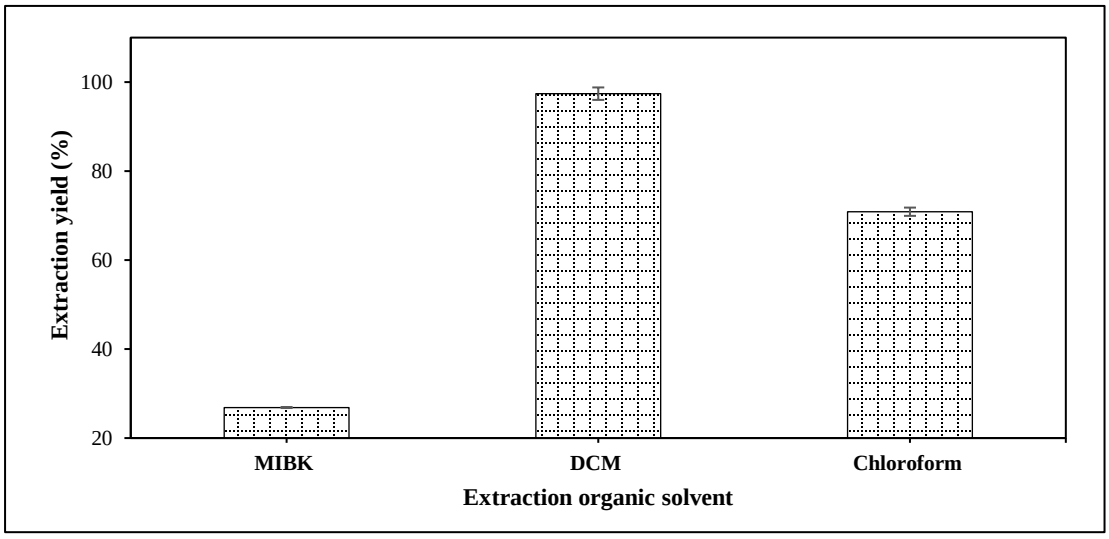

Figure 1. The Cr(VI) extraction efficiency using different extraction organic solvents

Effects of pH index in the aqueous phase

Depending on pH, predominant speciation of chromium could be changed to reach chemical equilibrium, which typically includes the formation of chromate (CrO_4^{2-}), dichromate ($Cr_2O_7^{2-}$), hydrogen chromate ($HCrO_4^-$), chromic acid (H_2CrO_4), hydrogen dichromate ($HCr_2O_7^-$), trichromate ($Cr_3O_{10}^{2-}$), and tetrachromate ($Cr_4O_{13}^{2-}$) [23, 24]. For instance, $HcrO_4^-$,

$Cr_2O_7^{2-}$, and H_2CrO_4 dominated the acid medium [25]. The different chromium species in water remarkably influence the extraction efficiency. The effects of pH on the extraction efficiency were investigated in the pH range from under 1.0 to 3.0. The extraction yield at different pH values is presented in Figure 2.

The results showed that the Cr(VI) ion quantitatively formed an ion-pair complex with TABHS at all the investigated pH, resulting in the extraction yields higher than 90%. Extraction yields generally remained unchanged within the ranges of pH tested in this current study (i.e., from less than 1.0 to 3.0). This phenomenon could be attributed to Cr(VI) mostly existing as $HCrO_4^-$ in the medium with a pH < 4.0, whereby the association was well-formed due to the big radius of $HCrO_4^-$[26]. The TBA^+–$HCrO_4^-$ ion association was formed in the interaction between the two phases (mostly in the aqueous phase) according to the following schematic representation (Figure 3). Therefore, the favorable pH for complex formation may vary in a relatively wide range, and pH adjustment in the sample preparation was not strictly (from very acidic, pH lower than 1.0, to pH of 3.0) [8, 20]. At pH > 4, lower extraction efficiency has been reported in previous publications, e.g., Ouejhani et al. [7], Baig et al. [21], and Kalihasan et al. [20]. The lower extraction yield of Cr(VI) in the alkaline medium could be explained due to the presence of dominant species, the CrO_4^{2-} and its potential hydrolysis [27]. In the present study, we did not investigate the extraction at high alkaline pH. The pH around 1.0 was chosen for further experiments and investigations due to the easy and convenient adjustment.

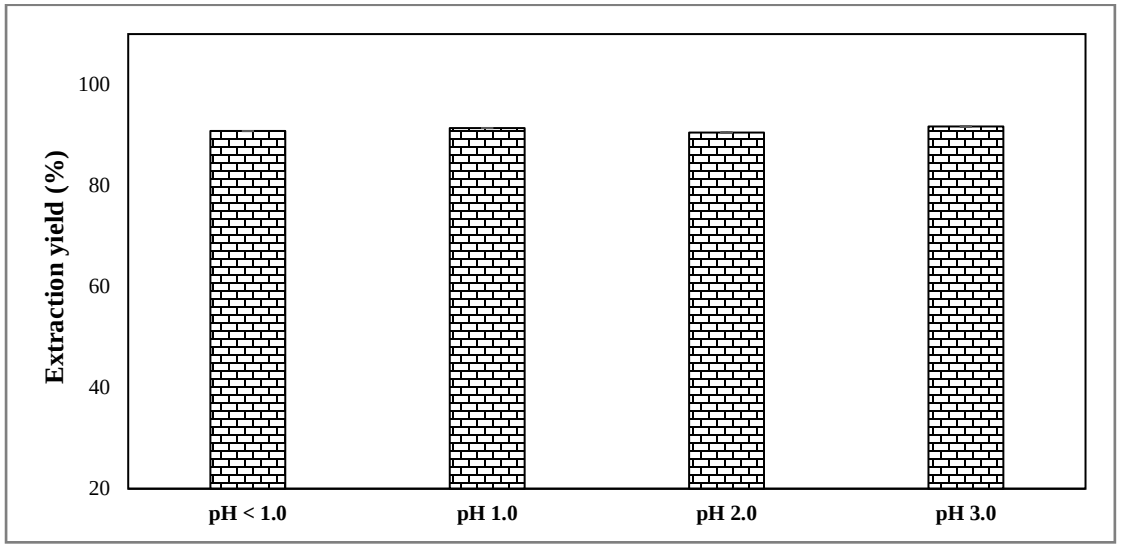

Figure 2. The Cr(VI) extraction efficiency at different pH

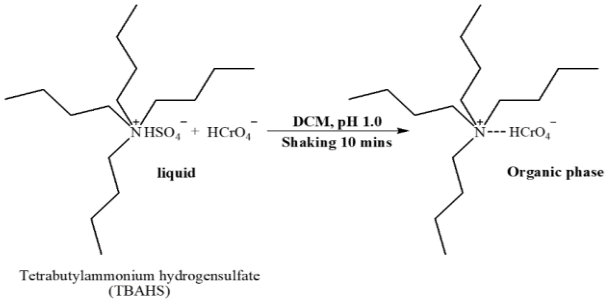

Figure 3. The chemical reaction for the formation of the ion-pair association

Effects of ion-pair reagent-TBAHS concentrations in DCM

As mentioned before, the ion-pair reagent of TBAHS was prepared in DCM to maximize the extraction efficiency [13]. The effects of TBAHS concentrations on the recovery were assessed, and the results are presented in Figure 4. It has been known that the formation of the ion-pair complex happens at the interface between two phases. However, the lower TBAHS concentration in the organic phase could lead to the lower concentrations of TBAHS as the ion-pair reagent at the interface, hence ineffective complexation between TBAHS and Cr(VI). Therefore, higher TBAHS concentrations were required to provide high TBAHS contents for favorable for ion-pair formation. Moreover, as shown in Figure 4, the chemical equilibrium was shifted forward to form the ion-pair complex when the concentrations of reactants (TBAHS) were higher. The increasing recovery as the concentration of TBAHS in DCM was increased was observed as the lowest (67.1%) and highest (103%) recovery was obtained at 0.02 mol L^{-1} and 0.05 mol L^{-1}, respectively. The TBAHS concentration of 0.04 mol L^{-1} resulted in relatively lower recovery (98.5%) and poorer precision (%RSD of 1.2%) than that of 0.05 mol L^{-1} (recovery of 103% and %RSDs of 0.68%). Based on the results, the 0.05 mol L^{-1} TBAHS in DCM was used for further experiments to ensure the most favorable recovery and precision.

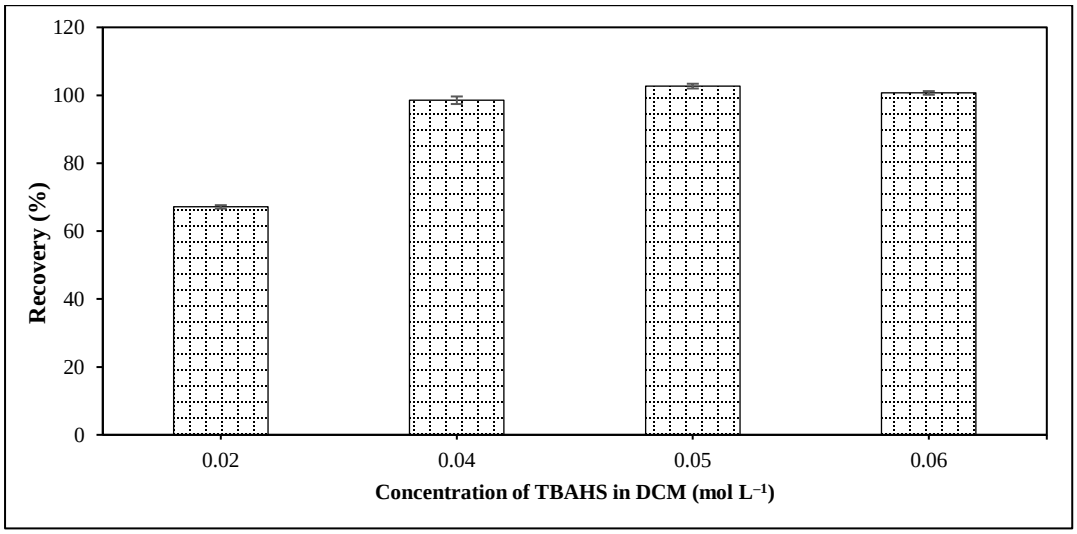

Figure 4. The extraction efficiency of Cr(VI) at different TBAHS concentrations in DCM

Effects of shaking duration and numbers of extraction cycles

During the extraction period, the shaking activity increases the interaction between Cr(VI) in the aqueous phase (wastewater samples) and the ion-pair reagents in the organic phase (DCM) at the interface of the two phases, and thus increases the chances for the formation of the ion-pair complex in the organic phase. The effects of shaking duration on the Cr(VI) recoveries are illustrated in Figure 5, which indicates that the longer shaking duration led to higher recoveries (i.e., 80.4% to 101%). We suggest that it is necessary to apply sufficient shaking for a certain duration to equilibriate the complex formation via a chemical reaction in the complicated wastewater matrices. In the present study, the recoveries mostly remained unchanged in the extraction performed for more than 15 minutes for each extraction cycle. Therefore, 15 minutes was determined as the shaking duration for each cycle of the extraction. In addition, to ensure the quantitative extraction of Cr(VI), the number of extraction cycles (i.e., repeated extraction)

was investigated. Double and triple extraction procedures were compared for their respective recoveries. The results showed higher recovery in triple than double extractions (i.e., 89.6% and 104%, respectively), which reflected the high partition coefficient of the complex in the organic phase.

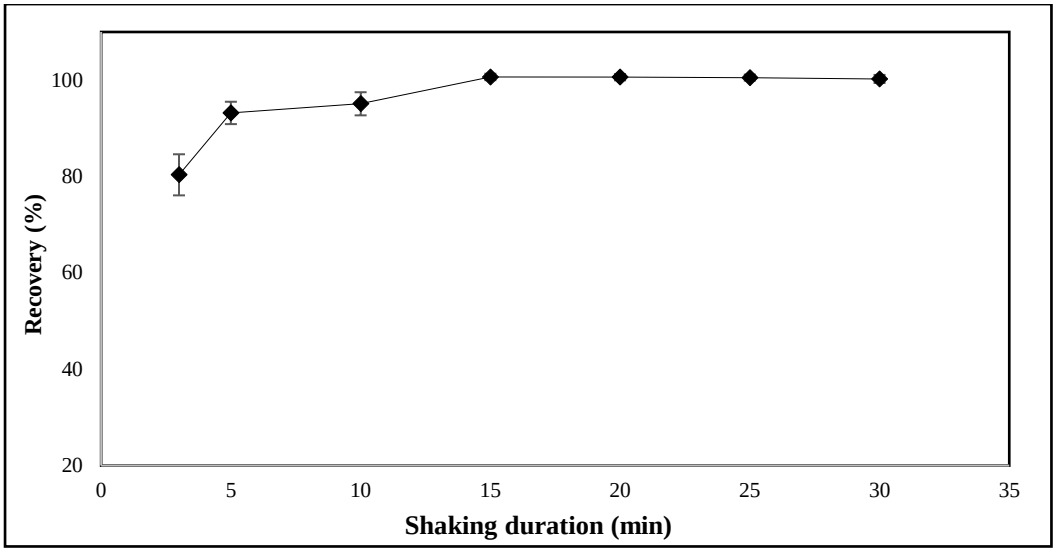

Figure 1. The variability of Cr(VI) recoveries at different shaking duration values (from 3 to 30 minutes), using 5.0 mL of DCM containing 0.05 mol L^{-1} TBAHS for 1.00 mg L^{-1} Cr(VI) standard solution

Effect of sample preservation on Cr(VI) analysis

The effects of sample matrices were investigated to obtain the most favorable sample preservation conditions at the ambient temperature. Cr(III) and Cr(VI) standard solutions were spiked into the real wastewater samples with free chromium to obtain the concentrations of 1.0 mg L^{-1} for both species to calculate the recoveries of Cr(VI) at different preservation duration values at the ambient temperature. The sample preparation for Cr(VI) analysis was carried out based on the optimized conditions, as shown in Figure 6.

The filtered sample solution endured FAAS measurement at 357.9 nm for quantification purposes. The results in Figure 7 showed that the immediate extraction within an hour resulted in no significant changes in the concentration of Cr(VI) as compared to its initial concentration, while the longer preservation duration resulted in lower recoveries (53.0% and 35.3% for 24-and 48-hour preservation, respectively). The result could be due to the presence of organic matters in the wastewater that may reduce Cr(VI) into Cr(III) [28, 29] and/or the presence of other substances that may interfere in the formation of Cr(VI) and the ion-pair reagent complexes. Therefore, to ensure reliable and accurate results, the wastewater samples should be analyzed right after being transported to the laboratory (within around one hour) or preserved at freezing temperature to minimize the conversion of Cr(VI) into Cr(III).

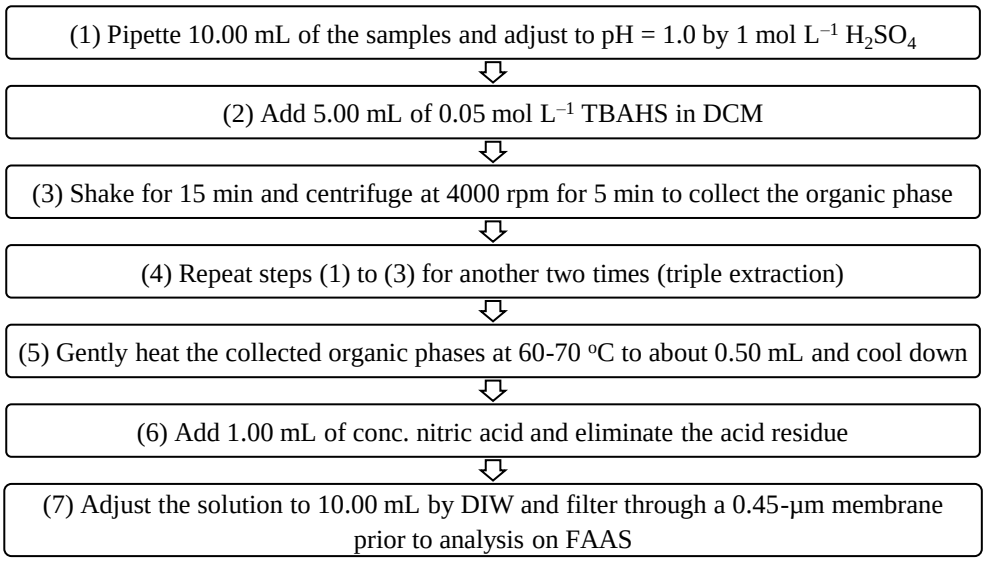

Figure 6. Optimized preparation procedure for Cr(VI) analysis

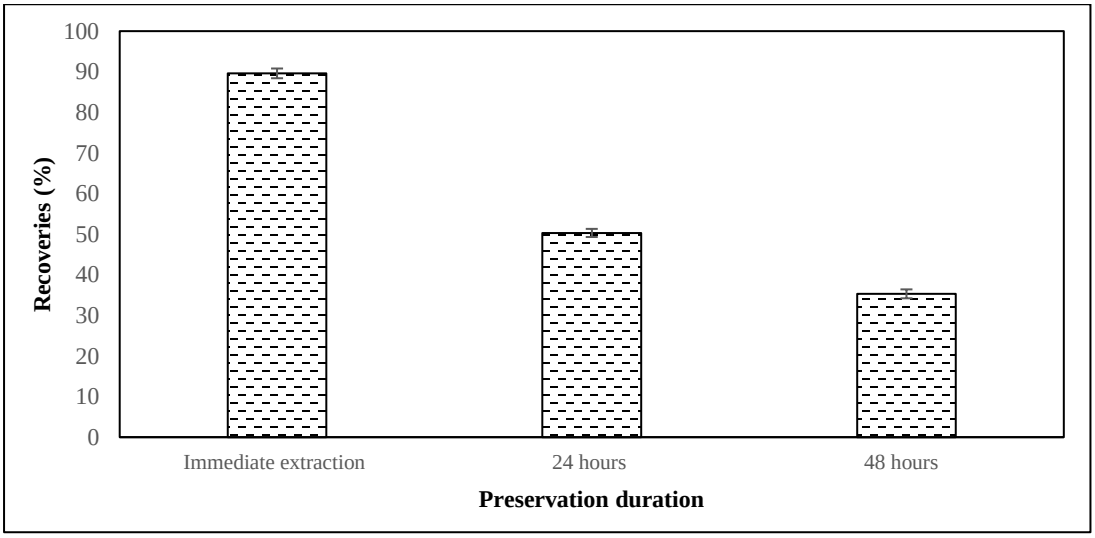

Figure 7. Recoveries of Cr(VI) in spiked samples with the co-existence of Cr(III) at different preservation duration values

Analytical method performance for analyzing Cr(VI)

The selective determination of Cr(VI) in wastewater following LLE with ion-pair reagent using FAAS was evaluated. The results are presented in Table 1. The estimated MDL and MQL were lower than regulated values in QCVN 24: 2009/BTNMT (National Technical Regulation on Industrial Wastewater) for industrial wastewater disposed to domestic and non-domestic water sources (0.05 and 0.1 mg L^{-1}) [30]. Therefore, the analytical method could be applied for industrial wastewater control and management of Cr(VI) content. The calibration curve was established based on the linear relationship between the chromium

concentrations and their atomic absorption values, which exhibited goodness of linearity (R^2 = 0.9994). The $\%RSD_r$ and $\%RSD_R$ were used to evaluate the repeatability (within one day) and reproducibility (for three separate days) of the proposed analytical method, which proved favorable according to the Appendix F of AOAC (2016) [31]. Besides, the recoveries varied from 91.1 to 109%, demonstrating the result accuracy obtained via the proposed method.

Table 1. Parameters for analytical method performance

Regression Equation	R^2	MDL (mg L^{-1})	MQL (mg L^{-1})	RSD_r (%)	RSD_R (%)	Recoveries (%)
y = 0.1068x + 0.0012	0.9994	0.012	0.040	0.71	1.1	91.1-109

The variability of Cr(VI) in the effluents

The sample preparation for Cr(VI) analysis in real wastewater samples or effluents was carried out based on the optimized procedure in Figure 6. The results of Cr(VI) analysis in real effluent samples are shown in Table 2. Most of the wastewater samples exhibited remarkably low Cr(VI) (i.e., below MQL values of 0.040 mg L^{-1}). The highest Cr(VI) in wastewater was determined as 0.37 mg L^{-1}. The Cr(VI) standard solution was spiked into all these samples for the recovery test, which demonstrated favorable recovery values (91.1-109%) according to the Appendix F of AOAC (2016) [31]. The recovery test was conducted to examine the matrix effects (mostly from the co-existing ions and organic matters present in wastewater). Therefore, the obtained high recoveries obtained in the test demonstrated the effectiveness of the LLE using the ion-pair reagent (TBAHS) for selective determination of Cr(VI) in complicated sample matrices.

Table 2. Analytical results of Cr(VI) in wastewater samples and recovery tests

Sample code	Cr(VI) (mg L^{-1})	Spiked Cr(VI) (mg L^{-1})	Recoveries (%)	RSD for Recoveries (%)
S1	n.d	1.00	96.8	1.6

Conclusion

The proposed analytical method for determining Cr(VI) in wastewater or effluents demonstrated its good sensitivity and selectivity. The measurement was performed on an inexpensive and common technique of FAAS following the liquid-liquid extraction with

TBAHS as the ion-pair reagent. The TBAHS was prepared in the organic solvent to improve the extraction efficiency due to the low potential of interferences. Dichloromethane (DCM) was found to be the most favorable organic solvent for the extraction process. Various analytical parameters related to the extraction procedure were investigated to discover the optimized working parameters, including 0.05 mol L^{-1} TBAHS as the ion-pair reagent in DCM, aqueous sample with pH index in the range of around 1.0 to 3.0 (i.e., before the extraction), triple extraction cycle or triple extraction, and 15 minutes of shaking duration for each cycle. The calibration curve was established using a standard solution with a concentration ranging from 0.05 to 2.0 mg L^{-1} based on the linear relationship between Cr concentrations and the respective atomic absorption values at the wavelength of 357.9 nm. The method limit of detection and quantification values were estimated as 0.012 mg L^{-1} and 0.040 mg L^{-1}, respectively. This proposed analytical method could serve as a simple and low-cost procedure to determine the severely low concentrations of Cr(VI) in wastewater samples or effluents, which indicated proper recoveries (91.1-109%) for spiked samples based on the Appendix F of AOAC (2016). Moreover, the LLE approaches coupled with the addition of ion-pair reagents may be applied for quantitative and qualitative analysis of other ion metals for trace analysis purposes.

Abstract

Nowadays, Kaffir lime oil is one of the highly demand in the industries and sold with various market prices. But sometime the most expensive price of kaffir lime oil does not guarantee the best quality of this oil. Currently, kaffir lime oil quality grading is based only on human sensory evaluation such as smell and visual which accompanying with confusion and inconsistent result. This is due to human sensory evaluations have limitations such as easily fatigue and unable to manage mass products of the oil in time. This paper presents the classification of significant chemical compound of kaffir lime oil in the oil quality grading by using Non-Linear Support Vector Machine (NSVM). The objective of this study is to classify the quality of kaffir lime oil whether it is high or low in quality only by tuning the two different kernels into NSVM. This project has used up to 90 samples of kaffir lime oil data from various high to low quality to prepare NSVM with two different kernels. The implementation of this project was performed by using MATLAB version R2020A. The result appeared NSVM model with RBF kernel is better than NSVM model with Polynomial kernel. It was discovered that RBF kernel was able to generate 100% accuracy, specificity, precision, and sensitivity compared to Polynomial kernel. Since the finding and outcome were effective and significant, thus this study contributes a lot of benefits for future study especially in kaffir lime field.

Keywords: non-linear support vector machine, radial basis function, polynomial, kaffir lime oil, high/low quality

Abstrak

Saat ini, minyak limau purut mendapat permintaan tinggi di industri, dan dijual dengan harga yang berbeda di pasar. Tetapi harga minyak limau purut yang mahal tidak menjamin kualiti tinggi minyak ini. Pada masa ini, penilaian kualiti minyak limau purut berdasarkan penilaian deria seperti hidung dan mata menimbulkan kekeliruan dan hasil yang tidak konsisten. Ini kerana penilaian deria mempunyai batasan dan mudah letih dan tidak dapat menangani banyak sampel sekaligus. Oleh itu, kajian inimembentangkan klasifikasi sebatian kimia yang penting dalam minyak limau purut untuk gred kualiti minyak dengan

menggunakan Mesin Vektor Sokongan Bukan Linear (NSVM). Objektif kajian ini adalah untuk mengklasifikasikan kualiti minyak limau purut sama ada berkualiti tinggi atau rendah dengan menyesuaikan dua kernel yang berbeza ke dalam NSVM. Projek ini menggunakan 90 sampel data minyak limau purut dari berkualiti tinggi hingga rendah untuk melatih NSVM dengan kernel yang berbeza. Pelaksanaan projek ini dilakukan dengan menggunakan MATLAB versi R2020A. Hasilnya menunjukkan model NSVM dengan kernel RBF lebih baik daripada model NSVM dengan kernel Polinomial. Didapati kernel RBF mampu menghasilkan ketepatan, kekhususan, ketepatan, dan kepekaan 100% berbanding dengan kernel Polinomial. Penemuan dan hasil ini berkesan dan signifikan sekali gus akan mendorong dan memberi banyak faedah untuk kajian masa depan terutama dalam bidag limau purut

Kata kunci: mesin vektor sokongan bukan linear, fungsi asas radial, polinomial, minyak limau purut, kualiti tinggi/rendah

Introduction

Kaffir lime oil or scientifically known as Citrus Hystrix which is originate from Rutacae family can be found in most Asian Countries. It was widely consumed in Asian dishes and other few industries such as aromatherapy, medicines, and fragrances. Despite all, Kaffir lime oil can also be obtained from its peels and leaves. Currently, the oil quality grading was performed manually based on human sensory evaluation. It was observed based on the physical properties of the samples. Human experienced and perception on the oil long-lasting aroma, color and odor is the only method to classify the quality of the oil. Natural sensory quality evaluation method like this produces less accuracy and subjective as it may vary from everyone. Usually, the result performed by natural sensory train grader were not consistent since it may vary to each other and the process itself take a high time consuming in the procedure [1-3]. Many researchers encountered that essential oil can be classified based on their chemical compound. This method of classification is more accurate compared to the human sensory evaluation [4]. The chemical compounds of essential oil need to be analyzed in order to classify the grading of their quality [5].

The quality of kaffir lime oil can be determined based on their abundances of major chemical compound. Many researchers found the major chemical compound of kaffir lime oil was monoterpene components. The monoterpene components discovered were Citronellal, Limonene, β-pinene, α-pinene and Sabinene [6-9] Besides that, caryophyllene was also identified by Ngan et al., researcher from Vietnam [10] and terpinene-4-ol was found by Hongatanaworkit & Buchbauer as another major compounds of kaffir lime oil [11].

Furthermore, to overcome the inconsistent result of classifying oil grading and the amount time consuming, this project proposed a latest technique of classifying major compounds in Kaffir lime essential oil using Non-Linear Support Vector Machine (NSVM) to perform the automated grading. A SVM is a method in supervised learning that usually used for classification. SVM is used to overcome the problem of classification and regression with linear or non-linear data [12, 13]. However, NSVM will be applied when the data consumed can't be easily separated with linear line. Therefore, the kernels ought to be used to make non-separable data into separable data. Kernels is used to map out the data from the vector input into the high dimension vector space [12]. In this project, the RBF kernel and polynomial were choosing to be tuning into NSVM. The abundance percentages (%) of major compounds act as an input and will be supplied to NSVM model develops by kernel. The output will determine the quality of kaffir lime oil whether it is low or high in quality. Hence, the oil quality and grading of kaffir lime will be classified by using an automated intelligent nonlinear support vector machine (NSVM) which regards to their chemical compounds and reduce the time-consuming during grading processes.

Materials and Methods

Sample preparations

The 90 samples data of kaffir lime oil that contains high and low in quality were used in this study that contains high and low quality. These data were

obtained from 15 samples kaffir lime oil before applying synthetic data. 12 samples of kaffir lime oil obtained in the market with different various brands. All 12 brands kaffir lime oil was sent to Forest Research Institute Malaysia (FRIM) to extract the chemical compound by applying gas chromatography-mass spectrometry (GC-MS). It was found kaffir lime oil has almost 96 chemical compounds. Another three samples kaffir lime oil data get from previous researcher[7, 9, 14].

Z-score technique

The Z-score technique was utilised to group the data and assign an explicit grouping to the data population sample in this study. Previous studies have used Z-score approaches to establish a specific set, with Z-score being a widely used application for standardising data and calculating a factor score. Thus, the Z-score technique was applied to identify the significant chemical compound of kaffir lime oil [4]. In this technique, the two significant chemical compounds of kaffir lime oil were found, which were β-pinene, limonene, linalool, citronellal, and terpinene-4-ol. The five chemical compounds were used as a marker compound for the NSVM classification method. Table 1 shows samples kaffir lime oil was used in this project and its significant chemical abundance (%). There are 11 HIGH samples and 4 LOW samples of kaffir lime oil. Samples AA, AB and AC got from previous researcher that were extract directly from kaffir lime, so they were labelled as a high quality. Another. 8 samples HIGH kaffir lime oils are traded as high quality by certified trader and some of them were published as high-quality kaffir lime oil

The quality of kaffir lime oil was determined based on its chemical abundance (%). The higher the abundance(%) of this chemical, the higher quality of kaffir lime oil [6, 8, 15–17].

Table 1. Significant Kaffir lime chemical constituents used for classification (Group' 1' for HIGH quality and '2' for LOW quality

LL	2.19	50.61	7.14	0	0	2

Synthetic data

All 15 data was added with synthetic data to become 90 samples data to increase the performances classification method[18]. Synthetic data was created by adding the SNR signal to the original input-output data. The synthetic data equations can be represented as follows, as recommended by Sevgi [19]:

$$Ysynthetic = Y_{\mathrm{NSVM}} + Y_{SNR} \quad (1)$$

The original NSVM input-output data is Y_{NSVM}, and the SNR signal or random noise is Y_{SNR}. The trend of the original data and original data with synthetic data should be the same. The calculation minimum, maximum and median of synthetic data are done to support the trend similarity.

Data pre-processing

Data pre-processing done for this experiment consists of a holdout cross-validation strategy for splitting data. The data is divided into ratios 80%:20% for training data and for testing data that was recommended by the authors [5, 20-22], which were for training data set it has 72 samples while the testing data has 18 samples. The ratio is applied in that manner due to the higher number of the training data collected, hence the higher accuracy results appeared on the model [22]. On the other hand, the difference between these two data sets is that the training data is used in model creation while the test data is performed as the model output prediction.

Build the NSVM classifier model

In the real world, data is rarely linearly separable. Most are non-linear. NSVM is modified by entering the kernel functions into SVM. There are a few types of kernel functions of NSVM: polynomial, quadratic, RBF, and sigmoid [23]. When using NSVMs in practice, it's especially vital to pick the correct kernel parameters. Thus, this experiment will test two different kernels to find the best kernel for modelling the quality kaffir lime oil grading. The two different kernels are the Polynomial kernel and RBF kernel. In general, the RBF kernel is a good starting point. This kernel nonlinearly maps samples into a higher-dimensional space to handle the case where the relationship between class labels and attributes is non-linear, unlike the linear kernel[24]. The polynomial kernel is selected because this kernel gives 100% accuracy for agarwood oil grading in a previous study [20] compared to the RBF kernel that is given only 89.5% [25].

The compounds gathered from the 90 samples of kaffir lime oil were used to train NSVM with Polynomial kernel and RBF kernel. The abundances (%) of the chemical compounds act as input, and this input were fed into NSVM model development, and hence the output is set to be either '1' or low '2' quality. All the analytical work was performed automatically by using MATLAB software version R2020A. Figure 1 shows the flowchart of NSVM modelling.

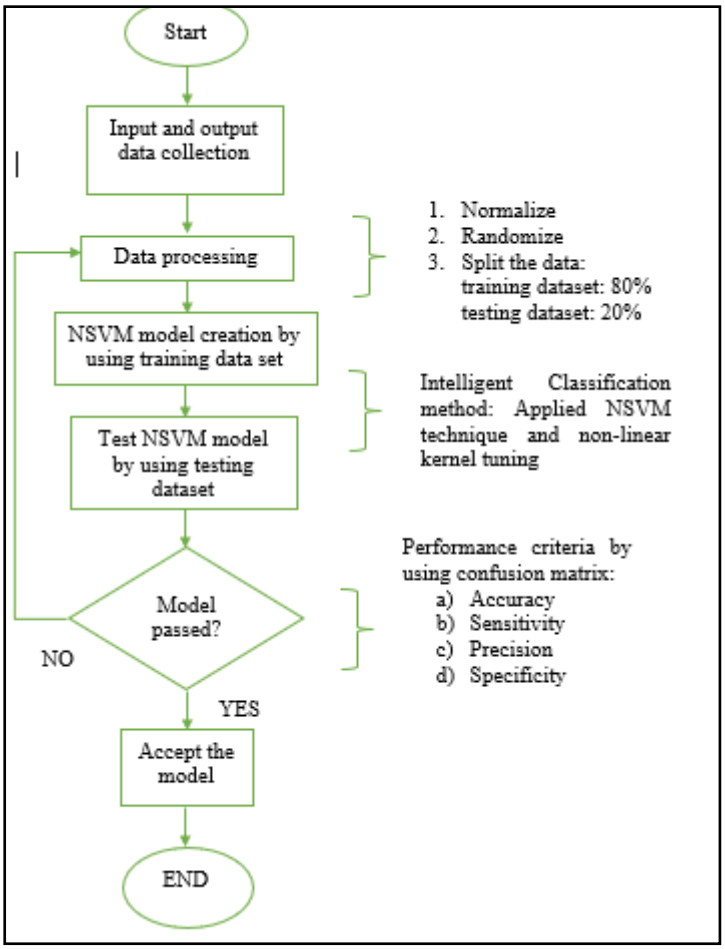

Figure 1. Flowchart NSVM modelling

Performance's measure

The performances for NSVM modelling were measured by using the confusion matrix. Other than that, measurements such as accuracy, sensitivity, specificity, precision, and Mean Absolute Error (MAE) would also be used to obtain more granular and precise model-building results. The accuracy (ACC) is defined as the effectiveness of the classifier. The calculation of the accuracy is as follows [29]:

$$ACC=(TP+TN)/(TP+FN+FP+TN) \quad (2)$$

Sensitivity (SENS) is defined as the rate of a true positive. The effectiveness of a classifier to identify the high quality of kaffir lime is as follow [29]:

$$SENS=TP/(TP+FN) \quad (3)$$

The specificity (SPEC) is interpreted as the rate of the negative. The effectiveness of a classifier to identify the low quality of kaffir lime is as follows [29]:

$$SPEC=TN/(TN+FP) \quad (4)$$

Precision (PREC) is interpreted how often it is correct when it predicts high quality of kaffir lime oil as follow:

$$PREC=TP/(TP+FP) \quad (5)$$

Results and Discussion

The confusion matrix result is shown in Table 2 for the polynomial kernel and Table 3 for the RBF kernel. Where TP (True positive): Classified as HIGH quality and the actual was HIGH quality, FP (False positive): Classifies as HIGH quality but the real is LOW quality, FN (False negative): classified as HIGH quality, but the actual was LOW quality and TN (True negative): classified as LOW negative and the actual is LOW quality. From the result in table 2 and table 3, the value of TP for Polynomial and RBF were 14 and the value of FN for both kernels is also the same, which is 0. FP value for table 1 was 4, while FP value in table 2 was 0. TN value in table 1 was 0 while TN value in table 2 was 4. This result shows that RBF kernel is better than the polynomial kernel because the best model does not have value of FP and FN.

Table 4 shows the comparison performances between the polynomial kernel with RBF kernel. It is clearly showing that RBF kernel is way better than polynomial. RBF kernel can reach up to 100% of its accuracy, sensitivity, specificity, precision, and 0% mean absolute error (MAE) compared to the polynomial kernel which only manage to achieve 100% in its sensitivity, 66.78% accuracy precision, and 0% specificity, and 0.22 for MAE. In general, the lower the MAE, the better a model's ability to match a dataset. We may compare the MAE of two distinct models to see which one delivers a better fit to a dataset when comparing them.

Table 2. Confusion matrix for polynomial

Data Class N=18	**Classified as HIGH**	**Classified as LOW**
actual HIGH	TP=14	FP=4
actual LOW	FN=0	TN=0

Table 3. Confusion matrix for RBF

Data Class N=18	**Classified as HIGH**	**Classified as LOW**
actual HIGH	TP=14	FP=0
actual LOW	FN=0	TN=4

Table 4. Confusion performances between polynomial kernel and RBF kernel

Performances	**Polynomial (%)**	**RBF (%)**
Accuracy	66.78	100
Sensitivity	100	100
Specificity	0	100
Precision	66.78	100
MAE	0.22	0

Conclusion

This paper has successfully evaluated the Kaffir lime oil quality either high or low by tuning in polynomial kernel and radial basis function (RBF) kernel into NSVM. The result shows RBF kernel was able to produce 100% in its accuracy, specificity, precision, and sensitivity compared to Polynomial kernel which was able only to produce 77.78% in its accuracy, 100% sensitivity, 0% specificity and 77.78% precision. Hence it is also can be concluded that RBF kernel parameter better than polynomial for kaffir lime oil grading classification. Since the finding and outcome were effective and significant, thus this study contributes a lot of benefits for future study especially in kaffir lime field.

Abstract

This study aims to prepare phosphotungstic acid supported on hydrotalcite (PTA-HT) for one-pot hydrothermal cellulose conversion into formic acid (FA). In this study, different percentages of PTA on HT (1, 5, 10, 15, 20, 25, and 33%) were prepared and the catalytic activity was observed for two different parameters such as time (1 to 5 hours) and reaction temperature (160 to 240 °C). The prepared catalysts were characterized using Fourier transform infrared (FTIR), X-ray powder diffraction (XRD), Brunauer-Emmet-Teller (BET) and field emission scanning electron microscopy-energy dispersive X-ray spectrometry (FESEM-EDX), while the production of FA was determined using ultra high-performance liquid chromatography (UHPLC). To avoid bias, raw PTA and calcined HT were compared with varying percentages of supported PTA. PTA-HT was successfully prepared through the impregnation method as confirmed by XRD, FTIR, BET and FESEM-EDX. According to the results, the optimum condition for cellulose conversion into formic acid was when 25% PTA-HT was applied at 220 °C for 4 hours, with a 30% cellulose conversion and 18 % FA yield. Due to the acidity and redox properties of PTA, it has been demonstrated that PTA-HT increased the catalytic activity by two-fold when compared to calcined HT alone (8%). The significance of this finding opens new suggestion of bifunctional catalyst in cellulose conversion into FA.

Keywords: catalyst, cellulose, formic acid, hydrothermal, phosphotungstic acid

Abstrak

Tujuan kajian ini adalah untuk menyediakan asid fosfotungstik yang disokong dengan oleh hidrotalsit (PTA-HT) bagi proses hidroterma penukaran selulosa kepada asid formik. Di dalam kajian ini, perbezaan peratus PTA ke atas HT (1, 5, 10, 15, 20, 25 dan 33%) telah disediakan dan aktiviti pemangkinan telah dijalankan terhadap dua parameter iaitu masa (1 jam hingga 5 jam) dan suhu (160 hingga 240 ℃). Pemangkin yang telah disediakan diperincikan menggunakan inframerah transformasi Fourier (FTIR), pembelauan sinar-X (XRD), Brunauer-Emmet-Teller (BET) and mikroskopi imbasan pancaran medan-spektrometri tenaga serakan sinar-X (FESEM-EDX) manakala asid formik yang terhasil ditentukan menggunakan kromatografi cecair berprestasi ultra tinggi (UHPLC). Bagi mengelakkan keputusan yang berat sebelah dalam kajian, PTA tulen dan HT yang dikalsin telah dibandingkan dengan perbezaan peratus PTA yang disokong. PTA-HT yang telah disediakan melalui kaedah

impregnasi dicirikan oleh XRD, FTIR, BET dan FESEM-EDX. Berdasarkan keputusan, keadaan yang paling optimum bagi penukaran selulosa kepada asid formik adalah apabila 25% PTA-HT digunakan pada 220 °C selama 4 jam dengan menghasilkan 30% penukaran selulosa dan 18% penghasilan asid formik. Oleh kerana ciri-ciri asid dan redoks yang dimiliki oleh PTA, keputusan kajian telah menunjukkan bahawa PTA yang disokong oleh HT meningkatkan aktiviti pemangkin sebanyak dua kali ganda berbanding HT yang telah dikalsin yang hanya menghasilkan 8% asid formik. Kepentingan kajian ini akan membuka cadangan baru terhadap penggunaan pemangkin dwifungsi dalam penukaran selulosa kepada asid formik.

Kata kunci: pemangkin, selulosa, asid formik, hidroterma, asid fosfotungstik

Introduction

Biomass is a great alternative for carbon sources in the production of platform chemicals as biomass originated from plants and animals [1]. Numbers of researches focused on forestry and agricultural residues as it is non-edible to address food competition issues such as wood [2], corncob waste [3] and rice husk [4]. Plant biomass is made up of three main constituents: cellulose, hemicellulose and lignin. Among these constituents, cellulose has the highest percentage and play important structural function for plant cell walls [5, 6]. Cellulose is a polymer that is highly crystalline due to rigid intermolecular bonds of hydrogen to hydroxyl group and oxygen with nearby glycosidic rings [7, 8]. Glycosidic bonds of cellulose causes difficulty in depolymerizing cellulose, which required highly reactive catalyst and rigorous experimental conditions. In converting cellulose, many techniques have been studied such as pretreatment of cellulose using ball-milling [9], addition of oxidant [10], Fenton reaction [11-13], hydrolysis [14, 15], ozonation [2] and oxidation [16]. A successful cellulose conversion provides production of important chemicals such as formic acid [17-19], lactic acid [20, 21], levulinic acid [22] and acetic acid [23]. Industries have been eyeing formic acid (FA) due to its nontoxicity, noncorrosive, easy handling and readily biodegradable qualities [24]. Formic acid is the most basic form of carboxylic acid and is commonly used as a byproduct in a variety of applications such as agriculture [25], cosmetics [26], textile [27] and pharmaceuticals [28].

Mineral acids such as hydrochloric acid, sulfuric acid and phosphoric acid have previously been used as acid catalysts for cellulose conversion due to their strong acidity and low cost, but these catalysts are highly corrosive [29-33]. Therefore, improvement had been made to convert cellulose using solid acid catalyst such as heteropoly acid [16], zirconia, zeolite and montmorillite [34]. The advantageous of using solid catalyst is that it is less corrosive, easier to handle, and separates the catalyst from the reaction medium. Among all catalysts, heteropoly acid (HPA) catalyst appears to be the most promising due to its strong Bronsted acidity and redox property [35] that able to hydrolyze and oxidize cellulose into FA. Nevertheless, drawbacks of homogenous HPA are low thermal stability, low surface area and easily soluble in polar solvent [35]. Supporting HPA on a suitable support is one way to heterogenized HPA, which can improve product yield, selectivity, and reduce HPA's drawbacks by providing more active sites and making it more porous [14, 22, 35, 36]. In addition, hydrotalcite (HT), a potential support material with a high surface area and basic properties that may aid in the catalytic conversion of cellulose, is one such material that has been widely used–in flame retardance, neutralizing additives, a base catalyst for cellulose conversion and adsorbent [37-40]. Therefore, in this work, cellulose conversion into FA by different percentages of PTA ($H_3PW_{12}O_4$) supported with HT ($Mg_6Al_2CO_3(_{16})\cdot 4H_2O$) were investigated to see the effects of temperature, time and PTA amount towards the production of FA.

Materials and Methods

Materials

All reagents were analytical grade and used without further purification such as hydrotalcite (Sigma-Aldrich), microcrystalline cellulose and ethanol 99.5% (Systerma) while formic acid 98-100% HPLC grade, tungstophsphoric acid hydrate, orthophosphoric acid and potassium dihydrogen phosphate were purchased from Merck.

Preparation of catalyst

The catalyst preparation starts with the reconstruction pathway in which commercial HT was calcined at 450 °C for 4 hours under nitrogen gas to remove carbonate ions. This step is to allow anions from raw PTA solution to enter into the empty interlayer region later [41]. The raw PTA was dissolved into deionized water to the desired amount (1, 5, 10, 15, 20, 25 and 33% by w/w%). Meanwhile, calcined HT was dissolved in another beaker. Subsequently, dissolved PTA was added dropwise into calcined HT solution. At this step, calcined HT will reconstruct into its original shape with new interlayer anions from PTA. This is because calcined HT regains its original structure when exposed to the aqueous solution [42]. Then, the mixture was stirred for 4 hours to ensure that PTA and calcined HT until both solutions were well-mixed. Lastly, the mixture was dried overnight to remove the water from the mixture forming a solid containing PTA and calcined HT.

Catalytic experiment

Cellulose conversion was conducted in a 100 mL hydrothermal reactor in which the contents of catalyst and cellulose fed were 0.1 g and 0.05 g respectively. Then, about 50 mL of deionized water was added. The reactor was tightened and placed inside an oven. Once reaction temperature and time were up, the cellulose conversion started. As soon as the required temperature and time were reached, the liquid product was filtered using a syringe filter and the solid residue was filtered using a vacuum pump. Cellulose conversion was calculated according to Equation 1. The concentration of FA was analyzed using the UHPLC system (1290 Infinity, Agilent Technologies) using Zorbax SB C18 column with an internal diameter of 21.2mm and 5µm particle size. The UHPLC system was connected with a DAD detector measuring at 210 nm. 10 mM phosphate buffer with pH adjusted to pH 2 was prepared, filtered and degassed. The concentration of FA from the sample was identified by comparing the retention times with standards. Standards calibration was used for FA quantification. The yield of FA was calculated using Equation 2 [43].

$$\text{Cellulose conversion} = \frac{\text{Cellulose fed} - (\text{Solid residue} - \text{Catalyst})}{\text{Cellulose fed}} \text{x} 100\% \quad (1)$$

$$\text{Formic acid yield} = \frac{\text{Liquid product}}{(\text{Stoichiometric coefficient FA from glucan})(\frac{\text{Cellulose fed}}{\text{Mass of glucan}})} \text{ x } 100 \quad (2)$$

Catalyst characterization

Nitrogen adsorption was done to differentiate specific surface area, pore size distribution and pore volume of PTA-HT, raw PTA, calcined HT and raw HT using Brunner-Emmet-Teller (BET) model 3 Flex Micromeritics. BET analysis started with degassing the sample to remove unwanted adsorbed molecules inside the sample pore. The thermal condition of degassing is prior to thermal gravimetric analysis to ensure that the sample was not destroyed during degassing. After degassing, the sample was placed inside the sample tube and liquid nitrogen was filled inside the dewar and placed below the sample tube for BET analysis. Then, phase characterization was carried out by X-ray diffraction (XRD) model Mini Flex 600, Rigaku with Cu Kα 1.54 (40 kV, 40 mA) X-ray radiation source at angle range 3^{θ} to 90^{θ}. In order to identify the crystalline phase compositions, the diffraction patterns were matched with Crystallography Open Database (COD). Chemical functional groups identification was carried out using Fourier Transform Infrared (FTIR) model Nicolet™ iS50 FTIR Spectrometer, Thermo Scientific. FTIR sample was grind using pestle and mortar until it become fine and thin. The sample analysis started after placing the sample onto the detector and background scanning was done. Then, surface morphology of sample was confirmed by Field Emission Scanning Electron Microscope (FESEM) model JSM-IT 800 FESEM, Joel with accelerating voltage 20 kV. Sample was coated with platinum using JEOL Smart Coater. The FESEM images were paired with Energy Dispersive X-ray Analysis (EDX) model Ultimax 45

Oxford to confirm the presence of elemental composition of each sample.

Results and Discussion

Catalytic activity

Three parameters were investigated to find the best conditions for FA production from cellulose using the PTA-HT catalyst: reaction time, temperature, and amount of PTA. The influence of reaction time towards FA production is displayed in Figure 1. To determine the best reaction time, the temperature and amount of PTA were kept constant at 180 ℃ and 5%, respectively. From the results, FA yield increased gradually from 0.08% to 0.22% between 1 to 3 hours of the reaction time. The value then increased slightly to 0.24% at 4 hours and remained constant until 5 hours. In the case of cellulose degradation, a longer reaction time allowed higher degradation rates ranging from 15% to 42% and does not achieve a plateau. From the result, it is observed that reaction condition for both cellulose degradation and FA yield at 180 ℃ is very mild although the reaction time varies from 1 hour to 5 hours. This can be seen when the reaction time was prolonged to 5 hours the cellulose degradation is slightly increased from 30 to 44% while FA yield remain constant as shown in Figure 1. Degradation of cellulose can be done independently without the presence of catalyst as reported in previous journal [44]. However, high temperature of water was required range 320 to 400 ℃ but cellulose was able to degrade into cellobiose, glucose and fructose [44]. Another study of cellulose degradation without presence of catalyst also observed the same trend where at 180℃ degradation products such as acids, furans and sugar were not detectable with only 12% cellulose converted [45]. Meanwhile, as shown in Figure 1, our experiment shows that at 180 ℃, cellulose degradation increases as reaction time prolonged and FA was detectable and reached a plateau at 4 hours reaction time. The production of FA which may cause by the presence of 5% PTA-HT that enhance cellulose degradation. This is because PTA contains tungsten ions and oxygen ions that does have an effect on hydrolysis and oxidation. Although hydrolysis mainly took place in a high temperature water medium, the production of the targeted product requires oxidation of cellulose where PTA provide additional oxygen located at bridging and terminal oxygen atom. However, the reaction time, water temperature and acidic strength of PTA was only able to hydrolyse cellulose but this condition is not enough to produce more FA. Hence, to improve this, we further with the next condition at 4 hours reaction time with the same amount of PTA to determine the suitable temperature and amount of PTA on HT catalyst.

Subsequently, the effect of reaction temperature on FA production was examined by varying the reaction temperature from 160 to 280 ℃. As illustrated in Figure 2, a noticeable increment can be seen towards cellulose degradation from 9% to nearly 50% with prolonged temperature. FA yield also showed better improvement with a maximum yield of 13.36% at 240 ℃. However, a very slight change in FA yield was observed between 220 ℃ (13.05 %) and 240 ℃ (13.36%). From the graph, the trend of FA yield started to decrease at 250 to 280 ℃ although cellulose degradation increases. The suggested mechanism pathway started with cellulose undergoes hydrolysis which form glucose [46]. The glucose further dehydrated into hydroxymethylfurfural (HMF) where later rehydrated into levulinic acid and decomposed into FA [47]. It is reasonable to speculate that higher temperature promotes degradation of cellulose as stated in [48] where cellulose can be degraded without the presence of acid at high temperature. However, previous journal [45] only highlighted the production of monosaccharides but our study proved that with the presence of PTA it enhances cellulose degradation route until FA was produced at suitable temperature. This occurs due to Brönsted acidity of PTA that highly protonate ions during reaction took place. Although, production of FA was a success, FA is an unstable compound which can easily decomposed into CO_2 [43][9]. Hence, selecting 220℃ as our reaction temperature is reasonable to avoid decomposition of FA.

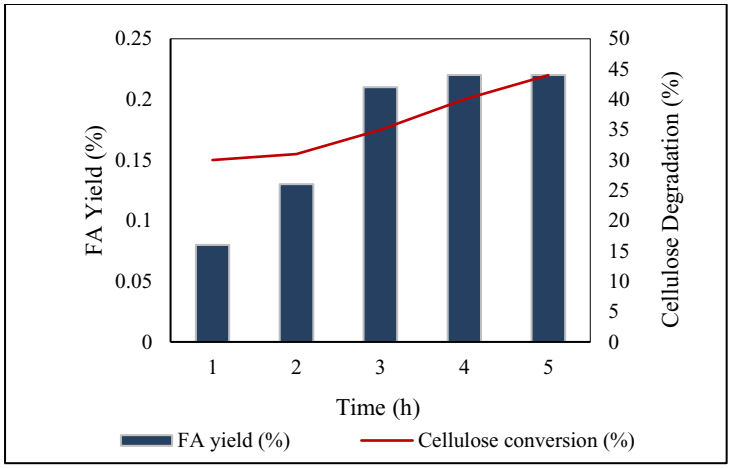

Figure 1. Effect of reaction time on cellulose conversion and FA yield by PTA-HT catalyst. Reaction condition: 0.05 g cellulose, 0.1 g PTA-HT, the temperature at 180 ℃ and PTA loading on HT is 5%

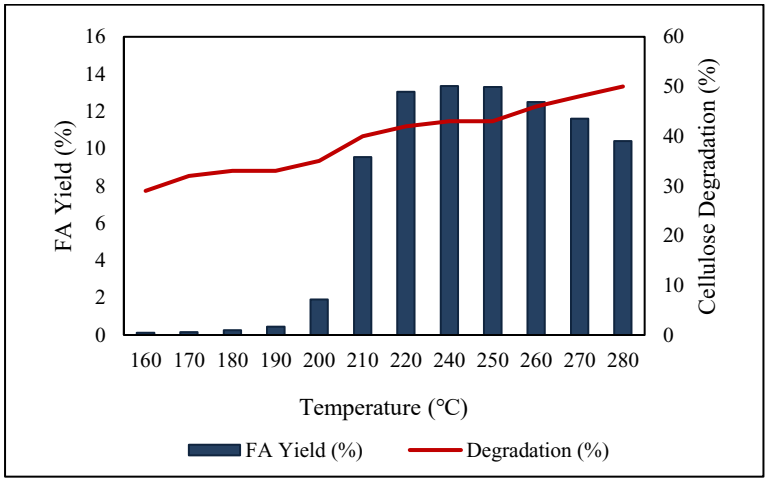

Figure 2. Effect of reaction temperature on cellulose conversion and FA yield by PTA-HT catalyst. Reaction condition: 0.05 g cellulose, 0.1 g PTA-HT, 5% PTA-HT and 4 hours reaction time

The influence of PTA amount supported on calcined HT was displayed in Figure 3. This investigation was compared with blank experiment where catalyst was not included during cellulose degradation. In Figure 3, although cellulose was degraded in blank experiment, FA yield was not obtained. However, other reactors that contained PTA-HT yielded FA. This phenomenon is possible to occur due to PTA criteria that is highly protonic acid which speed up the cellulose degradation [41]. Hence, FA can be obtained in 4 hours under 220 ℃ water temperature. A factor that allows hydrolysis to happen in blank experiment is when water medium is heated to high temperature but as observed our solid acid catalyst improves the hydrolysis rate and react further to form FA. Furthermore, the degradation rate in blank experiment was lesser as compared when PTA-HT was presence. The formation of FA occurred due to cascade reaction in which dehydration and rehydration took place before FA was formed. So as Brönsted acid was placed in the medium, hydrogen ions were highly dissociated which speed up dehydration of glucose into HMF which later

rehydrate into FA [44]. From our experiment, FA production depends on the acidic strength of our catalyst as FA yield increase with increasing amount of PTA but the FA yield was inconsistent. However, FA yield drops drastically to 0.08% when 33% of PTA-HT was placed in reaction medium while highest yield of FA (18%) was observed with 25% amount of PTA. To our surprise, calcined HT alone produce 8% FA which initially function as catalyst support.

Based on previous literature, calcined HT contains medium-strong Lewis basic O^{2+}-Mn^{n+} pairs and isolated O^{2-} as strong basic sites which promote production of FA compared with uncalcined HT that contain weak basic sites [49]. After cellulose was hydrolyze, glucose was not dehydrated into HMF instead isomerizes into fructose and retro-aldol forming glycolic acid. Then, dehydrated into lactic acid which later degraded into FA [50,51, 38]. From this, we understand that two possible routes occurred during FA production as illustrated in Scheme 1. PTA and HT when combined together consist of both acid and base sites. Having Brönsted acid feature increase degradation rate of cellulose while the basic site of calcined HT hindered decomposition of FA into carbon dioxide. 25 % PTA-HT was chosen to further investigate and characterize its properties in relation to the catalytic reaction. 25% PTA-HT was compared with calcined 25% PTA-HT to observe any difference in FA production. Cellulose degradation from calcined 25% PTA-HT was better than blank and calcined HT. The FA yield decreased drastically when PTA loading are more than 25%. This might happen due to leaching of PTA. Another similar study, compared uncalcined tungsten-based zirconia and calcined tungsten-based zirconia reported the same result [52]. From Figure 4, the UHPLC result shows the formation of FA together with other by-products that was obtained during FA production. Although other by-products were obtained, FA peak is one of the highest compared to the others.

Nitrogen adsorption-desorption analysis

BET measurement has been carried out on raw HT, raw PTA, calcined HT and 25% PTA-HT. The objective of this test is to evaluate the significance of impregnating PTA with calcined HT. One of the drawbacks implementing PTA as homogenous catalyst is because of its low surface area and difficulty to reuse. Hence, having large surface area and porous catalyst support can overcome this. Few journals have reported supported PTA with zirconia, activated carbon and carbon foam but as far as our knowledge there is no PTA supported with calcined HT for cellulose degradation study. As shown in Table 1, raw PTA have the lowest specific surface area as compared to 25% PTA-HT. The main reason to calcined HT is to provide larger surface area and porous surface to support PTA and open more active sites during cellulose degradation. If raw HT was not calcined and impregnated with PTA, we assumed that our catalyst will not be well supported as the surface area for raw HT is small compared to calcined HT. The specific surface area of 25% PTA-HT was significantly lesser than calcined HT is because PTA was deposited inside the pores of calcined HT. Hence, it is important to calcined HT so that the surface area is still larger despite being deposited with PTA.

Table 1. BET analysis of raw HT, calcined HT and 25% PTA-HT

Sample	Specific Surface Area (m^2/g)
Raw HT	10.63
Raw PTA	3.91
Calcined HT	206.62
25% PTA-HT	163.39

XRD analysis

XRD patterns of raw HT (2θ=11.58˚, 23.31˚, 34.42˚, 34.80˚, 35.30˚, 39.32˚, 46.71˚, 52.84˚, 56.32˚, 60.65˚and 61.98˚) and raw PTA (2θ=6.89˚, 8.62˚, 9.33˚, 9.5˚, 10.97˚, 11.66˚, 16.09˚, 17.41˚, 17.83˚, 18.60˚and 19.46˚) showed the typical crystalline structure of Mg-Al layered double hydroxides and phosphotungstic acid respectively. Meanwhile, the XRD peak of calcined HT showed significant difference as crystallinity of raw HT was destructed and formed amorphous mixed oxide phase. This can be seen at 2θ=26.55˚, 29.54˚, 39.52˚ and 62.32˚ that showed an appearance of $MgAl_2O_4$ (spinel) (COD Card No. 5000120). Calcination of HT also gave rise to weak and broad peaks that correlated to MgO known as periclase (COD Card No. 9013246) at 2θ=34.78˚, 43.29˚, 60.70˚ and 79.03˚. As shown in Figure 6, XRD peak of 25 % PTA-HT showed the presence of MgO at 2θ= 38.39˚, $MgAl_2O_4$ (2θ=43.01˚, 62.95˚ and 79.77˚) and (2θ=18.59˚, 28.66˚, 34.79˚ and 47.24˚). This phenomenon is related to calcination of HT that will generate mixed oxide and surface defects. Hence, after calcination of HT at 450 ℃ for 4 hours, original structure of HT lost water and carbonate ions [53]. Removing water and carbonate ions that located at interlayer region will allow incorporation of PTA in MgO framework. Therefore, it is observed that 25% PTA-HT peak follows calcined HT peak. From Figure 4, cellulose peak was observed in sample 25% PTA-HT after reaction because this sample was only separated from liquid product using vacuum filter. Although most peaks appear in 25% PTA-HT after reaction sample, there is missing peak of periclase which might cause from leaching due to reaction condition. However, most of the peaks are maintained in 25% PTA-HT after reaction sample.

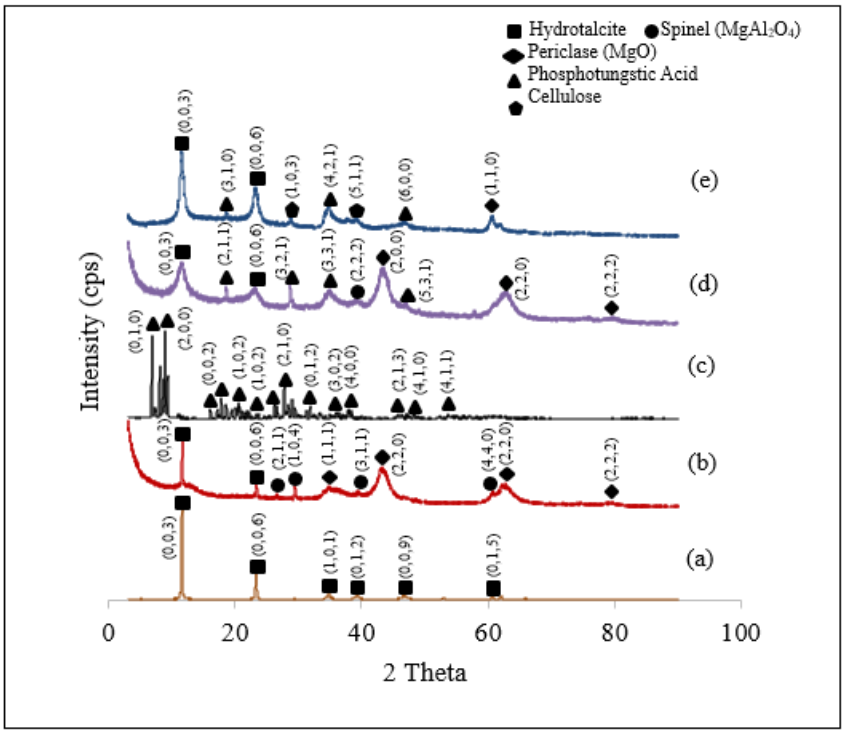

Figure 6. XRD patterns of (a) Raw HT, (b) Calcined HT, (c) Raw PTA, (d) 25% PTA-HT and (e) 25% PTA-HT after reaction

Infrared spectroscopy

IR spectroscopy was used to confirm the presence of PTA after impregnated with calcined HT. As shown in Figure 7, raw PTA was observed to have significant peaks of Keggin HPA at 1071 cm^{-1} (P-O), 970 cm^{-1} (W=O), 899 cm^{-1} (W-O-W) and 729 cm^{-1} (W-O-W) that attributed to stretching vibrational peaks of Keggin anions [54]. The peaks were not obvious because for 25% PTA-HT only 0.025g of PTA impregnated with 0.1g calcined HT. In the case of raw HT, peaks observed at low peaks range between 900-500 cm^{-1} corresponded to metal hydroxides such as $Mg(OH)_2$ and $Al(OH)_3$ [55]. Meanwhile, peaks near 937 cm^{-1} were caused by Mg-O and Al-O. The characteristic peak of raw HT is at 1359 cm^{-1} which is the carbonate and 3403 cm^{-1} for O-H group [56]. The disappearance peaks of metal hydroxides and weak peak of O-H at 3442 cm^{-1} in calcined HT is due to loss of water [57, 58]. IR spectra for 25% PTA-HT, showed the appearances of P-O (1003 cm^{-1}), W=O (801 cm^{-1}), W-O-W (700 cm^{-1}) and Mg-O and Al-O (501 cm^{-1} to 532 cm^{-1}) peaks, which indicated the successful impregnation between PTA and HT. This result can be confirmed with XRD analysis and EDX analysis that can show elements present in the sample.

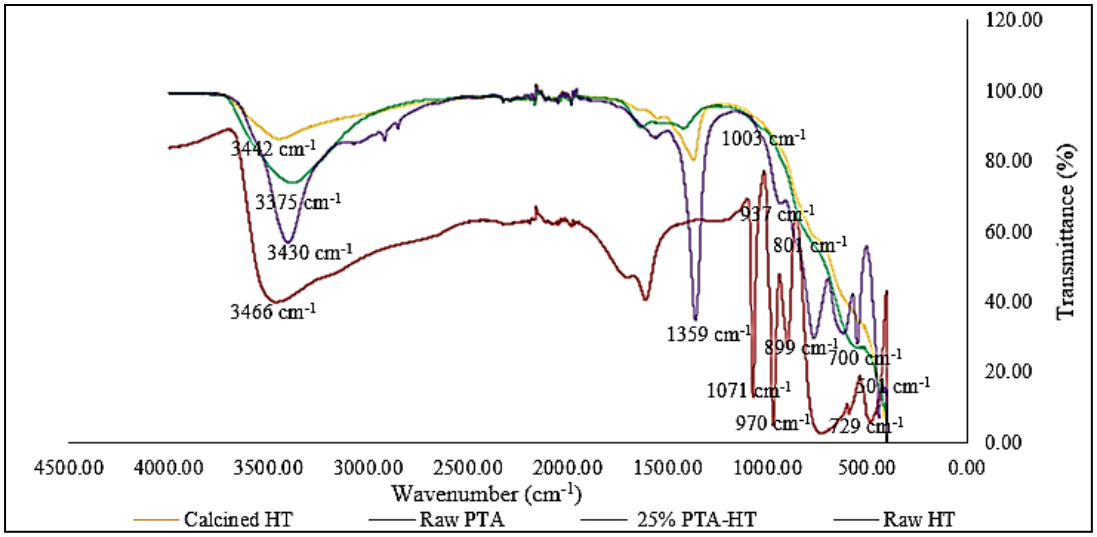

Figure 7. FTIR spectra of raw PTA, raw HT, calcined HT and 25% PTA-HT

FESEM-EDX analysis

FESEM was used to characterize the surface morphology of calcined HT and 25% PTA-HT as shown in Figure 8. Both calcined HT and 25% PTA-HT displayed a similar pattern of particles with irregular shapes. This is because small amount of PTA was impregnated with calcined HT which does not provide any distinguish pattern between calcined HT and 25% PTA-HT. Hence, EDX analysis is important for us to detect the presence of PTA incorporated with calcined HT that can be observed in Figures 9 and 10. As reported before, phosphorus-based HPAs are slightly more acidic than silicon-based HPAs [58]. The importance of tungsten (W) and oxygen (O) inside PTA is their proton affinity which contribute to its acidic site. As shown in Figure 7, the presence of tungsten (W), phosphorus (P) and oxygen (O) indicated the core elements of PTA. Calcination of HT remove carbonate and water at the interlayer and formed mixed oxide where only magnesium (Mg), aluminum (Al) and oxygen were present in Figure 8. The empty interlayer region will be filled with PTA elements and regains its original structure. The unlabeled peaks were carbon tape used for imaging. Both EDX results showed high intensity of Mg, O and Al peaks which shows that calcined HT is more dominant in 25% PTA-HT. Hence, there is no significant difference between FESEM images and FTIR results. Although, calcined HT was dominant the amount of PTA far important towards FA production.

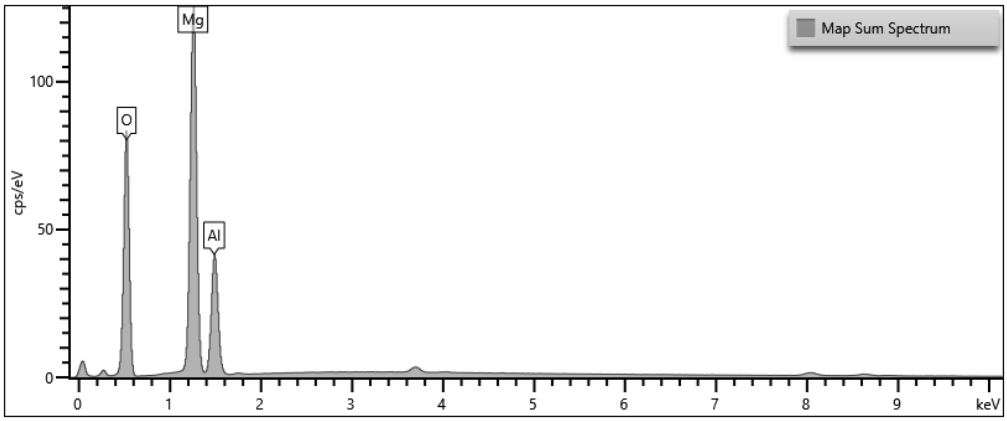

Figure 10. EDX analysis of calcined HT. Core elements belong to calcined HT were magnesium (Mg) and aluminum (Al) belong to HT

Conclusion

From our results, the FA production follows two possible routes contributed by Brönsted acid of PTA and basicity of calcined HT. The basicity of calcined HT may also promote formation of FA while performs well as catalyst support. Although calcined HT is dominant in the catalyst, acidity of PTA plays major role in degrading cellulose into FA. As reported, at optimum condition, 18% FA was yielded together with 30% cellulose degradation which was two times higher than calcined HT alone. To conclude this, the temperature and acidity of catalyst influence the cellulose degradation into FA. However, suitable temperature acidity is required to avoid decomposition of FA. Meanwhile, reaction time have minimal effect towards FA yield. The cellulose degradation can be done independently in water medium but regards to temperature and acid catalyst, the reaction was enhanced. Through catalyst characterization, PTA was successfully impregnated with calcined HT as proved from our results. According to the finding, FA was successfully produced in moderate amounts. Optimum condition for FA yield was as follows: 220℃, 4 hours with 25% catalyst loadings.

Abstract

ZnS has gained attention as an effective photocatalyst for the photocatalytic degradation method in wastewater treatment. Photocatalysis is believed to be a promising solution to solve the problem of water pollution and remove organic pollutants. Apart from other photocatalysts such as ZnO, TiO_2 and MoS_2, ZnS is a developing photocatalyst in this degradation method due to its large bandgap energy. This review paper comprehensively considered the preparation (hydrothermal, solvothermal, low temperature, green synthesis, solid-state reaction, and microwave-assisted synthesis) of ZnS, application, and some challenges that have been faced by photocatalytic degradation methods. The adsorption and photocatalytic properties of ZnS depend on the different morphology and size formed by different methods. ZnS modification presents higher decomposition efficiency in removing organic pollutants.

Keywords: metal disulfide, organic pollutants, photocatalytic degradation, sustainable water management

Abstrak

ZnS mendapat perhatian sebagai pemangkin cahaya yang terbaik untuk melakukan rawatan terhadap air yang tercemar. Fotokatalisis dipercayai sebagai penyelesaian dalam menyelesaikan masalah air yang tercemar dan menyingkirkan pencemaran semulajadi yang terdapat di dalam air. Selain daripada pemangkin cahaya seperti ZnO, TiO_2 dan MoS_2, ZnS dijadikan sebagai pemangkin cahaya dalam kaedah pemulihan air kerana ZnS mempunyai tenaga jurang pita yang tinggi. Kertas kajian ini merangkumi cara penyediaan (hidroterma, solvoterma, teknik suhu rendah, sintesis hijau, tindak balas keadaan pepejal, dan sintesis berteraskan gelombang mikro) ZnS, aplikasi dan beberapa cabaran yang perlu di hadapi dalam proses rawatan air. Ciri-ciri penyerapan dan fotokatalitik ZnS bergantung kepada perbezaan struktur permukaan dan saiz yang terbentuk dari perbezaan penyediaan. Pengubahsuaian ZnS menunjukkan kecekapan penguraian yang tinggi kepada pencemaran semulajadi.

Kata kunci: logam disulfida, pencemar organik, penyingkiran fotokatalitik, pengurusan lestari air

Introduction

Filtration, chemical precipitation, ion exchange adsorption, electro deposition and membrane system are several conventional methods of water treatment. However, they exhibit slow and non-destructive effects on some organic contaminants [1]. Application of advanced oxidation methods such as photodegradation is significant due to their complete degradation without leaving any by-product behind. Photocatalysis has been widely studied because it requires an exceptionally simple procedure to generate free radicals that can degrade organic pollutants [2]. Photocatalytic study can be defined as the ability of some materials to speed up a certain reaction as a catalyst in combination with light including sunlight, UV and visible light. The term 'photocatalytic' designated reactions accelerated by light but maintaining the same course as the thermal reactions [3]. Photocatalytic activity is influenced by the crystal structure, particle size, band gap, dispersibility and hydroxyl of the catalyst. Photocatalytic degradation is a study that is still currently developing. Semiconductor photocatalysts play an important role in photocatalytic activities. Various studies were widely carried out by many researchers around the globe. Among all semiconductors, titanium dioxide (TiO_2) is the most frequently used photocatalyst in study and research regarding oxidation of organic pollutants. However, its high potential for charge recombination has become a limiting factor of TiO_2 for sunlight photocatalytic applications [4].

Meanwhile, the single semiconductor which is the photocatalyst only consists of one medium of photocatalyst to degrade organic pollutant that shows ineffective degradation rates, such as bismuth vanadate ($BiVO_4$), zinc oxide (ZnO) and cadmium selenide (CdSe) [5]. ZnS is a II-VI semiconductor material that exhibits a high excitation energy which is approximately 40 meV. ZnS also has a band gap energy of 3.7 eV and ZnS can be used as semiconductor photocatalyst to degrade pollutants due to its non-toxic nature, highly negative reduction potential of excited electrons and high rate of formation of electron-hole pairs that leads to higher conduction band position in aqueous media [6,7]. A study reported that ZnS is an important inorganic material for various applications such as solar cell, field effect transistor, photoconductors, sensors, light-emitting materials and optical coating [8]. Moreover, ZnS is chosen to be a photocatalyst because of its direct wide band gap (e.g., = 3.7 eV), good mechanical stability, highly efficient conductivity, and high electron transfer ability, aside from the ZnS nanoparticle having a high rate of success when doped with the polyaniline matrix [6,5]. Thus, this mini review aimed to examine the recent preparation technique of ZnS and its application as a photocatalyst in water remediation.

Fundamental of photocatalytic degradation

Photocatalytic degradation technology is one of the advanced oxidation processes (AOP) that involves semiconductor photocatalyst and oxygen to produce radicals in which the activity is influenced by the crystal structure, particle size, band gap, dispersibility and hydroxyl of the catalyst. The basic principle of photocatalyst activation mechanism can be seen in Figure 1. During this reaction, these photons contribute to the excitation of electrons (e^-) on the surface of photocatalyst in the valence band when the energy of the photons is higher than the band gap which makes the e^- rise up into the conduction band and causes the production of a hole (h^+) in the valence band. These separated holes and electrons can recombine and release the absorbed energy to form heat. The excited electrons that are now in the conduction band (e^-_{CB}) will react with oxygen (O_2) to form superoxide radicals (O_2^-) or hydroperoxide radicals (HO_2). Next, these reactive oxygen species will be used for the degradation of pollutants into water (H_2O) and carbon dioxide (CO_2). O_2^- can be further used again in secondary degradation steps where these reactions could result in the oxidation of water molecules at the positive hole in the valence band (h^+_{VB}) that produces hydroxyl radicals (OH) and hydrogen ions (H^+). Lastly, the OH would react with pollutants and result in H_2O and CO_2 [9,10].

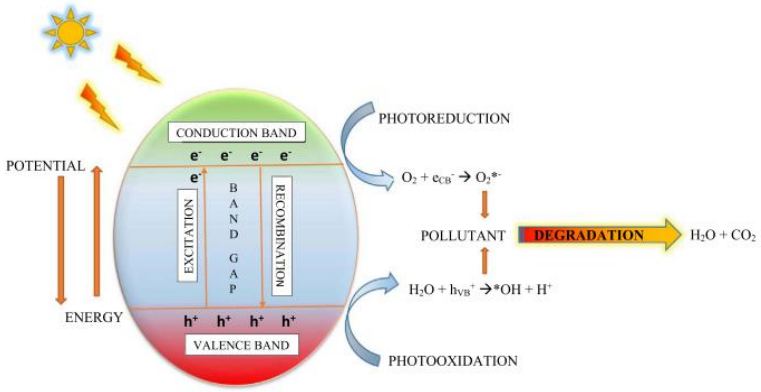

Figure 1. Basic principle of photocatalysis [9]

Many studies have been carried out to test a variety of light sources and mostly focused on the implementation of UV light because this light provides enough photons to generate electron hole pairs within the catalyst. Thus, it could perform efficiently in the production of radicals and the oxidative degradation of the toxic and dangerous pollutants [11]. Photocatalytic processes can use artificial UV lamps and sunlight as the radiation source in photocatalysis. Mostly used artificial UV lamps that were mercury lamps that can be divided into low pressure, medium pressure and high pressure. Moreover, sunlight also has been used in this reaction as nearly 4 to 5% of the sunlight that reaches the surface of earth is in the range of 300 to 400 nm. ZnS is powerful as a photocatalyst in UV range compared to visible range [12]. Furthermore, sunlight has its own limitation because of its graphical variation when compared with artificial UV lamps [13]. Munawaroh and co-author stated that zinc oxide/graphene oxide (ZnO/GO) had high adsorption capacity and GO addition made the band gap narrower, which prevented the recombination of electron and led to high electron transfer on the ZnO [14]. The photocatalytic activity of ZnO/GO is performed in different irradiation times which are 15, 30, 45 and 60 minutes and the maximum wavelength is 665 nm. Figure 3 shows that UV light is involved to activate the photocatalytic properties of the material to form radical species that lead to degradation of the methylene blue dye into green compounds. From Figure 2, it is proven that the longer the contact time, the more electrons would be excited which contribute to production of more h^+. Mechanisms (1) to (6) show the formation of h^+ which contributes to formation of hydroxyl radicals in the photocatalytic degradation. More production of h^+ would increase the photocatalytic degradation. The percent efficiency of degradation based on formula (7) in methylene blue with ZnO/GO 1:2 is 94.05% [14].

Excitation: Photon ($h\nu$) + Semiconductor $\rightarrow e^-_{CB} + h^+_{VB}$ (1)

Recombination: $e^- + h^+ \rightarrow$ energy (2)

Oxidation of H_2O: $H_2O + h^+_{VB} \rightarrow {}^{\bullet}OH + H^+$ (3)

Reduction of adsorbed O_2: $O_2 + e^- \rightarrow O_2^{\bullet-}$ (4)

Reaction with H^+: $O_2^{\bullet-} + H^+ \rightarrow {}^{\bullet}OOH$ (5)

Electrochemical reduction: ${}^{\bullet}OOH + {}^{\bullet}OOH \rightarrow H_2O_2 + O_2$ (6)

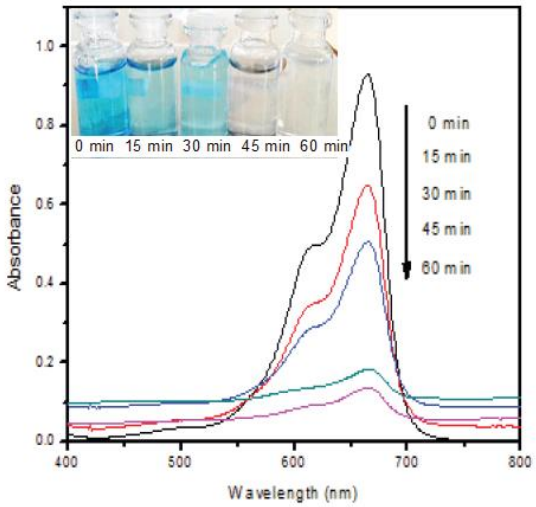

Figure 2. UV-vis spectra of methylene blue with ZnO/GO (1:2) and under UV illumination [14]

Preparation of zinc sulfide

In general, ZnS can be synthesised via various methods such as solution-phase reaction, hydrothermal, solvothermal, exfoliation, high pressure autoclave processes, physical vapour deposition (PVD) and chemical vapour deposition (CVD). ZnS can be easily synthesised with the aid of autoclave at high pressure and low temperature without the need of a catalyst [15]. At ambient conditions, ZnS possess two crystal structures which are zinc blend (cubic) and wurtzite (hexagonal), meanwhile at high pressure "rock salt" crystalline shape can be achieved but only in case of nanostructures of ZnS [15].

Hydrothermal method

Hydrothermal method refers to the heterogeneous reactions for synthesising inorganic materials in an aqueous media above ambient temperature and pressure which is used to obtain nanoparticles, generally at relatively high temperature which is around 200°C by using an autoclave reactor and high pressure. In order to get the desired size and shape of ZnS, a capping agent is applied to control the size and shape of ZnS such as surfactants, ligands, dendrimers and polymers [16]. In hydrothermal synthesis, this capping agent is used to control the nanometre size of ZnS. Thioglycolic acid (TGA) is a common capping agent that has been studied for synthesising ZnS. It is proven that ZnO/ZnS nanocable, ZnS/organic composite nanoribbons and ZnS nanotube arrays have been successfully synthesised by using TGA. In the previous study, TGA was used to prevent the chalcogenide nanocrystal accumulation which is known as stability agents. Thus, TGA is a perfect choice during the hydrothermal process as a capping agent for self-assembly and crystal growth of ZnS crystal to cluster. In this process, the temperature of 105°C is maintained during the autoclave for 7 hours. Based on the transmission electron microscopy (TEM) and selected area electron diffraction (SAED) in the range of 50 to 150 nm as shown in Figure 3, the morphology of ZnS crystal forms some loose spheres by accumulation of small particles. Most of the organic molecules are degraded because of the temperature that took place during the process. The ZnS nanocluster is formed at the final process due to only a part of the TGA molecule which is diffused into the ZnS nanoparticle. The SAED pattern also shows sharp rings of (1 1 1), (2 2 0) and (3 1 1) planes of cubic zinc blended ZnS that corresponded to the XRD study Figure. 4. The size of the nanocrystals based on the Scherrer formula ($D= 0.89\lambda/\beta \cos \theta$), estimated from the full width at half maxima (FWHM) of the (1 1 1) diffraction peak is about 4 nm for synthesised

nanoparticles which are much smaller than the spherical diameters. This indicates that the clusters are formed from nanocrystal mass assembly. It is fair to assume that the TGA-assisted hydrothermal process provides a great opportunity to scale-up other chalcogenides morphology preparation [17]. Based on a previous study, a composite of SnO_2/ZnS prepared by hydrothermal method at 180°C showed the highest photocatalytic activity to degrade RhB [18]. The photocatalytic degradation of 95% is reached at the 1 g/L SnO_2/ZnS dosage with 10 mg/L initial RhB concentration, 4.59 initial solution pH and 23°C. The photocatalytic degradation of the RhB really fitted to the first-order kinetic model and it is also showing the decrease of initial RhB concentration with the increase of SnO_2/ZnS dosage. The composited SnO_2/ZnS that are prepared by hydrothermal method also showed a stable performance during 5 runs of reuse [18].

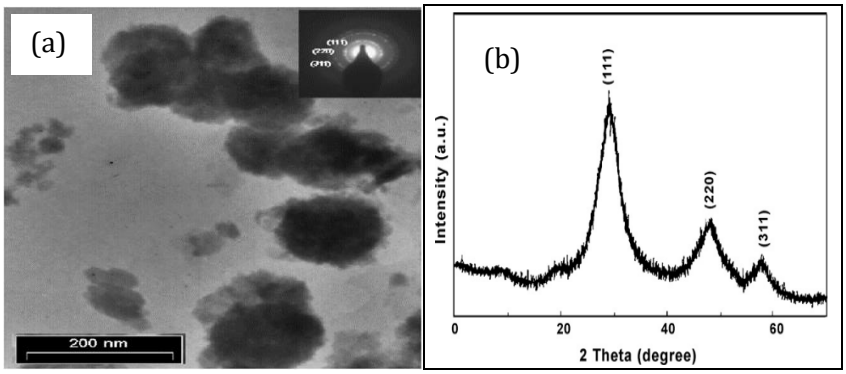

Figure 3. (a) TEM image of ZnS nanocluster; (b) Figure 4 XRD pattern of as-prepared ZnS nanocluster [17]

Solvothermal method

Solvothermal process refers to a heterogeneous reaction involving the thermal decomposition of metal complexes using the solvent mineraliser either by boiling the contents in an inert atmosphere or in a sealed vessel (autoclave). Solvothermal method possesses advantages including less energy consumption and simple and also some disadvantages including need for expensive autoclaves and Teflon liners in stainless steel, which can lead to safety problems during reaction processes and the impossibility of studying in-situ reactions due to their closed system [19]. Unlike hydrothermal route which needs a surfactant, toxic template or capping agent to control the size of ZnS morphology, solvothermal method is without surfactant and needs propylene glycol solvent at 140 °C for 12 hours to produce the ZnS nanoplates. The SEM image in Figure 4 (a) of ZnS exhibits flower-like morphology and a large amount of quasi hexagonal plates which were produced via solvothermal method. However, in the solvothermal method, the right choice of temperature is crucial. As can be seen in Figure 4 (b), higher temperature at 160 °C yielded non-uniform and amorphous nature of ZnS. Obviously, this condition via solvothermal technique did not favour the synthesis of ZnS. This is due to the decreasing crystallisation temperature which can be attributed to a slight increase in photocatalytic activity, hence temperatures higher than 140 °C mostly do not support this method [20]. Song and co-worker carried out the preparation of a ternary photocatalyst of zinc cadmium sulphide by this method which was synthesised at a maintained temperature of 120-140 °C for 3 hours [21]. The methylene blue (MB) was degraded by the photocatalytic activity of zinc cadmium sulphide. 0.4 g zinc cadmium sulphide photocatalyst was dispersed in 250 mL of MB solution. In this study, after a 1-hour reaction time, at 120 °C the photocatalytic activity showed the best photocatalytic activity compared to 140 and 130 °C as shown in Figure 5 below due to 120 °C being the lowest temperature so it is suitable for the solvothermal method.

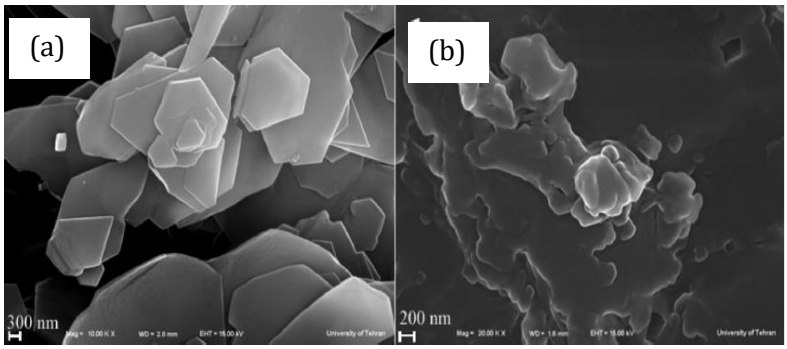

Figure 4. SEM image of as-synthesized product in propylene glycol for 12 hours: (a) 140 °C and (b) 160 °C [20]

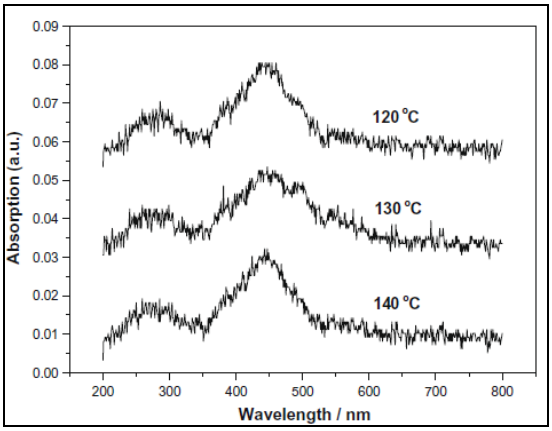

Figure 5. UV-vis absorbance spectra of sample treated at 120-140 °C [21]

Low temperature method

This method basically involves low temperature (below 100°C) by a chemical reaction that occurs between zinc ions and reduces sulphide ions in ethanol as a reaction medium. This method requires a strong reducing agent to have a better control reaction such as hydrazine hydrate to have better control to convert elemental sulphur (S_8) to reactive sulphide ions (S^{2-}) by in-situ reduction. The sulphide ions then react on impulse with zinc ions, since zinc chloride and elemental sulphur were used separately as sources of zinc and sulphur [22]. Low temperature method exhibited preferable characteristics as it is less toxic, less time consuming, low cost and needs low temperature without any solvent release, low waste and environmentally friendly [22]. The less time consumption can be observed when the reduction of S_8 into S^{2-} took place in a very short time. The reaction can be represented in Equation (7) [20].

Equation (7) showed a rapid process as it only takes a few seconds (30-40 seconds) of the elemental sulphur reduction to happen. The concentration of zinc before and after reaction was calculated to know the yield of the reaction by using an ICP-OES spectrometer. The reading of the ICP-OES spectrometer showed 99% consumption of zinc precursor in the reaction which means a very high conversion yield of the precursor to the final product was obtained. Study of the reaction time impact showed that longer reaction times lead to agglomeration of less particles to bigger ones. Hence, the reaction time should be adjusted to form the particles as soon as hydrazine hydrate has been added. Figure 6 (a) shows UV-Vis absorption spectra of ZnS

quantum dots at 60 °C with different reaction times of 2, 3, 5, 7 and 12 minutes which displayed that the size of ZnS quantum dots were almost the same and that longer time which was up to 60 minutes at 60 °C did not influenced the particle size with absorption peak at ~257 nm. Meanwhile, Figure 6 (b) shows UV-Vis absorption spectrum of ZnS quantum dots at 120 °C for 60 minutes. An absorption peak at 277 nm was observed which is red shifted as compared to the absorption peak at 60 ºC, displaying an increase in size [22]. The photocatalytic activity of ZnS synthesised by this method can be observed on the removal of MB with a photocatalyst of ZnS under UV irradiation. This study showed that ZnS succeeded in achieving removal efficiency of 75% during photocatalytic degradation of MB [23].

$$ZnCl_2 + \frac{1}{8S} + N_2H_2.H_2O \xrightarrow[C_3H_8O_2S]{C_2H_5OH,60\,^{\circ}C} ZnS + 2HCl + N_{2(g)}H_{2(g)} + H_2O \quad \textbf{(7)}$$

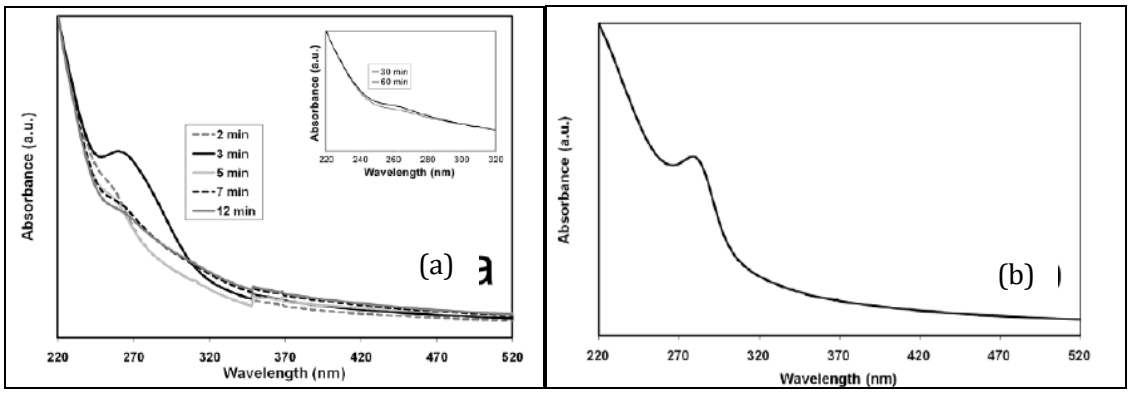

Figure 6. (a) UV-Vis absorption spectrum of ZnS quantum dots at 60 °C for reaction time 2, 3, 5, 7, 12 minutes (a) at 60 °C for reaction time 30 and 60 minutes (b) at 120 °C for 60 minutes [22]

Green synthesis method

Green synthesis method is a biological synthesis of nanoparticles that basically uses plants or plant extract which is low cost, nontoxic and environmental friendly method. A study on glucose was used as both stabilizer and capping agent while latex solution prepared from *Jatropha curcas* L. In the *Jatropha curcas* L there were curcacycline A (an octapeptide), curcain (an enzyme) and curcacyline B (a nanopeptide) equipped inside as a potential stabilizing and reducing agent [24,25]. Glucose is a monosaccharide that present in the plants with five hydroxyl groups are arranged in its own manners along its six-carbon backbone and it is renewable, natural, large quantity and biodegradable. Glucose is used in this method while zinc nitrate and sodium sulfide as zinc and sulphur source respectively. In this method, the resulting solution was heated at 70 °C up to 6 hours. The final product of this synthesis, can be observed in the Equation (8). The ZnS that obtained via this method, exhibited crystallinity peak at 28.38°, 47.73° and 56.50° as shown in Figure. 7. The peaks were assigned to the cubic of ZnS as (1 1 1), (2 2 0) and (3 1 1). The broad peaks in XRD indicated the formation of nanoparticles. Thus, it proved that ZnS nanoparticles succesfully synthesized by green method by using glucose as capping agent [24].

This method can be observed in its photocatalytic activity in a study by Kannan et al. (2020) involving ZnS that had been synthesised using plant extract of *Tridax procumbens* (T:ZnS). Biosynthesised T:ZnS (40 mL) nanoparticles displayed high surface area which was 131.84 m^2/g and also exhibited larger pore size which was 12.15 nm. This high surface area was able to promote more active sites, hence increasing the photocatalytic ability to degrade MB achieved 98% of degradation efficiency under visible light irradiation.

$$Zn(NO_3)_2 + Na_2S \xrightarrow{Glucose} ZnS + 2NaNO_3 \quad (8)$$

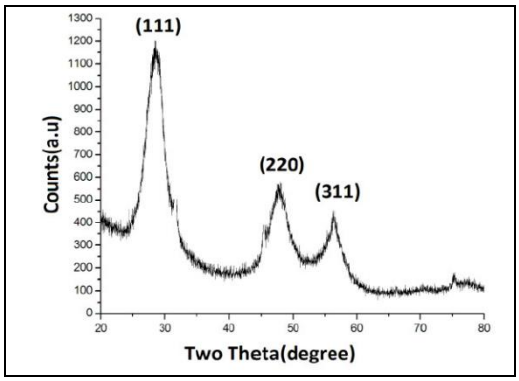

Figure 7. XRD spectra of ZnS nanoparticles [23]

Solid-state reaction method

Solid state reaction method is a simple reaction for the preparation of ZnS nanorods. This method utilises simple techniques such as melting or grinding together the starting materials or simply applying heat to a mixture of starting materials and also without any metal catalyst, solvent or templates. The nanoparticles were prepared by one-step, typically solid-state reaction of zinc chloride and sodium sulphide as zinc and sulphide sources, respectively which will be ground with mortar and pestle at ambient temperature in sodium chloride flux. This method, however, needs high temperatures because it involves precursors to synthesise nanotubes by using a furnace at 800 °C for 2 hours for the heat treatment sample. Figure 8 shows XRD spectra of final nanoparticle ZnS nanorods fabricated by annealing precursor ZnS nanoparticle in sodium chloride flux. The synthesised ZnS nanorods have changed from cubic to hexagonal structure via solid state reaction method [27].

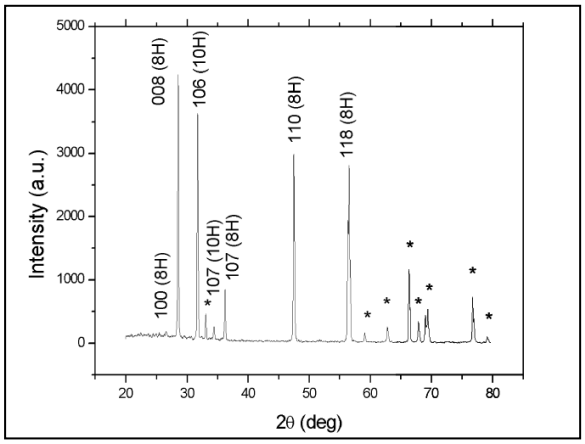

Figure 8. XRD spectra of final nanoparticle ZnS nanorods fabricated by annealing precursor ZnS nanoparticle in sodium chloride [27]

The photocatalytic performance is known to be dependent on the crystallinity, morphology and surface area that are able to enhance the recombination of photogenerated electron-hole pairs. Jothibas et al. (2018) showed the photocatalytic activity of ZnS doped with nickel (Ni) that was synthesised by this method. The ZnS doped Ni was used to degrade the MB. It proved the MB concentration decreases in the presence of ZnS doped Ni due to destruction of the homo and hetero-poly aromatic ring present in the MB or the fast degradation of the dye [27].

Microwave assisted synthesis method

Microwave (MW) assisted synthesis is a heating method that uses ionic liquids (ILs) as MW absorbing medium to synthesise the highly crystalline ZnS quantum dots (QDs). Imidazolium or phosphonium cations together with many types of anions ranging from simple anions including halides to more complex ones included bis(trifluoromethanesulphonyl) amide based, are two types of ionic liquids that were used in this method. The QDs that were synthesised as the final product were less than 5 nm in size and of wurtzite ZnS type. MW irradiation basically is a heating method where the dielectric heating mechanism involves bipolar polarisation and ionic conduction that allows for faster reactions with higher yields and higher purities without high vacuum requirements [22]. ILs are considered as friendly environmental media that can be replaced with other volatile and toxic organic solvent. It is also exhibiting some properties of high polarity, high thermal stability, high ionic conductivity and a good solvent for both electrolyte and organic compounds. Hence MW assisted with IL method that produced via 'green' synthesis route to produce the nanoparticles [23]. The microwave-assisted synthesis method to produce ZnS nanoballs with an average diameter of 41.9 nm was composited with graphene nanosheets (GNS) [29]. These ZnS nanoballs are made up of many small self-assembled ZnS crystals with an average size of 3 nm. 0.20 g of ZnS-GNS composite was used to degrade the MB, resulting in the intensity of the adsorption peaks of MB which gradually diminished with increasing exposure time and finally disappeared after about 32 minutes. This showed a complete degradation of MB as no new absorption peaks appeared in the visible and UV region.

Zinc sulfide as photocatalyst in photodegradation of organic pollutant

Overall, from the syntheses listed above, they show that photocatalytic performance of photocatalysts can be influenced by their crystallinity, morphology, size and surface area. Morphology-controlled synthesis are increasing in popularity because of the structure that decides the characteristics. Different sizes, morphology and structure of materials exhibited different properties. Scale quantisation of particles with semiconductors resulted in dramatic shifts of other essential properties of the materials. Firstly, the quantisation of the scale affects the electronics characteristics of the semiconductor particle, with ultra-small crystallites made up of a few molecular units maintaining their subtle HOMOs (Highest Occupied Molecular Orbitals) and LUMOs (Lowest Unoccupied Orbital Molecular Orbitals). Next, chemical and physical properties which are dedicated to electronic properties of the semiconductor really depend on the size of the nanoparticles. The band gap of the semiconductor becomes larger as the particle size decreases and is related to an absorption shift at shorter wavelengths hence, the level of valence band is shifted to lower energy while conduction band are strongly shifted to higher energies. To summarise, Table 1 represents comparable methods of ZnS preparation, properties and their degradation efficiency towards degradation of pollutants.

On the other hand, many methods have been developed to remove organic pollutants including photodegradation with usage of ZnS as semiconductor/photocatalyst. Among the semiconductors/photocatalysts mentioned above, degradation efficiency of ZnS also can be enhanced as in binary and ternary photocatalysts.

Table 1. Methods of preparation, properties, and their degradation efficiency

Methods of Preparation	Particle Size and Shape	Pollutants	Source of Light	Degradation Efficiency	References
Hydrothermal	Clearly observed lattice fringes indicate that the particles are crystalline.	Methyl Orange (MO)	UV lamp	70% in 120 min	[30]
Solvothermal	The shape and size are uniform and it is observed that all the nanorods are well dispersed.	Rhodamine B	UV lamp	98% in 90 minutes	[31]
Solid-state reaction	The orbital composition of well-defined particles, which has spherical shapes	MO	Visible	88% in 75 minutes	[32]
Green synthesis	Revealed the crystal structures and obvious atomic planes for single particles .	Phenanthrene	Visible	82% in 90 minutes	[33]
Microwave assisted	Looked like agglomerated spherical clusters with particle size	4-chlorophenol	UV lamp	100%	[34]

Binary photocatalyst

Binary photocatalyst of ZnS is when ZnS is composited with another filler for example graphene. This composite (ZnS-graphene) can result in new properties of photocatalysts. The photocatalytic activity of ZnS-graphene was observed by degrading methylene blue (MB) in water [29]. This study used a graphene nanosheet and the UV-Vis spectrum in the range of 300 to 800 nm is given in Figure 9. The characteristic absorption peak of methylene blue solution at 663 nm was selected as the parameter monitored to detect the methylene blue concentration. Figure 13 shows the evolution of absorption spectra of MB in the presence of 0.20 g ZnS-graphene composites. It was found that the intensity of the absorption peaks aligned directly to MB which gradually declined with increasing exposure time and finally vanished after about 32 minutes. There were no new absorption peaks pop up in the visible and ultraviolet region, showing the complete degradation of MB. In addition, the photocatalytic activity of ZnS-graphene can be observed to degrade 4-nitrophenol (4-NP) [34]. The declining of absorption peak intensity of nitrophenolate ion with ZnS-graphene was recorded over time under simulated light to observe the photocatalytic activity of the composite toward reduction of 4-NP.

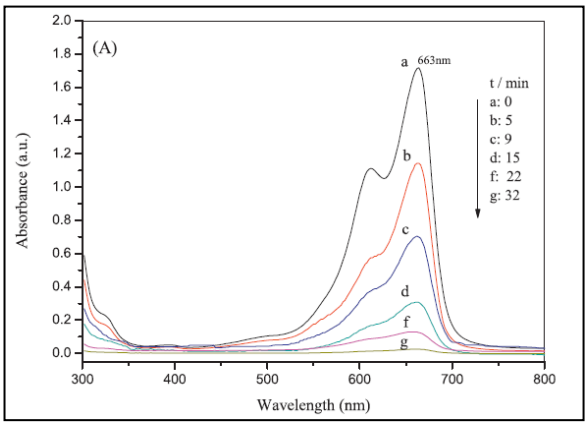

Figure 9. Absorption spectra of a solution of MB with ZnS-graphene [29]

The reduction efficiency of ZnS-graphene and ZnS was compared under simulated solar light illumination as indicated in Figure 10 (a) and (b) respectively. The time used for illumination was 70 minutes to achieve 87% of reduction efficiency with the composite while it was only 34% with single ZnS under similar experimental conditions. Hence, based on formula (10) of reduction rate constant, k shows the results of pseudo-first order reduction kinetics of 4-NP where the k of ZnS is 6×10^{-3} min^{-1} while ZnS-graphene composite is 30×10^{-3} min^{-1}. This shows that ZnS-graphene composite results in better efficiency compared to ZnS and 5 times higher k than ZnS because of its synergistic effect between reduced graphene oxide and ZnS where graphene is responsible for an efficient photo-induced charge separation and transportation [35]. Then, the photo-induced electrons generated in the ZnS nanorod high-band gap pass from its conduction bands to the 4-NP LUMO level through the graphene sheets and reduce the 4-NP to 4-aminophenol [35].

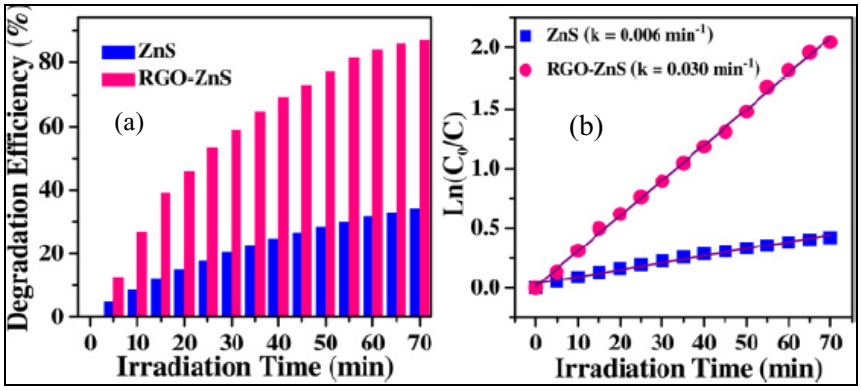

Figure 10. (a) The comparison of the reduction efficiency versus irradiation time over ZnS and ZnS-graphene (b) Plot of In (C_0/C) for the photocatalysis of 4-NP solution with ZnS and ZnS-graphene composite [35]

Ternary photocatalyst

Ternary photocatalyst is a photocatalyst that has a three-system photocatalysis; for example, reduced graphene oxide-ZnS-TiO_2 (rGO-ZnS-TiO_2). The photocatalytic activity of ternary photocatalysts of rGO-ZnS-TiO_2 nanocomposite can be observed on its application for crystal violet dye (CV) removal [36]. This combination is proven to be an effective photocatalyst for the treatment of wastewater. Through this study, the result showed that almost 97% CV dye was removed by adsorption and photodegradation at temperature of 35 °C with initial dye concentration of 50 ppm and nanocomposite amount of 0.4 g/L. The study was carried out with varied loadings of catalyst to decide the optimal amount of rGO-ZnS-TiO_2 nanocomposite prepared with the aid of ultrasonic irradiation. Based on Figure 11, the overall photocatalytic degradations are 94.83%, 97.02% and 96.30% obtained for 0.3 g/L, 0.4 g/L and 0.5 g/L of rGO-ZnS-TiO_2 nanocomposite respectively. The results also showed that the quantity of nanocomposite increased from 0.3 g/L to 0.4 g/L. The degradation of CV was also increased from 94.83% to 97.02% independently and continuous increase in the loading of rGO-ZnS-TiO_2 nanocomposite at 0.5 g/L exhibited a marginal decline in the degradation, which was meant to be at 96.30%. rGO-ZnS-TiO_2 nanoparticles displayed strong adsorption abilities and the excessive adsorption reduced the photocatalytic activity. Hence, the distribution of impudent loaded nanocomposite will hinder the UV light irradiation and the restriction can result in an efficient usage of light resulting in declining photocatalytic degradation of CV dye. So, the result concluded that the optimal dose of rGO-ZnS-TiO_2 is 0.4 g/L with the aid of ultrasonic illumination to obtain effective degradation of CV dye [36].

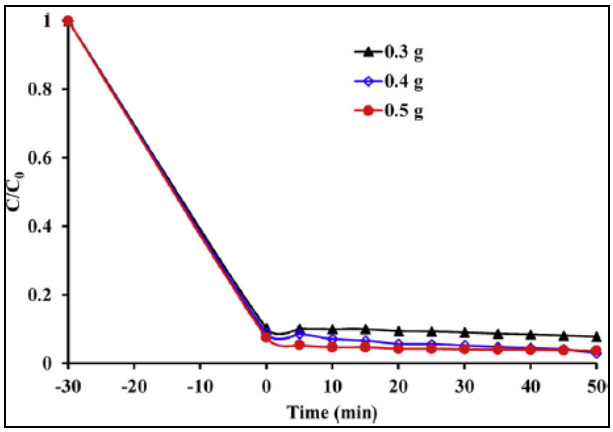

Figure 11. The effect of catalyst loading on degradation of CV dye [36]

Table 2. Comparison between binary and ternary ZnS composites in photocatalytic degradation

Types of ZnS Photocatalyst	Pollutants	Source of Light	Degradation Efficiency	References
Binary				
ZnS-graphene	methylene blue (MB)	UV light	98%	[29]
RGO-ZnS	4-nitrophenol	Solar Light	87%	[35]
Cadmium-ZnS	Methyl Orange	Visible light	90%	[32]
ZnS layers of ZnS(en)x complex	Chromium IV	Hg lamp	99%	[37]
Ternary				
rGO-ZnS-TiO_2	crystal violet dye	UV light	97%	[36]
ZnS–TiO_2/RGO	Methylene blue	Visible light	90%	[38]
ZnO/reduced graphene oxide (rGO)/polyaniline (PANI)	Methyl Orange	Visible Light	100%	[39]
ZnO-ZnS@Pani	2-chlorophenol	Visible Light	87%	[40]
Ag_2S–ZnS loaded on cellulose	Rhodamine B	Visible light	95%	[41]

Conclusion

Based on the overall review towards the application of ZnS, it can be concluded that ZnS can be successfully composited with conducting polymers and other photocatalysts. ZnS was able to be prepared through various preparations and methods resulting in different sizes and morphologies based on their SEM and TEM images. It is also proven that different sizes and morphologies of ZnS would result in different reactions of ZnS towards photocatalytic studies. The smaller the size of ZnS, the better the photocatalytic degradation of organic pollutants. Moreover, ZnS can also act as a photocatalyst in different forms including single semiconductor, binary photocatalyst and ternary photocatalyst. Ternary photocatalysts proved to be the better photocatalytic as three media compositions increased the photocatalytic behaviour of ZnS. This is because ternary photocatalysts improved the electric properties of the photocatalyst, hence improving the photocatalytic degradation of organic pollutants. Last but not least, it can be proven on the basis of the analysis that ZnS exhibited a strong photocatalytic activity to degrade organic contaminants such as organic dye and nitrophenols. Future studies can explore whether ZnS is able to act as a photocatalyst which is a composite with conducting polymer. Conducting polymer is widely used in applications such as sensors because of its characteristics including ease of synthesis, low density and conducting properties. Conducting polymers show potential as it can greatly increase conductivity has the advantages of conventional organic polymers including strength, plasticity, toughness and flexibility. It is believed that composited photocatalysts with conducting polymer increase the effectiveness of degradation because of the increasing appropriate surface of the photocatalyst.

Abstract

This work, using a batch study, revealed the performance of modified magnetite millscales with a cationic surfactant [cetyl trimethyl ammonium bromide (CTAB)] (Fe_3O_4/CTAB MNS) in cadmium ion removal from aqueous solution. The self-assembly method was employed to modify Fe_3O_4 with CTAB. As prepared Fe_3O_4 limited the modification method to *ex situ*. Therefore, a heterocoagulation method was used to self-assemble CTAB on Fe_3O_4. The prepared magnetic nanosorbents (MNSs) were used in batch adsorption to optimize cadmium adsorption. In addition, characterization with Fourier transform infrared spectroscopy (FTIR) and transmission electron microscopy (TEM) revealed new characteristics of that modified Fe_3O_4 that contributed to the enhancement of the adsorption efficiency (Q) to reach 21.6 mg/g. The higher removal percentage shown by Fe_3O_4/CTAB MNS was 89%, which confirmed the successful modification. Therefore, Fe_3O_4 modified with CTAB has higher potential to be used as magnetic nanosorbent owing to lower cost of production with compatible adsorption capacity.

Keywords: stabilized magnetite, magnetic nanosorbents, cadmium solution, cation polymer, cetyl trimethyl ammonium bromide

Abstrak

Kajian ini mendedahkan prestasi skala magnetit yang diubah suai dengan surfaktan kationik (setil trimetil ammonium bromida (CTAB)) (Fe_3O_4 / CTAB), digunakan sebagai penyingkiran ion kadmium dari larutan akues melalui kajian kumpulan. Kaedah pemasangan diri digunakan untuk mengubah Fe_3O_4 dengan CTAB. Fe_3O_4 yang telah disiapkan telah membatasi kaedah modifikasi menjadi *ex situ*. Oleh itu, kaedah heterokoagulasi digunakan untuk memasang CTAB pada Fe_3O_4. Penjerap nano magnetik yang disiapkan (MNS) digunakan dalam penjerapan kumpulan untuk mengoptimumkan penjerapan kadmium. Selain itu, pencirian dengan spektroskopi infra merah transformasi Fourier (FTIR), dan mikroskopi elektron transmisi (TEM) telah

mengungkapkan ciri-ciri baru Fe_3O_4 yang dimodifikasi yang menyumbang kepada peningkatan kecekapan penjerapan (Q) menjadi 21.6 mg/g. Peratusan penyingkiran yang lebih tinggi yang ditunjukkan oleh Fe_3O_4 / CTAB MNS adalah 89% yang membuktikan pengubahsuaian berjaya. Oleh itu, dapat disimpulkan bahawa modifikasi dengan CTAB berpotensi lebih tinggi untuk digunakan sebagai penjerap nano magnetik kerana melibatkan kos pengeluaran yang lebih rendah dengan kapasiti penjerapan yang serasi.

Introduction

Contamination of water is a serious global issue that must be addressed. Contaminated water greatly affects the human well-being. Even if people do not directly drink the contaminated water, it may still cause harm to seafood through the spread of contaminants. Cadmium is a nonessential metal with a high exchange factor. Zinc deficiency increases the risk of Cd poisoning. Zinc acts as an antidote to the toxic effects of Cd. The use of foods and grains (developed in soil polluted by superphosphate compost and sewage slime), the use of refined food sources (exposed to cadmium at specific locations such as cadmium coating on iron and copper), and the consumption of plastics have contributed to an increase in zinc deficiency. Workers at the production line of battery anodes and semiconductors are particularly vulnerable to Cd poisoning. [1].

Cd is a heavy metal; it is a highly harmful industrial and environmental pollutant. It is not biodegradable and accumulates throughout the food chain as a result of plant uptake in polluted soils, which poses a serious health risk to humans. In Malaysia, the maximum allowed Cd concentration in drinking water is 0.005 mg/L. Cd toxicity has been reported by many researchers [2, 3, 4]. Any significant level of Cd in the body causes rapid poisoning and liver damage. Renal tubule failure is the cause of kidney disease [5]. Cd is also harmful to endocrine organs, especially the pituitary gland. Cd-containing compounds are strong carcinogens [6]. According to Hotz et al. [7], there is substantial evidence regarding the carcinogenicity of Cd and Cd compounds in humans. Renal dysfunction, bone degeneration, liver damage, and blood damage have all been linked to chronic exposure to high levels of Cd [5-7].

Ion exchange, membrane filtration, chemical reduction and precipitation, adsorption on activated carbon, nanotechnology treatments, electrochemical removal, and advanced oxidation processes are some of the traditional treatment techniques for removing heavy metal contaminants from the environment or wastewater effluents [4, 8-10]. Unfortunately, many of these traditional techniques have significant drawbacks such as low selectivity, high cost, partial removal, high energy consumption, or the production of large amounts of toxic waste. As a result, the demand for safe, less expensive, and more efficient technologies to remove heavy metals from polluted water has prompted research into low-cost alternatives to commercially available methods [10].

Currently, adsorption is widely accepted as a viable and cost-effective approach for heavy metal wastewater treatment. The adsorption process is versatile in terms of design and operation, and it typically produces high-quality treated effluent. Adsorbents can also be renewed using an appropriate desorption procedure because adsorption is sometimes reversible. Thus, extensive research was conducted to identify the best adsorbents that are low-cost, mass-produced in large quantities, and have a simple and rapid separation process, ensuring that this technology can replace the traditional method of removing heavy metals in wastewater treatment [6, 9].

Owing to their unique features, nanometer-sized materials have recently attracted considerable interest among mainstream researchers. These materials have been used in various areas including biotechnology, design, biomedical science, natural science, and materials science. The use of nanoparticles (NPs) as

effective adsorbentsfor heavy metals removal is gaining popularity among scientists [10]. Compared to micrometer-sized particles, NPs have a considerably larger surface area to volume ratio and a shorter diffusion path, which results in high extraction limit, fast extraction of elements, and high extraction efficiency.

Mill scale waste is a by-product of steel production that occurs during the hot rolling process. The annual output exceeds a million tonnes, and it may contribute to ground contamination [11]. Thus, repurposing mill scale in various applications may help to reduce waste and transform it into a useful agent. Mill scale contains 50% of wurtzite (FeO), 10% of hematite (Fe_2O_3), and 40% of magnetite (Fe_3O_4) [12]. Fe_3O_4 is a metal oxide that behaves as an amphoteric solid, allowing protonation and deprotonation on the surface to produce surface charge. This property is interesting for studying the adsorption mechanism of heavy metals on Fe_3O_4 because Fe_3O_4 easily reacts with the surrounding particles. Therefore, each year [13-16], several synthetic approaches for extracting magnetite from mill scales have been published. Furthermore, magnetite nanoparticles are receiving more attention owing to their superior magnetic properties and high specific surface area. To extract high purity magnetite from mill scale waste, Azis et al. developed a magnetic separation process. Specifically, 1 T of external magnetic field has been used for the extraction [12-14].

High-energy ball milling (HEBM) is a straightforward approach for size reduction. This approach decreases the size of particles from micrometer to nanometer size. However, nano-sized magnetite is unstable and readily oxidizes to form a new composite that does not exhibit the unique high magnetization behavior. Furthermore, because magnetite has a stronger magnetic force, the agglomeration is higher among the particles [11-15].

Therefore, the modification of the surface process may help to reduce the agglomeration problems and the unstable state of Fe_3O_4 NPs. CTAB is a cationic polymer that can self-assemble with other composites [16,17]. Previously, CTAB-modified Fe_3O_4 NPs have been used in removing dye. Faraji et al. believed that CTAB was essential in the dye adsorption mechanism. Therefore, they added CTAB into the dye solution, and CTAB was expected to coat Fe_3O_4 during the batch adsorption experiment; finally, the particles were separated together using an external magnetic field [18].

In this work, Fe_3O_4 was magnetically extracted from mill scale waste and underwent HEBM to become nano-sized. Then, the prepared Fe_3O_4 was coated with CTAB using an ultrasonication bath. The obtained product was used in batch adsorption to remove Cd ions from an aqueous solution. An equilibrium study was performed to evaluate the relevance of using the obtained material at an industrial scale. Thus, the obtained adsorption capacity of the particles, which was enhanced after coating with CTAB, indicates the potential of using the obtained material in removing heavy metals.

Materials and Methods

Sample preparation (adsorbent)

The first step of extraction was to remove the impurities from raw millscales collected at a steel factory in Malaysia. The manual removal of impurities (e.g., stones, sand, dust, or pieces of plastic) that may contaminate the samples was also performed. Then, approximately 100 g of MS flakes was crushed using conventional milling (Pascal Engineering, UK) for 24 h under dry conditions, 700 rpm speed, and 10:1 BRP. The first separation method was impurity magnetic separation (IMS) used to extract the magnetic particles from the RM. The iron oxides (IO) powder was placed inside a glass tube (with a stopper at the bottom) with deionized water (DI) (at room temperature of 22-24 °C) with the presence of a 1 T external field, as shown in Figures 1 and 2. Then, the tube was manually shaken for 10–15 min. Separation II: The Curie Temperature Separation Technique (CTST) was then used to remove stronger magnetic components from the magnetic powder. Separations I and II of waste mill scales were carried out in the same way as previously reported by Azis et al. [12]. CTST's magnetite (Fe_3O_4)

output was dried in an oven at 120°C for 24 h. The magnetite powder was processed for 8 h on a SPEX 8000D milling machine with a 10:1 ball-to-powder (BPR) ratio.

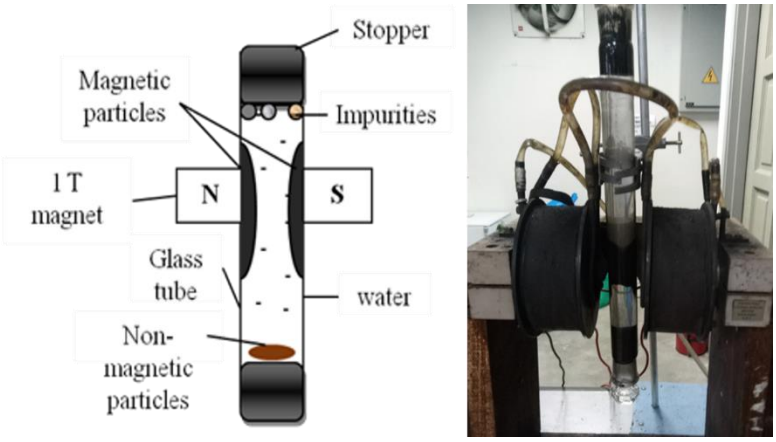

Figure 1. Set up for impurity magnetic separation

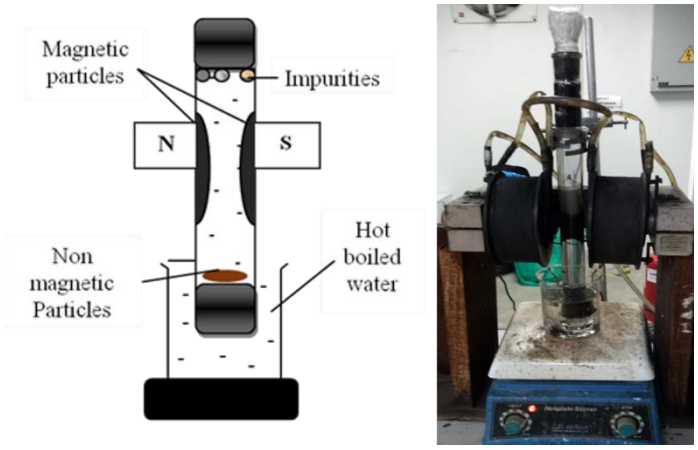

Figure 2. Set up for the curie temperature separation technique

Fe_3O_4/CTAB magnetic nanosorbents

CTAB with a 0.02 M concentration was prepared by mixing the CTAB powder with deionized water and stirred for 30 min in an ultrasonication bath. Then, 20 ml of CTAB solution at a concentration of 0.20 M was mixed with 1.0 g of magnetite extracted from millscales. After 30 min of mixing, an external magnetic field was applied to the mixture, and the collected magnetite coated with CTAB was dried in an oven for 24 h at 60 °C. A summary of the modification method is shown in Figure 3. Next, agitation by sonication in an ultrasonic bath for 20 min was performed. The pH to perform this was at optimum for the CTAB, which has a higher positivity and the highest negativity potential for MNPs (via zeta potential analysis). The pH was then adjusted by using NaOH and nitric acid using the titration method. This step was performed to increase the dispersity of Fe_3O_4 NPs in the CTAB. The Fe_3O_4/CTAB was then magnetically separated using an external magnetic field

to separate the modified magnetic NPs from the residue, as shown in Figure 3. The modified magnetic NPs were collected and then rinsed twice before being dried overnight in the oven at 60 °C. The dried samples were then ground using a mortar to obtain a fine powder of modified magnetic NPs. The surface modification of magnetic NPs using CTAB is summarized in Figure 3, the method was adjusted from previous works [16, 18, 19].

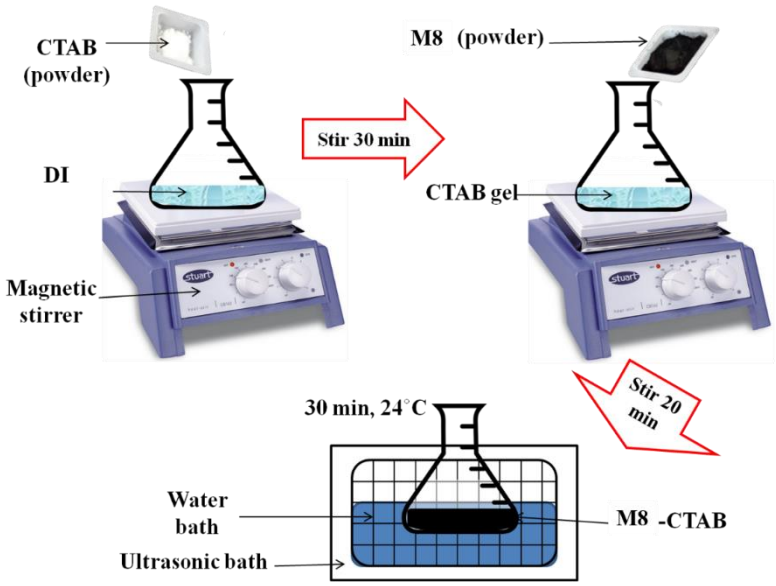

Figure 3. Summarized preparation steps of modified MNPs with CTAB

Adsorbate

All the compounds used to prepare the reagent solutions were of analytical reagent grade. The stock solution of cadmium nitrate ($Cd(NO_3)_2$) (99%, Sigma-Aldrich, UK) (3 mg/L) was prepared by dissolving a weighed quantity of the respective $Cd(NO_3)_2$ in deionized water. The concentration of the metal solution and pH used in this work were 3 mg/L with pH 7, respectively. The pH of the solution was adjusted by using sodium hydroxide (NaOH) and nitric acid (HNO_3).

Batch adsorption experiment

The 100 mL of Cd solution was mixed with 10 mg of Fe_3O_4 nanoparticle adsorbent and placed in a vibrator bath (variable speed reciprocal vibrator (model HY-8)) with a fixed 160 rpm for 5, 10, 15, 20, 25, 30, 35, and 40 min of contact time. All adsorption tests were performed in a vibrator at room temperature (22-25 °C) using accurately weighed amounts of adsorbents in a covered bottle with adsorbate solutions of specific concentrations. The pH of the solution was adjusted from 1 to 10. The adsorption capacity at any time, Q_t (mg g^{-1}), was calculated according to the following Equation 1:

$$Q_t = \frac{C_o - C_t}{m} V \quad (1)$$

where C_o and C_t (mgL/1) are the initial and residual Cd ions concentrations at any time (min), respectively. The volume of Cd ion solution was V (mL), and the mass of dry adsorbent was m (mg). Equation 2 was used to calculate the adsorption capacity at equilibrium:

$$Q_e = \frac{C_o - C_e}{m} V \quad (2)$$

Removal efficiency and adsorption capacity

The removal percentage of metal ions refers to the percentage of metal ions removed from the initial metal concentration solutions. Equation 3 was used to calculate the removal efficiency of Cd^{2+} from the aqueous solution.

$$Cd\ \%Removal = \frac{C_o - C_e}{C_o} \times 100\% \quad (3)$$

Sample characterization

Structural and phase composition

A JEM JEOL 2100 HR transmission electron microscope was used to examine the sample morphology, particle size, and atom arrangement (HR-TEM). Spectroscopic analysis using the infrared FTIR spectrometer was performed by recording infrared spectra (200-4000 cm^{-1}) (Thermo Nicolet, Model Nicolet 6700). Atomic adsorption spectroscopy (AAS) is a technique for determining the concentration of heavy metals in a solution.

Results and Discussion

Morphology analysis

Figure 4a shows the HR-TEM images, which show that aggregation occurred between the Fe_3O_4 nanoparticles that were a range of 5-20 nm in size. The particle sizes increased after coated with CTAB. The result is in agreement with previous works [21, 18]. The nanoparticles aggregated with higher dispersity, indicating good connectivity between the grains due to the higher magnetic forces and subjected to the modification process. The agglomeration was reduced after coated with CTAB [17]. Figure 4b shows images of Fe_3O_4 and Fe_3O_4/CTAB nanosorbents with a scale of 20 nm. Table 1 represent the average value of Fe_3O_4 and Fe_3O_4/CTAB MNS. The average size of the particles was calculated by using Image J. In total, 200 particles were used to determine the average particles. Clearly, the modified Fe_3O_4 was a larger size due to the presence of the CTAB layer on the particles. However, this result was in contrast with the previous publication, considering agglomerations [16-19]. The smaller size is due to the measurement of the real sizes of the particles without the occurrence of agglomeration.

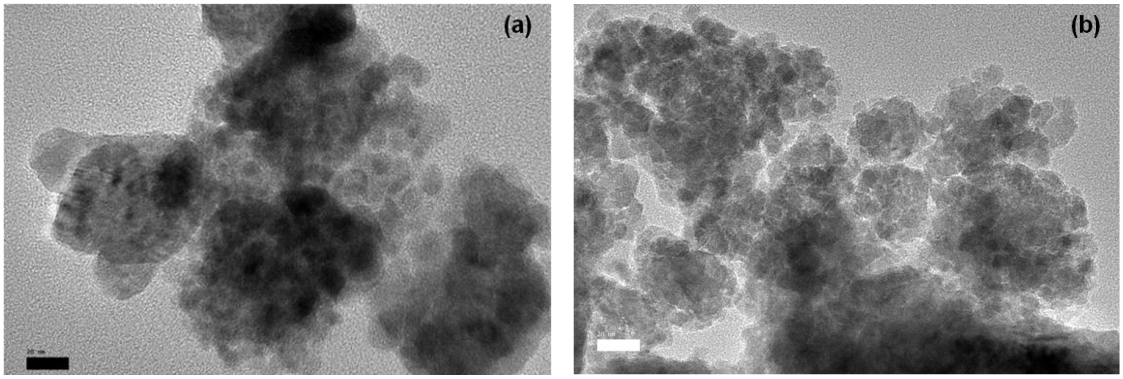

Figure 4. Fe_3O_4 extracted from (a) millscales waste and (b) Fe_3O_4/CTAB

Table 1. HR-TEM particle sizes

Adsorbent	**HR-TEM Particle Size, d_{TEM} (nm)**
Fe_3O_4	13.10
Fe_3O_4/CTAB	15.26

Phase analysis

Figure 5 shows the XRD spectrum of Fe_3O_4, and Fe_3O_4/CTAB MNS. As shown, diffraction peaks of all samples after HEBM completely correspond to standard pattern characteristic peaks of the magnetite hexagonal inverse spinel structure (JCPDS: 98-005-9302) 220 (30.1), 113 (35.45), 004 (43.07), 333 (56.97), 044 (62.47). As can be seen from the spectra, the main peaks which correspond to hkl (113) were observed to be broader as the milling time increased. The spectrum after modified with CTAB not showing any phase changes indicated that the modification process preserve the phase. In addition, it proved that the core shell of the MNS is still Fe_3O_4. This finding is in agreement with the previous report [18].

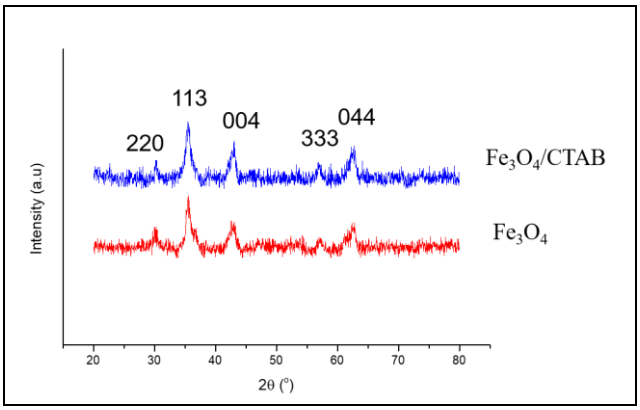

Figure 5. XRD spectrum of Fe_3O_4, and Fe_3O_4/CTAB MNS

Optical analysis

Figure 6 shows the FTIR spectrum of Fe_3O_4, Fe_3O_4/CTAB, and pure CTAB. CTAB's IR spectrum (Figure 6) contains a band at 3420 cm^{-1}, which could be attributed to the ammonium moiety's vibrations. Two distinct CH bands vibrations of the $–CH_2$ group in CTAB are responsible for the peaks at 2918 and 2848 cm^{-1}. The asymmetric and symmetric stretching vibrations of $N^+–CH_3$ are represented by the bands at 1630 and 1467 cm^{-1}, respectively, while the out-of-plane –CH vibration of CH_3 is represented by the band at 960 cm^{-1}. Br^- could be represented by the band at 720 cm^{-1}. The signal at 566 cm^{-1} in the FTIR spectrum of Fe_3O_4/CTAB MNS (Figure 5) reflects Fe-O of Fe_3O_4. The electrostatic interaction between Fe_3O_4 surface hydroxyl groups and the ammonium moiety in CTAB (OH....N^+) could account for the bandwidth at 3430 cm^{-1} [16-18].

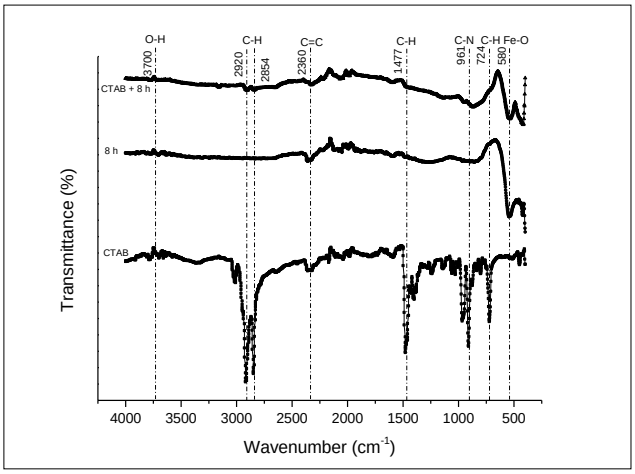

Figure 6. FTIR spectrum of Fe_3O_4 extracted from millscale waste and Fe_3O_4/CTAB MNS

Figure 7 shows magnetic behavior of the magnetic nanosorbents (MNS). The M-H curve indicated that both MNS are ferromagnetic materials with 50 and 28 emu/g. In addition, magnetic hysteresis loops measured at room temperature. The magnetization values observed in nanostructure materials are smaller than the corresponding bulk materials, assuming that is no changes in ionic configurations occurred. The reduction and lack of saturation after that are likely related to the smaller particle size and high surface areas, which could lead to some spin canting [12].

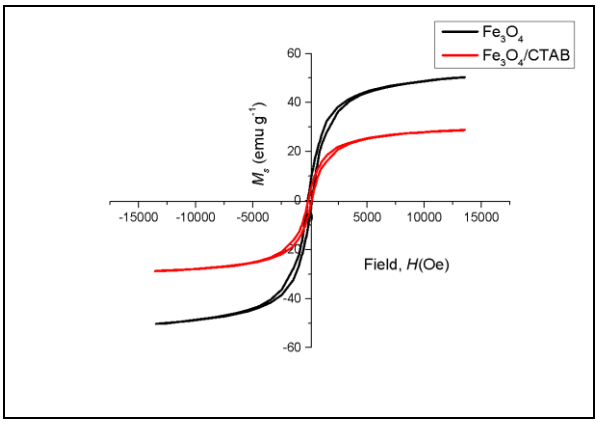

Figure 7. M-H hysteresis of Fe_3O_4 extracted from millscale waste and Fe_3O_4/CTAB MNS

Figure 8 shows that the formation of vesicular Fe_3O_4/CTAB. The coating showed self-assembly when the pH was 7. At that pH, CTAB had a higher positivity; meanwhile, Fe_3O_4 showed a higher negative surface charge. Therefore, it electrostatically self-assembled to form a vesicle [16]. The formation of the vesicle provided new surface charge for the nanoparticles. The new surface charge caused the repulsive force to increase. This is visible in the HR-TEM images showing that nanoparticles with higher dispersity formed. However, when more than a bilayer micelle already formed, the excess CTAB reacted on the surface, and the hydrophobic side formed a new layer. Therefore, when we added more CTAB, it did not increase the surface area; in fact, the surface area likely decreased [22].

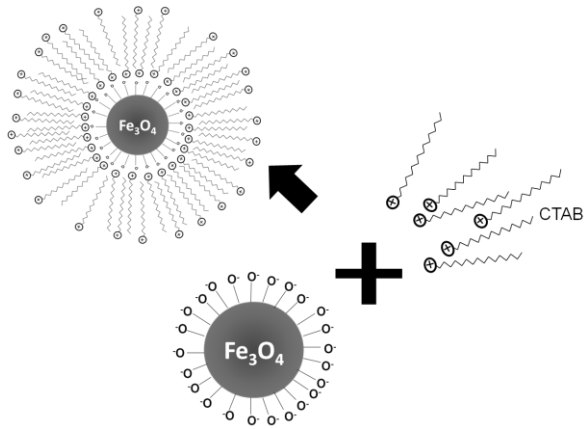

Figure 8. Schematic mechanism of the coating process of Fe_3O_4/CTAB MNS

Adsorption equilibrium studies

Effect of contact time

The influence of contact time on the adsorption capacity of Cd ions on Fe_3O_4/CTAB is shown in Figure 9. For the adsorption of Cd ions, the adsorption amount, Q_t, grew rapidly at first and then reached equilibrium in approximately 10 to 15 min. The increase in driving force produced by the concentration gradient of cations in solution and the presence of a considerable number of active sites on the surface of Fe_3O_4/CTAB MNS could be attributed to the fast adsorption rate in the incipient stage [13]. In the adsorption of Cd ions, a contact duration of 15 min was adequate to achieve equilibrium for Fe_3O_4/CTAB MNS. The adsorption capacity of Fe_3O_4 is 10.01 mg/g; meanwhile, that of Fe_3O_4/CTAB MNS is 21.6 mg/g.

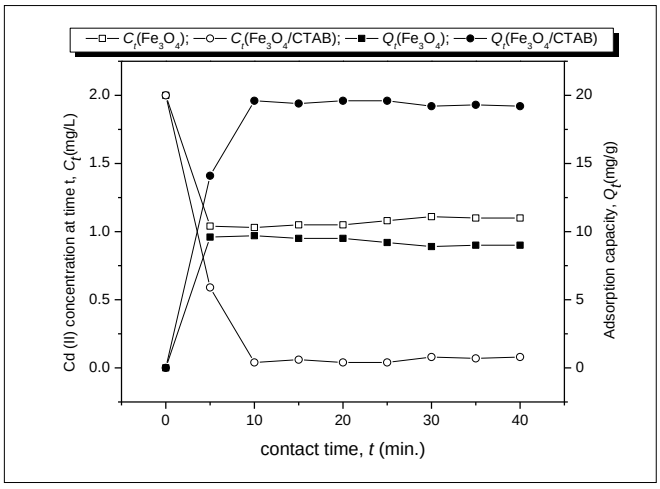

Figure 9. Effect of contact time on the adsorption capacity and concentration at equilibrium of Fe_3O_4 and Fe_3O_4/CTAB MNS

Effect of solution pH

According to the findings of a previous paper [14], adsorption can occur at various pH values. The pH setting would aid in the optimal uptake of Cd ions. As a result, the influence of solution pH on Cd ion adsorption onto Fe_3O_4/CTAB was investigated in the pH range of 1 to 10, as shown in Figure 8. For both modified and unmodified MNS, no adsorption was detected at pH values of 1 and 2, while half Cd ion absorption was recorded at pH 3 (>50%). Despite this, the adsorption capacity of the solution gradually increased from 3 to 6 and plateaued between pH 6 and 10. The ion exchange was responsible for the rapid increase in adsorption before pH 6. As a result, chemisorption, mainly ion exchange, is used exclusively for adsorption. The increase in adsorption after pH 6 could be due to electrostatic repulsion between H_3O^+ ions and cationic Cd ions, which cause Cd ions to be attracted to the Fe_3O_4/CTAB's negative surface charge. Van der Waal forces create an increase in the amount of Cd ions on a solid's surface (including dipole-dipole, dipole-induced dipole, London forces, and possibly hydrogen bonding). The increase can be explained as shown in Figure 6, where active hydroxyls can be found on the adsorbent surface based on FTIR data. These findings corroborate the intensity change in the IR spectra, as shown in Figure 10 [19]. As a result, the Q was highest at pH 9 for Fe_3O_4/CTAB MNS with 20.19 mg/g; meanwhile, 10.03 mg/g of Cd was removed by Fe_3O_4 MNS.

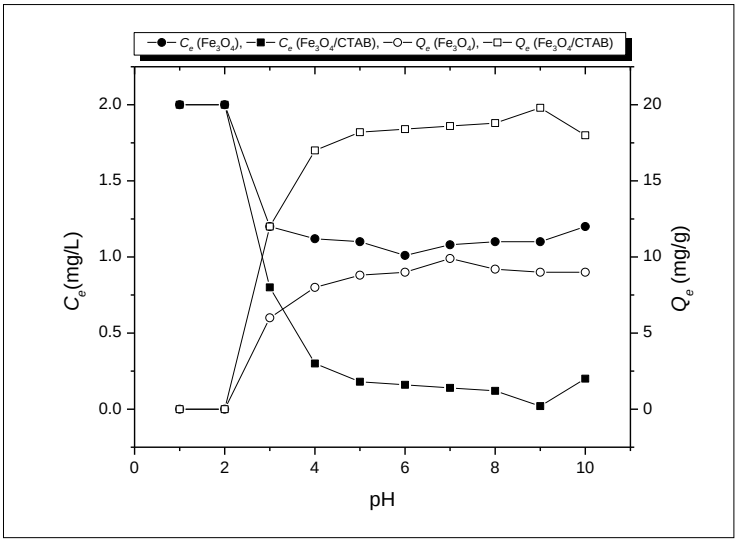

Figure 10. Effect of pH on the adsorption capacity and concentration at equilibrium of Fe_3O_4 and Fe_3O_4/CTAB MNS

Effect of initial Cd^{2+} concentration

One of the criteria utilized to examine the equilibrium of magnetic nano-adsorbents is initial concentration. The initial metal ion concentration serves as a driving factor for breaking through the mass transfer barrier between the adsorbent and the adsorbate medium. The

Fe_3O_4/CTAB MNS was first studied for its ability to remove metal ions from aqueous solutions. For the different beginning concentrations, the solution concentrations were 1, 2, 3, 4, and 5 mg/L, with an adsorbent dosage of 10 mg as the constant, as shown in Figure 11. For model Cd ions solutions with starting concentrations of 1 to 5 mg/L, the removal percentage approached 95%. As a result, increasing the concentration of Cd ions reduced the efficiency of Cd ion removal slightly. Furthermore, once equilibrium is reached, it will no longer be able to adsorb the other ions. This same pattern was discovered in a few other published studies [21, 22, 23].

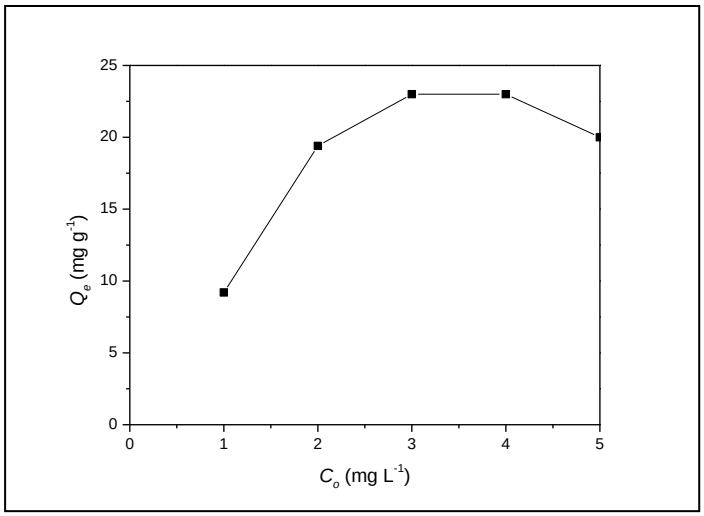

Figure 11. Effect of initial concentration on the adsorption capacity of the adsorption of Cd by using Fe_3O_4/CTAB

Conclusion

In this study, Fe_3O_4/CTAB MNS was prepared via the self-assembly method. The confirmation of success was supported by the characterization via FTIR and HR-TEM images before and after coating. Then, the Fe_3O_4/CTAB MNS was used as an adsorbent for removal of Cd ions from aqueous solution. The Fe_3O_4/CTAB MNS showed excellent performance in removing Cd ions from aqueous solution, which was evaluated by the equilibrium studied. The affecting parameters were studied, and the results showed that the presence of CTAB significantly affected the removal efficiency of the Cd ions. Due to the higher dispersity and magnetically assisted separability of the Fe_3O_4/CTAB MNS, high adsorption capacities could be obtained in a very short time. The reported data should be useful for the design and fabrication of an economically viable treatment process using batch or stirred tank reactors for Cd ion adsorption. This work involved a valuable contribution where the usage of millscales successfully lowered the production cost of the MNS.

Abstract

Within the context of a circular economy, the recycling or valorisation of eggshells, which are typically discarded in landfills, represents an opportunity. The primary compound in eggshells is calcium carbonate ($CaCO_3$), which can be decomposed into calcium oxide (CaO) by calcination. This study examined the calcination conditions (temperature and contact time) for the optimum $CaCO_3$ decomposition rate. The eggshell samples were pre-treated to eliminate dirt and unnecessary biological substance, ground into powder and sieved. The primary physical and chemical characteristics of eggshell powder were studied, including colour changes, mass loss, bulk density, moisture content, pH, thermal properties, and identification of chemical bonds and compounds in a molecule. This study evaluated the physical and chemical properties of the synthesised $CaCO_3$ from eggshells, moisture content, bulk density, pH, FTIR, and XRD. The results showed significant differences in the samples' colour transition at various temperatures and contact times based on the physical observation. The TGA analysis showed that eggshell powder decomposed at a temperature range of 600–900 °C. The FTIR results reported that for the calcine samples, the grey powder consists of $CaCO_3$, while the solid white powder consists of metal oxide content. Similar seven diffraction peaks were observed in the XRD analysis for calcination at 900 °C and industrial CaO (32.25, 37.41, 53.92, 64.18, 67.41, 79.70, and 88.58). The eggshell powder calcined at the temperature of 900 °C and contact time of 3 h was identified as an ideal condition for the decomposition of raw eggshell powder based on FTIR and XRD analyses. Both results showed that CaO corresponded to the wavelength spectrum and diffraction analysis of the sample.

Abstrak

Dalam konteks ekonomi kitaran, terdapat peluang untuk mengitar semula kulit telur yang biasanya dibuang di tempat pembuangan sampah. Sebatian utama dalam kulit telur ialah kalsium karbonat dan ia boleh diuraikan kepada kalsium oksida melalui proses pengkalsinan. Kajian ini dilakukan untuk mengkaji keadaan kalsinasi (suhu dan masa pembakaran) yang sesuai

bagi kadar penguraian kalsium karbonat yang optimum. Sampel kulit telur diproses terlebih dahulu untuk membuang kotoran dan sisa biologi yang tidak diperlukan dan seterusnya dikisar menjadi serbuk serta diayak. Ciri-ciri fizikal dan kimia utama serbuk kulit telur seperti perubahan warna, kehilangan jisim, ketumpatan, kandungan lembapan, pH, sifat terma, dan mengenal pasti ikatan kimia dan sebatian dalam molekul telah dikaji. Untuk mengkaji ciri-ciri fizikal dan kimia sintesis kalsium karbonat daripada kulit telur, ujian kandungan lembapan, ketumpatan pukal, pH, FTIR, and XRD dilaksanakan. Daripada pemerhatian fizikal, hasil menunjukkan terdapat perbezaan dalam perubahan warna sampel pada pelbagai suhu dan masa pembakaran. Analisis TGA menunjukkan serbuk kulit telur terurai pada julat suhu 600°C hingga 900°C. Hasil FTIR melaporkan bahawa warna kelabu sampel terkalsin terdiri daripada kalsium karbonat sementara serbuk putih terdiri daripada kandungan oksida logam. Terdapat tujuh puncak difraksi yang serupa yang dilaporkan dalam analisis XRD untuk kalsinasi pada suhu 900 °C dan kalsium oksida (32.25, 37.41, 53.92, 64.18, 67.41, 79.70, dan 88.58). Pengkalsinan serbuk kulit telur pada suhu 900 °C selama 3 jam dikenal pasti sebagai keadaan yang sesuai untuk penguraian serbuk kulit telur mentah berdasarkan analisis FTIR dan XRD. Kedua-dua hasil menunjukkan terdapat kalsium oksida berdasarkan spektrum gelombang dan analisis difraksi sampel.

Kata kunci: kalsium karbonat, kalsium oksida, kulit telur, kalsinasi

Introduction

Poultry egg is a cost-effective food source due to its high protein and nutritional content [1]. The egg from a chicken or hen (Gallus gallus domesticus, Linnaeus, 1758) is now a global mass-production industry. Quail, duck, goose, turkey, and ostrich eggs are popular choices. Both white and yellow yolks contain aqua, protein, glucose, fat, and ash, but the proportions of these components differ in every egg breed [2]. Essential lipids, proteins, minerals, and low-calorie sources are also found in eggs. Egg products are utilised in various food industrial applications, including thickening, binding, leavening, glazing, and garnishing [3]. A three-layered structure makes up an eggshell: cuticle, spongeous, and lamellar layers. The cuticle layer is the outermost layer, mainly made up of proteins. Protein fibres coupled to calcium carbonate ($CaCO_3$) crystals form a matrix made up of spongey and lamellar layers. $CaCO_3$ accounts for 94% of the eggshell, followed by calcium phosphate (1%), magnesium carbonate (1%), and organic matter (4%) [4]. The eggshell and albumen are two thin eggshell membranes primarily of collagen, alkynes, alkanes, amines, protein amides, and carboxylic acids [5].

Approximately 8 million tons of eggshell wastes are produced annually worldwide [6]. Meanwhile, in Malaysia, 70,686 tons of eggshell waste are produced by various industries [7]. Eggshell waste is listed in the European Union regulation as hazardous waste, and this regulation leads to elevated costs of disposal management [8-11]. In America, companies spend millions of dollars annually to dispose of eggshells in landfills, and the capacity is reached by the fillings [12]. The majority of eggshells are usually disposed to landfills without being treated as eggshells are considered unusable and have no commercial value [13]. However, there have been many studies utilising eggshells in various applications, such as agricultural green chemicals [13, 14, 15], a low-cost catalyst for biodiesel production [16], biofilter in wastewater treatment [17], construction materials [18, 19, 20], biomedical [21], health supplements [22], and craft [23, 24]. [25] studied the effects of eggshell powder as a supplementary material to produce recycled paper.

Various researchers have studied calcined eggshell powder (CESP) waste as a source of calcium oxide (CaO). [26] studied calcined eggshells as a catalyst in biodiesel production, [27] reported the characterisation of nano-CaO based on eggshell waste, [28] studied the CaO sorbents from chicken eggshells for enhanced carbon dioxide (CO_2) capture, [29] utilised calcined eggshells to formulate mortar for building restoration, [30] studied the effects of calcined eggshells as biomaterials for the preparation of linear low-density polyethene, [31] examined the effects of calcined eggshell catalyst in the transesterification of waste cooking oil, and [32] identified the thermoluminescence properties of CaO powder obtained from chicken eggshells.

The calcination process can decompose $CaCO_3$ to CaO. Calcination is a technique for extracting volatile

chemicals from solids by heating them to a high temperature, oxidising a portion of the mass, or making them brittle [33]. Calcination is frequently thought of as a purifying method. $CaCO_3$ is calcined using two methods: combustion with CO_2/oxygen gas (O_2) or steam [34]. The process produces a completely decomposed substance depending on the temperature selected. $CaCO_3$ completely decomposed at the temperature range of 500–900 °C [35]. Research by [36] identified that seashell calcination at the temperature of 800 °C produced a higher amount of CaO based on Fourier transform infrared (FTIR) spectroscopy, scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDX), and thermal gravimetric analysis (TGA) tests. Although seashells and eggshells are made of $CaCO_3$, their structure is different. It can be seen through their surface morphology. According to [37], the SEM image for seashell (cockle) is platy-shaped. On the other hand, the eggshell is porous and fibril [38]. Furthermore, based on the TGA result, the thermal decomposition of ESP and seashell varied. [39] established that the decomposition of raw eggshell powder (RESP) was in the range of 600–850 °C, while according to [40], the decomposition of cockle was in the range of 500–700 °C. [41] indicated that calcination was highly dependent on temperature, heating rate, and particle size. [39] identified no significant differences in the weight variation of eggshell powder samples during calcination. It was observed that the optimum operating conditions for the decomposition of $CaCO_3$ samples were 900 °C with a heating rate of 20 °C/min and particle size of 0.3 mm. Therefore, it is established that the best temperature for $CaCO_3$ calcination is 800 °C and above.

Researchers have recently studied CaO derived from eggshells for new green chemistry and catalyst by reducing dependence on limestone. However, variations in calcination temperatures and contact hours have been reported. Therefore, this study aimed at finding the ideal conditions in the calcination process for converting $CaCO_3$ from chicken eggshells to CaO. The experiments were conducted based on two parameters: contact time (h) and temperature (°C). The primary physical and chemical characteristics of eggshell powder were studied, including colour changes, mass loss, bulk density, moisture content, pH value, thermal properties, and identification of chemical bonds and compounds in a molecule.

Materials and Methods

Raw materials

Chicken eggshells were collected from local food truck vendors. The eggshells were instantly washed with gentle soap and tap water after being collected as preparation for cleaning treatment. The eggshells were boiled for 30 min [42]. This process is vital to avoid biological contamination and decaying of the eggshells. Next, the eggshells were cleaned by running tap water, air-dried for 24 h at room temperature, and stored in a dark-coloured container [43, 44]. The chicken eggshell samples were ground using an electrical powder grinder (SY-25) 2,000 W to obtain RESP. Then, the RESP was sieved with a 500-µm mesh to eliminate granular sizes. Figure 1 shows the pre-treated eggshells and ground eggshell powder.

Pre-treated eggshells Raw eggshell powder

Figure 1. Preparation of chicken eggshells samples

Material's thermal stability and the fraction of volatile components - Thermogravimetric analysis

TGA was performed using a Shimadzu TGA-50 thermobalance. In this study, approximately 8 g of eggshell powder was heated at 50–950 °C in a nitrogen atmosphere with a flow rate of 20 mL/min and a heating rate of 25 °C/min [45].

Calcination of chicken eggshell

The eggshell powder samples were placed in closed porcelain crucibles and calcined in a chamber furnace (Carbolite ELF 11/14B) according to the eight experiment sets as shown in Table 1. Two parameters were varied to examine the calcination process (i.e., temperature (°C) and contact time (h)) with a constant weight RESP (i.e., 20 g). Each calcination protocol was done in triplicates. To avoid a reaction with moisture and atmospheric air, the CESP was stored in flasks and placed atop a desiccator after calcination [46].

Table 1. Calcination parameters

No.	Sample Code	Parameter	
		Temperature (ºC)	Contact Time (hour)
1	CESP $T_{600\text{-}3}$	600	3
2	CESP $T_{600\text{-}4}$	600	4
3	CESP $T_{700\text{-}3}$	700	3
4	CESP $T_{700\text{-}4}$	700	4
5	CESP $T_{800\text{-}3}$	800	3
6	CESP $T_{800\text{-}4}$	800	4
7	CESP $T_{900\text{-}3}$	900	3
8	CESP $T_{900\text{-}4}$	900	4

Results and Discussion

Thermogravimetric analysis

TGA is carried out to determine the thermal stability of a material and its fraction of volatile components by monitoring the weight change that occurs as a sample is heated at a constant rate. Based on Figure 2, four reaction steps occurred in this experiment.

The first step showed that 1.13% mass decreased at midpoint 84.23 °C. The temperature range at step 1 can be considered as eliminating moisture of the sample. [48] supported this statement, stating that biomass drying is conducted in the range of 40–200 °C. Referring to [49], the slight decrease of mass in the second step was due to the decomposition of organic matter in the range of 200–600 °C. The RESP started to decompose from $CaCO_3$ to CaO and released CO_2 at 600 °C and ended at 850 °C in step 3. A slight mass loss in step 4 at 950 °C can be referred to as the end of the reaction.

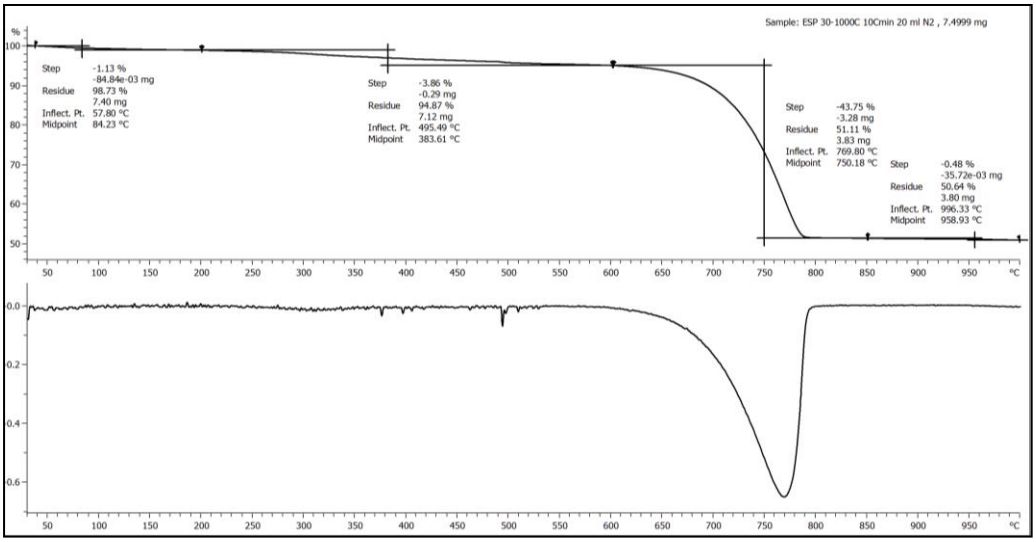

Figure 2. Thermogravimetric analysis of RESP

Calcination process

Calcination is the process of decomposing $CaCO_3$ by burning the compound at high temperatures. The catalysts were completely decomposed at the temperature range of 500–900 °C [39]. The optimum temperature for the calcination of $CaCO_3$ from cockle shell was 900 °C for 2 h with a particle size of 0.3 mm under inert conditions [41]. [13] supported this statement and reported that the suitable temperature and time for complete decomposition in the calcination of $CaCO_3$ from duck eggshells were 900 °C and 1 h, respectively. [50] and [40] argued that calcite fully decomposed to form CaO at 800 °C. Based on these studies, three conditions may affect the calcination process. In this study, CaO is derived from eggshell powder, as shown in Equation 3.

$$CaCO_{3(s)} \rightarrow CaO_{(s)} + CO_{2(g)} \quad (3)$$

The primary characteristics of CESP were studied and recorded, including physical observation (colour changes), moisture content, bulk density, and average mass loss. Based on the TGA result in Figure 2, the RESP decomposed in the temperature range of 600–850 °C. Therefore, the range of calcination temperature in this study was chosen from 600 °C to 900 °C. By referring to Table 2, as the temperature increases, the bulk density value decreases, and consequently, the mass loss increases. From the result, it shows that calcination temperature affected the reduction in mass for eggshell powder. Different colour changes were observed between uncalcined and calcined samples. The colour of the uncalcined eggshell is light brown based on its original colour. In comparison, a perfect CESP should be solid white. Based on the result, low calcination temperatures produced dark or grey colour, whereas at high calcination temperatures, solid white colour was obtained. More metal oxide (solid white powder) was produced for higher calcination temperatures. [51] stated that the higher temperature would produce a higher amount of metal oxide and the colour would become whiter. [41] established the optimum temperature of 900 °C for $CaCO_3$ decomposition. High temperatures are required for CESP to produce perfect CaO. The dark powder obtained at low temperatures indicates that eggshell powder has not completely decomposed.

Compared to other manipulated variables, the samples calcined at different contact times showed a massive percentage of mass loss. This could be explained by the longer calcination duration, which resulted in greater mass loss [52]. The colour transition for different contact times is presented in Table 2. Even though the samples of eggshell powder were calcined at the same temperature and weight, the calcination result was

affected by the contact time. The formation of dark grey powder at low contact time was due to a lack of heat distribution. The grey powder at the inner part of the sample showed that the heat was not well distributed to the whole part of the sample. Therefore, increasing the calcination period is one of the significant ways to improve the formation of metal oxide. [13] stated that higher temperature and longer calcination time produced better CaO quality.

Moisture loss occurred during calcination, which corresponds to the loss of water and/or gas of the eggshell powder. In this study, the moisture loss percentages of CESP in all conditions were too insignificant, and therefore, could be ignored. [54] stated that the decomposition of volatile materials (e.g., water and organic matter) occurred in the temperature range of 30–400 °C. There were no changes in the acidity of RESP and dark powder. Meanwhile, the acidity for solid white powder changed to alkali. Therefore, if the amount of dark powder is more significant than solid white powder, the sample can be considered as $CaCO_3$.

The bulk density values of eggshell powder calcined with different parameters are tabulated in Table 2. The solid white powder of CESP $T_{900\text{-}3}$ and CESP $T_{900\text{-}4}$ showed a softer and more refined texture. [13] reported that calcination at 900 °C for 1 h reduced the particle size of the samples. According to Equation 2, density is inversely proportional to volume. The bulk density decreased as the particle size increased [53]. The volume depends on the particle size of the samples.

The pH of RESP changed to alkali when it was calcined at high temperatures. The alkalinity value increased as the temperature and contact time increased. The samples of $CESP_{700\text{-}4}$ to $CESP_{900\text{-}4}$ showed an alkaline pH value of 12.70–13.26, indicating the presence of CaO. The result is correlated with previous findings, where the calcination temperature of 700 °C produced sufficient CaO and achieved the critical value of an alkaline solution [54].

Table 2. Calcination of ESP with different parameters

Sample	Physical Observation	Mass Loss (%)	Moisture Content (%)	Bulk Density (g/ml)	pH
Uncalcined		N/A	0.451	2.47	7.00
CESP $T_{600\text{-}3}$		0.84	N/A	1.38	9.36
CESP $T_{600\text{-}4}$		0.83	N/A	1.41	10.84
CESP $T_{700\text{-}3}$		1.13	N/A	1.36	11.64

Table 2 (cont'd). Calcination of ESP with different parameters

Sample	Physical Observation	Mass Loss (%)	Moisture Content (%)	Bulk Density (g/ml)	pH
CESP T_{700-4}		0.98	N/A	1.33	12.70
CESP T_{800-3}		2.19	N/A	1.38	12.67

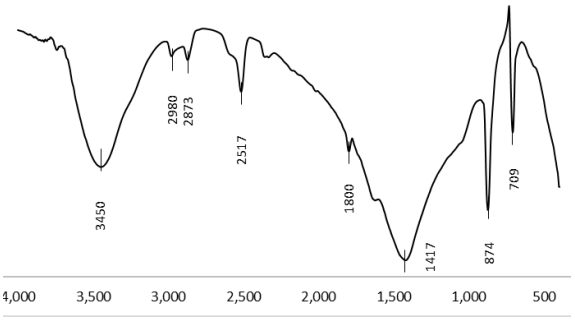
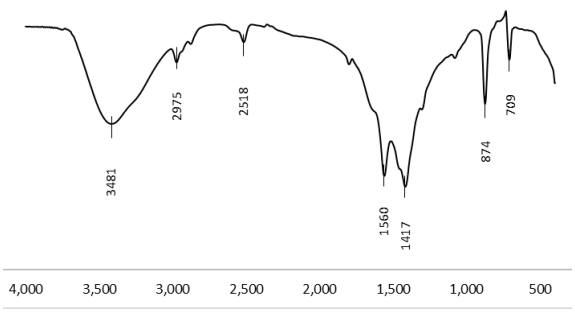
CESP T_{900-3}		11.00	N/A	3.00	12.96
CESP T_{900-4}		11.43	N/A	3.33	13.26

Compounds identification



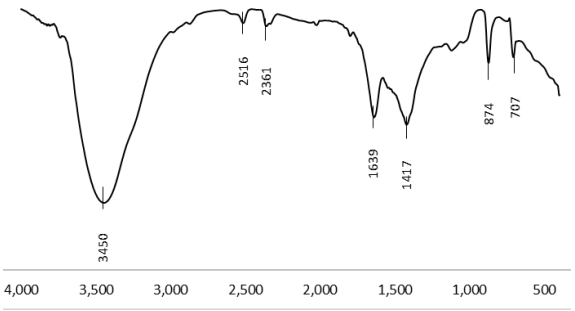
The FTIR analysis can be divided into three broad regions. The first region is from 4000 cm^{-1} to 3000 cm^{-1}, which represents hydrogen bonding. The second region, which is from 3000 cm^{-1} to 1500 cm^{-1}, shows functional groups. Meanwhile, the third region reveals the existence of biominerals. Based on physical observation and pH values in Table 2, chemical characterisation was conducted for the selected samples of CESP T_{700-4}, CESP T_{800-3}, CESP T_{800-4}, CESP T_{900-3}, and CESP T_{900-4}. Sufficient CaO content produced from the calcination of eggshells will make the pH value reach the critical value of 12.7 [56]. Therefore, the FTIR analysis identifies the functional groups present in the eggshells calcined at 900 °C with different contact times.

Figure 3 below presents the FTIR spectra for CESP at various temperatures and contact times. Small sharp peaks were detected at 874 cm^{-1} and 1417 cm^{-1} for CESP T_{700-3}, CESP T_{700-4}, CESP T_{800-3}, and CESP T_{800-4}. The bands at both wavelength indicated $CaCO_3$ in the tested samples [55,56]. Another strong peak was observed at 2516 cm^{-1} due to the presence of $CaCO_3$ [57]. According to [7], the observable peaks in the range of 713–875 cm^{-1} can be associated with the presence of $CaCO_3$. The observation by [58] for the band at 1430 cm^{-1} was attributed to the stretching vibration of $CaCO_3$. Meanwhile, the bands at 875 cm^{-1} and 715 cm^{-1} strongly corresponded to $CaCO_3$ [59]. The lowest band represents the weak band to indicate $CaCO_3$.

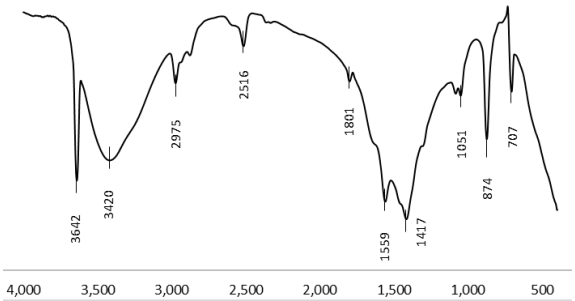


Sharp peaks were observed at 707 cm^{-1} and 709 cm^{-1}. The wavenumber increased as the transmittance increased intensely at the peak of 874 cm^{-1}. Both peaks are associated with in-plane deformation and out-plane deformation modes of eggshell powder in the presence of $CaCO_3$, as described by [7]. The sharp, strong band detected at 1560 cm^{-1} is attributed to the oxidation process [60].

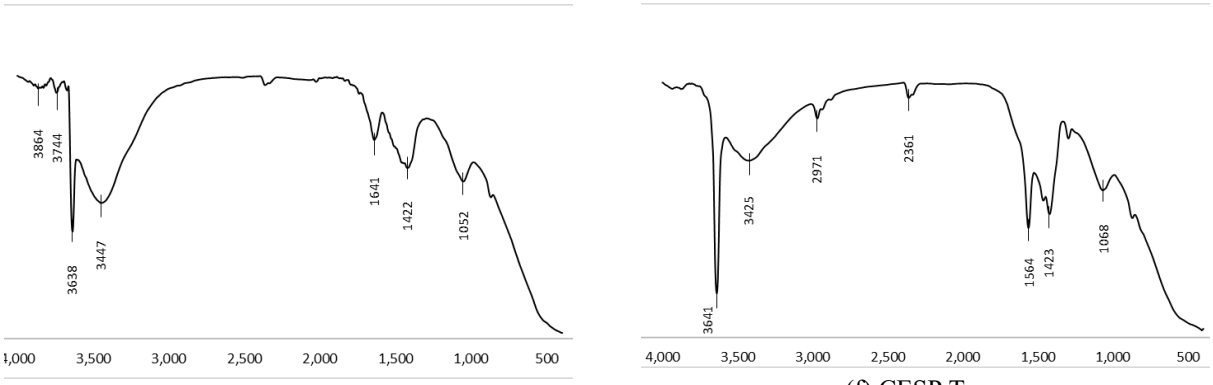
An amine group was present at the band of 1055 cm^{-1}. According to [61], the presence of the functional groups of amines and amides was observed due to the chemical composition of fibrous proteins. As referred to [62], CESP $T_{900\text{-}3}$ showed a medium-sized peak at 1052 cm^{-1} corresponding to the stretching of both C-O in the C-OH bond. The peaks at 1424 cm^{-1} and 1422 cm^{-1} indicated the presence of OH bonding. The existence of hydroxide might be due to exposure to the atmosphere during calcination [63]. Another significant peak was detected at 2361 cm^{-1} in regard to the presence of O=C=O bonds. The presence of O=C=O bonds indicated the carbonation of CaO, as shown in Equation 4 [64].



$$Ca(OH)^2 + CO_2 \rightarrow CaCO_3 + H_2O \quad (4)$$



(a) CESP $T_{700\text{-}3}$



(b) CESP $T_{700\text{-}4}$

(c) CESP $T_{800\text{-}3}$

(d) CESP $T_{800\text{-}4}$

(e) CESP $T_{900\text{-}3}$ (f) CESP $T_{900\text{-}4}$

Figure 3. The FTIR spectra for CESP at different contact times and temperatures

The XRD analysis was carried out to identify CaO in CESP at different temperatures. Figure 4 illustrates the results of XRD analysis for RESP and CESP at 900 °C (CESP $T_{900\text{-}3}$), 700 °C (CESP $T_{700\text{-}3}$), and industrial CaO as a reference. The intensity of $CaCO_3$ showed the primary compound of RESP. The diffraction showed both distinct components of CaO and $CaCO_3$ for CESP $T_{700\text{-}3}$. Thus, the intensity of $CaCO_3$ decreased compared to RESP. At 700 °C, incomplete decomposition of $CaCO_3$ occurred, based on the diffraction pattern (c). A similar study by [53] claimed that CaO was absent at 700 °C. CESP $T_{700\text{-}3}$ showed a different peak pattern of CaO than CESP $T_{900\text{-}3}$ and industrial CaO. Meanwhile, CESP $T_{900\text{-}3}$ showed seven diffraction peaks similar to the diffraction peaks of industrial CaO. The simplified XRD analysis is shown in Table 3.

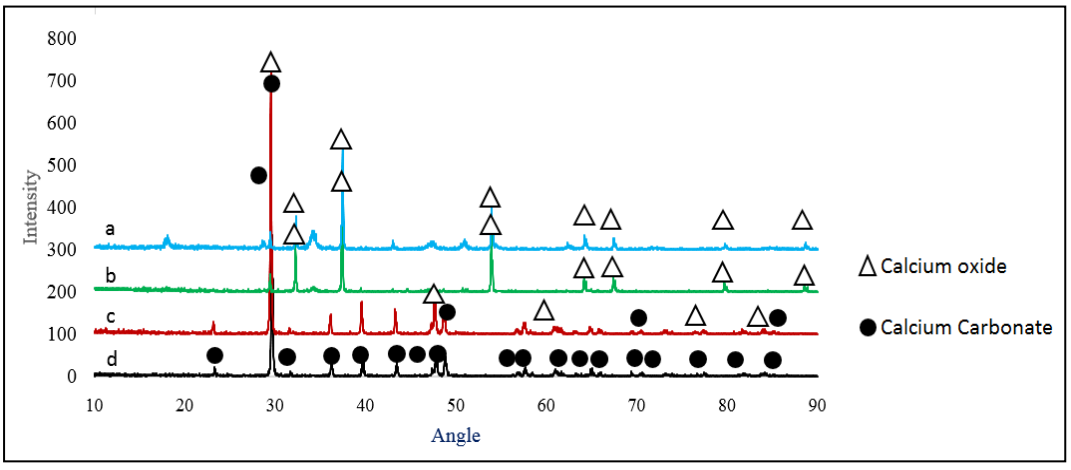


Figure 4. XRD patterns of a) industrial CaO, b) CESP $T_{900\text{-}3}$, c) CESP $T_{700\text{-}3}$, and d) RESP

Table 3. X-ray diffraction results for CaO and $CaCO_3$ from synthesised eggshell powder

Sample	Compound	Angle (2θ)						
CESP $T_{700\text{-}3}$	$CaCO_3$	28.78	47.25	62.73	71.79	84.88	-	-
	CaO	29.52	47.67	60.84	77.45	84.02	-	-
CESP $T_{900\text{-}3}$	CaO	32.25	37.41	53.92	64.18	67.41	79.70	88.58
Industrial CaO	CaO	32.33	37.45	56.97	64.24	67.47	79.78	88.66

Conclusion

Different calcination temperatures and contact times were applied in the calcination of eggshell waste to decompose $CaCO_3$ into CaO. Based on physical inspection, higher temperature and increased contact time produced white powder, which was later identified as CaO. Among the studied calcination conditions, the best conditions were the temperature of 900 °C and the contact time of 3 h. The CaO synthesized from eggshells can be used in various applications, such as in the laboratory (gas absorber), construction (lime putty and cement production), soil stabiliser, medicinal purposes, and others. Hence, it is believed that calcined chicken eggshells can be an alternative source of CaO to reduce the dependency on limestone resources.

Acknowledgement

An industrial research fund partially supported this research under the MRT-SSP-V208-Second Tier ICP Agreement 2019 (Grant Number: ICP/MTDC/2019). We would like to thank our colleagues from Universiti Kuala Lumpur – MICET and Universiti Teknikal Melaka Malaysia, who provided insight and expertise that greatly assisted the research.

Abstract

The growing interest in anthocyanins in plants has brought about the importance of investigating their pharmacological properties. Sensitive and specific analytical methods are required to accurately analyze the anthocyanins present in samples. One of the anthocyanins found in plants is cyanidin-3-O-glucoside. The objective of this study was to develop and optimize a rapid resolution liquid chromatography (RRLC) method for cyanidin-3-O-glucoside determination in rat plasma. Spectrophotometric analysis was performed to determine the best ultraviolet (UV) absorbance wavelength. Liquid-liquid extraction (LLE) and solid-phase extraction (SPE) methods were compared to determine the best extraction method for cyanidin-3-O-glucoside in rat plasma samples. The effects of varying the type and proportion of organic solvents, the type and concentration of buffer solutions, flow rates, column temperatures, and UV wavelengths were examined. The optimized chromatographic method for RRLC analysis of cyanidin-3-O-glucoside was a mobile phase composition of 0.1% trifluoroacetic acid aqueous solution and acetonitrile in a ratio of 81:19, respectively, with a 0.5 mL/min flow rate, at 30°C column temperature and 525 nm detection wavelength. SPE was our choice of final extraction method. Our findings revealed that the optimized RRLC method can be used to determine cyanidin-3-O-glucoside in rat plasma.

Keywords: rapid resolution liquid chromatography, method development, cyanidin-3-o-glucoside, rat plasma

Abstrak

Kajian antosianin dalam rosel yang semakin meluas mengetengahkan kepentingan analisis sebatian tersebut untuk mengkaji ciri-ciri farmakologinya. Kaedah analisis yang sensitif dan spesifik diperlukan untuk menganalisis antosianin yang terdapat dalam sampel dengan tepat. Salah satu antosianin yang terdapat dalam tumbuhan ialah sianidin-3-O-glukosida. Objektif kajian ini adalah untuk membangunkan dan mengoptimumkan kaedah kromatografi cecair resolusi pantas (RRLC) untuk sianidin-3-O-glukosida di dalam plasma tikus. Analisis spektrofotometri dilakukan untuk memilih penyerapan ultraungu yang terbaik. Kaedah pengekstrakan cecair-cecair (LLE) dan pengekstrakan fasa pepejal (SPE) juga dijalankan untuk menilai kaedah pengekstrakan

terbaik bagi antosianin daripada sampel plasma tikus. Kesan mempelbagaikan jenis dan peratusan pelarut organik, jenis dan kepekatan larutan penimbal, kadar aliran fasa bergerak, suhu turus dan panjang gelombang pengesan ultraungu telah diuji. Kaedah pengoptimuman kromatografi menunjukkan komposisi fasa bergerak bagi larutan akueus asid trifluoroasettik 0.1% dan asetonitril dalam nisbah 81:19, dengan kadar aliran 0.5 mL/min, pada suhu turus 30°C dan panjang gelombang pengesanan 525 nm adalah sesuai untuk analisis sianidin-3-O-glukosida. Kaedah SPE dipilih sebagai kaedah pengekstrakan terbaik kerana ia menghasilkan puncak kromatogram yang lebih baik berbanding kaedah LLE. Kesimpulannya, kaedah RRLC yang dibangunkan dalam kajian ini boleh digunakan untuk menentukan sianidin-3-O-glukosida dalam plasma tikus.

Introduction

Anthocyanins are polyphenolic pigments that belong to the flavonoid group and are present in the vacuolar sap of the epidermal tissues of flowers and fruits [1, 2]. These compounds are responsible for various colors of plant organs, such as fruits, flowers, and leaves, and they are also present in vegetables [1]. One of the anthocyanins found in plants is cyanidin-3-O-glucoside [3]. The ever-increasing evidence about anthocyanins has drawn many researchers to investigate more about these plant flavonoids. The increasing importance of elucidating their health -promoting properties has raised the need for specific tasks for their determination methods.

The development of a combined extraction method—spectrophotometric and chromatographic methods is regarded as having the most significant impact on the analysis of anthocyanins [3, 4]. Although liquid chromatography has been the most employed technique to identify or quantify anthocyanins [5], an advanced and improved method of high-performance liquid chromatography (HPLC), such as rapid resolution liquid chromatography (RRLC), is currently applied in anthocyanin research, as it offers better separation and identification of specific components of anthocyanins. Therefore, the objective of this study was to develop and optimize an RRLC method for cyanidin-3-O-glucoside in rat plasma. Spectrophotometric analysis was performed to determine the appropriate UV absorbance. Both liquid-liquid extraction (LLE) and solid-phase extraction (SPE) methods were performed to determine the best extraction method for cyanidin-3-O-glucoside chloride in the rat plasma sample. We tested the effects of varying the type and percentage of organic solvents, the type and concentration of buffer solutions, flow rates, and column temperatures.

Materials and Methods

Chromatographic equipment

The chromatographic system and machine consisted of the Agilent Technologies 1200 Series system consisted of a binary pump, an autosampler, thermostat column compartment, variable wavelength detector and a vacuum degasser (Agilent Technologies, Santa Clara, California, USA). The analytical column was Agilent Reverse Phase EC-C18 (4.6 x 150 mm I. D, particle size 2.7 µm) (Agilent Technologies, Santa Clara, California, USA). The guard column was Agilent Reverse Phase EC-C18 2.7 µm (4.6 x 5 mm) (Agilent Technologies, Santa Clara, California, USA).

Chemicals and reagents

All chemicals were HPLC grade. Acetonitrile (ACN), 5-sulfosalicylic acid dihydrate, ethyl acetate, methyl tert-butyl ether (MTBE), methanol (MeOH), formic acid (CH_2O_2), phosphoric acid (H_3PO_4), hydrochloric acid (HCL) and trifluoroacetic acid (TFA) were from Merck® (Darmstadt, Germany). Diethyl ether was from Fisher Chemical (Massachusetts, USA).

Drug standard and internal standard

The drug standard, cyanidin-3-O-glucoside chloride was purchased from ChemFaces (catalogue no. CFN99740) (CAS no. 7084-24-4). The internal standard, cyanidin-3,5-O-diglucoside chloride was also purchased from ChemFaces (catalogue no. CFN92138) (CAS no. 2611-67-8).

Standard stock solutions of cyanidin-3-O-glucoside chloride (100 µg/ml) and internal standard, cyanidin-3,5-O-diglucoside chloride (100 µg/ml) were prepared by dissolving 1 mg of each compound in 10 ml MeOH, respectively. The solutions were then stored at -20°C in clear vials and were protected from light with aluminum foils. The working cyanidin-3-O-glucoside chloride and internal standard solutions were prepared fresh daily by diluting the stock solutions with the mobile phase. The concentration of working solution for internal standard and cyanidin-3-O-glucoside chloride used for the optimization of chromatographic conditions were 250 ng/ml and 500 ng/ml, respectively.

Preparation of plasma standard and samples

The rats used in this study were approved by the USM Institutional Animal Care and Use Committee (USM IACUC) [USM/IACUC/2019/(118)(1000)] and supplied by the Animal Research and Service Centre (ARASC), Health Campus, USM Kelantan, Malaysia. Rats' blood was collected and stored in heparin blood tubes before being centrifuged to separate the plasma. Then, the rat plasma was stored at -80 °C within 8 hours of collection.

The fresh-frozen rat plasma was allowed to thaw naturally on the bench at room temperature for approximately 45-60 minutes. It was then vortexed for a few seconds to ensure uniform distribution. The plasma standard was prepared in the same ratio with different volumes for each extraction method.

Spectrophotometry analysis

The spectrophotometric analysis of cyanidin-3-O-glucoside chloride and the internal standard were performed on a Cary 100 UV-visible spectrophotometer. Dilutions of aliquots of standard stock solution (100 ug/mL) of both cyanidin-3-O-glucoside chloride and internal standard were carried out with 0.1% HCL in 75% MeOH to reach the concentration range 10 ug/mL and 50 ug/mL. The wavelength of range 300 to 700 nm was selected for the quantitation of cyanidin-3-O-glucoside chloride and internal standard.

Optimization of chromatographic conditions

We followed the RRLC optimisation guideline provided by Agilent Technologies to equilibrate the column and detector with 10 column volumes of the mobile phase prior to use (1 – 5 mL) depending on column size [6]. The approximate time to equilibrate the instrument was 20 minutes to 45 minutes or until the pressure pump reading was stabilized. The column of RRLC should be equilibrated each time before use and need to be performed when run for the new solvent of different mobile phases. The pressure pump was maintained at 147 bar during the equilibration process. The effect of varying the type and percentage of organic solvents, type and concentration of buffer solutions, flow rates, column temperatures and ultraviolet wavelengths were tested.

Optimization of extraction methods

Liquid-liquid extraction (LLE) and solid-phase extraction (SPE) methods were carried out to decide which extraction method is more suitable to be used in extracting the cyanidin-3-O-glucoside chloride from rat plasma. The method which demonstrated the best extraction results of cyanidin-3-O-glucoside chloride and internal standard would be chosen for further testing.

Liquid-liquid extraction

The LLE method was performed by referring to a study conducted by Banaszewski et al. [7]. In this method, 50 µL of working cyanidin-3-O-glucoside chloride and internal standard solutions were added to the 500 µL of rat plasma. The freshly prepared plasma standard was then acidified to pH 2 with CH_2O_2 because anthocyanin is more stable at low pH and then extracted with 1.5 mL of ACN. The sample was then centrifuged at 10,000 rpm for 15 minutes at a temperature of 4 °C. After that, they were re-extracted with 1.5 mL MeOH. The extracts were then pooled and the supernatants were collected. Then, the supernatants underwent an evaporation process in the pre-heated water bath at 35 °C, in vacuo using a vacuum pump. Next, they were reconstituted in 250 µL of mobile phase and centrifuged at 10,000 rpm for 30 minutes at 4 °C. Lastly, the samples were transferred to the amber vials and immediately analyzed by RRLC. We also

compared different extraction solvents to extract the anthocyanin from plasma such as diethyl ether, ethyl acetate and MTBE using the same procedure.

Solid-phase extraction

The SPE method was carried out by referring to a study conducted by Harada et al. [8]. The cartridge was firstly conditioned, by washing with 1 to 2 mL of MeOH and then equilibrated with the same volume of 0.1% TFA aqueous solution. The plasma standards were prepared by mixing 200 µL of cyanidin and internal standard working solutions of selected concentrations into 2 mL of the thawed plasma, followed by vortexing the solution for 5 seconds. Then, the plasma standard was subsequently mixed with 2 mL of 0.1% TFA aqueous solution and 100 µL of 20% sulfosalicylic acid aqueous solution. After that, it was vortex-mixed and centrifuged at 4000 x g for 20 minutes at 4 °C. The supernatant then was further treated in the conditioned and equilibrated Sep-Pak C18 cartridge. Next, the cartridge was rinsed with 2 mL of 0.1% TFA solution and subsequently purged with air. The dried cartridge was then eluted with 2 mL of MeOH and evaporated to dryness using a vacuum pump at a temperature below 40 °C (35 - 37°C). The resultant dry residue then was dissolved in 50 µL of 0.1% TFA aqueous solution. Afterwards, it was centrifuged at 6000 rpm for 15 minutes at 10 °C using an Ultrafree®-MC centrifugal filter (Merck, Germany). Lastly, the solution was subjected to RRLC for analysis.

Results and Discussion

Spectrophotometry analysis

The UV absorbances of cyanidin-3-O-glucoside chloride and cyanidin-3,5-O-diglucoside chloride were measured using a Cary 100 UV-visible spectrophotometer (Varian, California, USA). Spectrophotometry analysis of both cyanidin-3-O-glucoside chloride and cyanidin-3,5-O-diglucoside chloride showed that the maximum absorption was 524 nm, as shown in Figure 1. Thus, UV absorbance was used throughout the study.

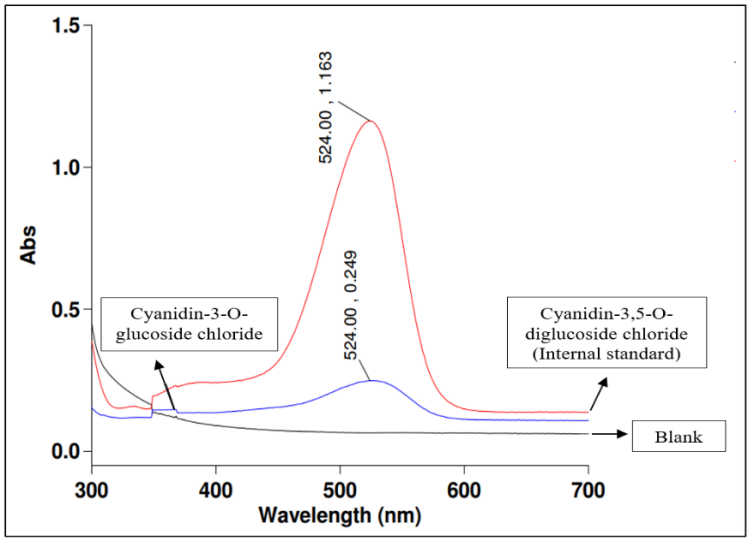

Figure 1. Spectrophotometry of the blank sample, cyanidin-3-O-glucoside chloride and cyanidin-3,5-O-diglucoside chloride (internal standard)

Absorption spectroscopy, especially UV-Vis spectroscopy, has been extensively utilized to identify anthocyanins and has revealed a lot about the structural properties and identification of these molecules [9]. From the results, the absorption peak of both cyanidin-O-glucoside chloride and the internal standard emerged at a wavelength of 524 nm. Using UV-Vis spectroscopy, absorption peaks emerged at

wavelengths of 266 nm and 530 nm, indicating that the extract contains anthocyanin compounds [10]. UV-Vis spectrophotometer demonstrated that absorption at an absorption maxima (λ_{max}) 536 nm was the specification of anthocyanins [11]. A typical UV-Vis spectrum of anthocyanin exhibits two basic absorbance clusters [9]. The first one is at 260–280 nm (UV area) and the second at 490–550 nm (VIS region) (visible region), in which the λ_{max} in the visible range is typically measured at 510–520 nm. The typical absorption bands of anthocyanins are in the 490 to 550 nm region of the visible spectra [12].

Optimization of chromatographic conditions: Type and concentration buffer solutions

Three different buffer solutions were investigated: 5% CH_2O_2 aqueous solution, 1% H_3PO_4 aqueous solution, and 0.1% TFA aqueous solution with acetonitrile (ACN) as the organic solvent. Each of the solvents was prepared with different concentrations according to the manufacturer's datasheet, as well as based on respective previous studies [8, 13]. The column temperature, mobile phase flow rate, and wavelength signal were kept constant. Among the three buffer solutions, the mobile phase of 0.1% TFA aqueous solution and ACN showed faster retention time and good peak shapes, with the least peak tailing. Thus, this combination of solvents was selected.

One of the factors that affects the retention of substances in RRLC is the mobile phase composition [14]. Buffers are usually used in mobile phases to hold and adjust the pH constant. The pH of the mobile phase is kept constant because it is always freshly prepared before RRLC analysis. The acid is used to improve the chromatographic peak shape and to provide a source of protons in reversed-phase LC/MS [15]. In this method, we also utilized isocratic elution, as it offers greater simplicity, lower cost, simpler instrumentation, and no need for column re-equilibration between consecutive injections [16].

The percentage of organic solvents

We investigated three ratios of TFA:ACN: 90%:10%, 85%:15%, and 81%:19%. The column temperature, wavelength signal, and mobile phase flow rate were kept constant. The ratio combination was determined based on the previous literature on anthocyanins [8]. Among the three ratios tested, only the 81%:19% composition showed the presence of peaks. The chromatograms of the other two ratios did not generate any peaks, possibly due to differences in the percentage of ACN used. The higher the percentage of acetonitrile, the faster the retention time for anthocyanins. Hence, the 81%:19% TFA:CAN combination was chosen because it also exhibited a faster retention time and good peak shapes.

Optimization of type of organic solvents

The selection of proper organic solvents is also important for retaining substances in RRLC. The two organic solvents tested, ACN and MeOH, are the most commonly used solvents in RRLC. We tested ACN and MeOH in combination with a 0.1% TFA aqueous solution. The column temperature, mobile phase flow rate, wavelength signal, and percentage of organic solvent in the mobile phase were kept constant.

The results showed that using ACN as an organic solvent generated peaks in the chromatogram, while there was no peak when MeOH was used. This could be due to the elution strength of the organic solvents. ACN has a higher elution strength than MeOH [17]. Thus, at the same percentage of organic solvent in the mobile phase, which was 19% for ACN and MeOH, we observed shorter retention times for the analytes with ACN than with MeOH. ACN has a lower viscosity than MeOH [18]. Hence, with increasing column temperature, the pressure also tends to decrease as the viscosity of the solvent decreases. ACN is also often used because of its low UV cut-off wavelength, which is lower than that of MeOH (190 nm and 205 nm for ACN and MeOH, respectively) [19]. Thus, ACN was chosen for further investigation, as the chromatogram showed peaks of cyanidin-3-O-glucoside chloride and an internal standard .

Optimization of flow rates

Another chromatographic parameter that affects chromatographic separation is the flow rate. Three different mobile phase flow rates 0.5, 0.8, and 1.0 ml/min were investigated. The percentage of organic

solvent in the mobile phase, column temperature, and injection volume were kept constant. An increase in the flow rate will decrease the retention factor, thereby resulting in rapid analysis [20]. A flow rate of 0.5 mL/min was chosen, as it displayed a good retention time of about 4 min, good area counts, and good peak shape. Although the peaks at other flow rates were generated at a shorter retention time, they were not chosen, as the increase in the flow rate caused a reduction in the peak area. Increased flow rates may shorten retention time, but they may contribute to band broadening and a decrease in the column's efficiency [20].

Optimization of column temperatures

One of the important chromatographic conditions is column temperature, as it is an important variable in LC separation [21]. The column temperature was optimized at three different temperatures: 30, 35, and 40°C. The percentage of organic solvent in the mobile phase, wavelength signal, and mobile phase flow rate were kept constant. The column temperature of 30°C was chosen because it gave the best peak area ratio, as recommended by the manufacturer.

Higher column temperatures can affect column pressure due to their effect on lowering mobile phase viscosities. Thus, a desirable lower systemic pressure will be produced. This, in return, allows a lower linear velocity for the chromatographic system and thus produces a sharper peak [22]. In this study, although column temperatures of 35 and 40°C generated shorter retention times, the column temperature of 30°C was selected because it also gave fast retention time and better peak shape without compromising the peak area. Further, a lower column temperature is preferable to sustaining the stability of cyanidin, as a higher temperature would result in a faster degradation rate of anthocyanins [23]. High temperatures could also be detrimental to the column's packing when used over a prolonged time [22].

Final chromatographic conditions

We performed the detection of cyanidin-3-O-glucoside chloride and internal standard cyanidin-3,5-O-diglucoside chloride at 525 nm with the ratio of mobile phase at 81:19 (0.1% TFA:ACN) (v/v). The mobile phase flow rate was set at 0.5 ml/min. The column temperature was set at 30°C. Using the column chromatographic conditions described above, the average retention times for cyanidin-3-O-glucoside chloride and cyanidin-3,5-O-diglucoside chloride were 4.4 min and 3.2 min, respectively , with a total run time of 10 min and a stop time of 5 min (Figure 2).

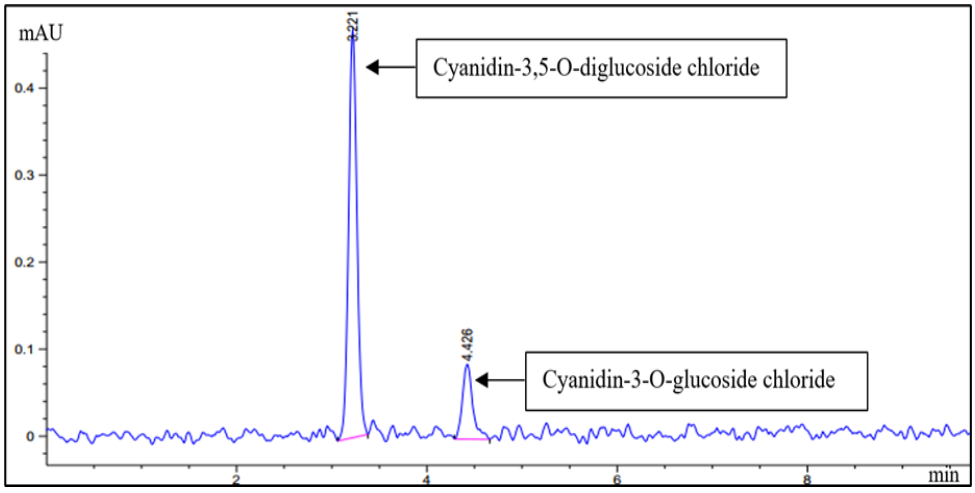

Figure 2. Chromatograms of standard solutions of cyanidin-3-O-glucoside chloride (3.221 min) and the internal standard, cyanidin-3,5-O-diglucoside chloride (4.426 min)

Optimization of liquid-liquid extraction method

The optimized chromatographic condition was applied for the analysis of plasma samples using the LLE method.

Effect of using different extracting solvents

The percentage recoveries of compounds extracted using different solvents were calculated (Table 1). The acetonitrile was chosen as the extracting solvent because both the percentage recoveries of analyte and internal standard were higher than those of the other solvents. The internal standard was used in this test to aid in quantification of analytes (anthocyanin) and improve the accuracy and precision of the method. Internal standard is used to compare the peak area of target analytes to the peak area of internal standard to obtain the peak area ratio.

Table 1. Percentage recoveries of cyanidin-3-O-glucoside chloride and cyanidin-3,5-O-diglucoside chloride by liquid-liquid extraction method when different extracting solvents were used

Solvent	Recovery for cyanidin-3-O-glucoside chloride (%)	Recovery for cyanidin-3,5-O-diglucoside chloride (%)
Acetonitrile (ACN)	72.85	119.05
Diethyl ether (Et_2O)	No peak seen	No peak seen
Ethyl acetate (EtAc)	66.72	38.85
Methyl tert-butyl ether (MTBE)	110.46	44.85

Optimization of solid-phase extraction method

The optimized chromatographic conditions were also applied for the analysis of the plasma samples using SPE.

Selection of final extraction method

The chromatograms of cyanidin-3-O-glucoside chloride for both the LLE and SPE methods were analyzed at concentrations of 500 ng/mL and 1000 ng/mL respectively. The recovery percentage of cyanidin-3-O-glucoside chloride from LLE was slightly better than that of SPE (72.85% and 68.36%, respectively). However, the chromatogram generated from the SPE method demonstrated better peak shapes for cyanidin-3-O-glucoside chloride and the internal standard compared to the chromatogram of the LLE method. In addition, the chromatogram of the SPE method showed less peak tailing compared to the LLE method. The chromatogram of the SPE method also exhibited similar retention times for cyanidin-O-glucoside chloride and internal standard prior to extraction. Hence, we chose SPE as the final extraction method, as it yielded more favorable results than LLE in the extraction cyanidin-O-glucoside chloride in rat plasma based on the results of RRLC analysis (Figure 3).

Extraction is a critical step in sample preparation, as the presence of endogenous impurities in biological fluids might cause interference in anthocyanin analysis. SPE and LLE are among the extraction methods used for anthocyanins, with increasing selectivity or specificity and improved recoveries and reproducibility [24]. In this experiment, we performed both methods to determine the most suitable extraction method for cyanidin-3-O-glucoside chloride.

LLE offers an advantage as an extraction method, in that the technique is relatively cheaper than SPE. However, this method requires costly and hazardous organic solvents, which are undesirable for health and disposal reasons [25]. LLE also requires a lengthy analysis period, which can give rise to the possible degradation of anthocyanins. By contrast, SPE techniques can overcome many of the problems associated with LLE, such as incomplete phase

separations, less-than-quantitative recoveries, and the use and disposal of large and expensive quantities of organic solvents [25]. The only drawback of the SPE compared to the LLE technique is that the cost of the equipment required for SPE is higher than for LLE. Another advantage of SPE is that this technique can be used not only in preparing liquid samples and extracting semi-volatile or non-volatile analytes but also for solids that are pre-extracted into solvents [25].

From our results, although the percentage recoveries of anthocyanin from the LLE method were slightly better than those from the SPE method, we also considered other factors. The chromatographic peak shapes obtained with the SPE method were better than those obtained with LLE. An optimum chromatographic peak shape is important to ensure more accurate quantitation of analytes. Abnormal peak shapes, such as peak tailing, generate imprecise results. The chromatograms of SPE displayed lesser peak tailing than those of LLE. Peak tailing is one of the common chromatographic peak shape distortions [26], which can occur for several reasons, including the purity of the packing material, a quality that can influence the peak shape [27]. Contaminants in the material can enhance secondary interactions, which lead to peak tailing. Thus, using an extraction method that employs a sample cleanup procedure will offer better results [26]. Here, the SPE method involved a filtration step that used an Ultrafree-MC 0.45 µm filter unit before RRLC analysis. Therefore, given its chromatogram results and advantages compared to LLE, the SPE method was adopted as the extraction method in this study.

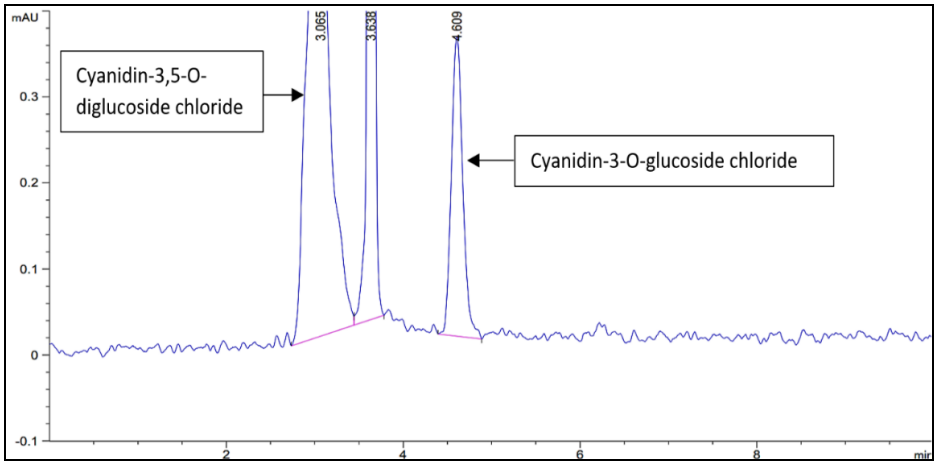

Figure 3. Chromatogram of cyanidin-3-O-glucoside chloride (4.609 min) and internal standard, cyanidin-3,5-O-diglucoside chloride (3.065 min) at concentration 1000 ng/mL following SPE method

Conclusion

We successfully determined cyanidin-3-O-glucoside chloride in rat plasma using RRLC analysis. The spectrophotometry analysis showed that the maximal absorbance of the compound was in the absorption range reported in the previous literature. The optimization of chromatographic conditions demonstrated that the mobile phase composition of 0.1% TFA aqueous solution and ACN in the ratio of 81:19%, respectively, with a flow rate of 0.5 ml/min, at 30°C column temperature and detection wavelength of 525 nm, were suitable for RRLC analysis of cyanidin-3-O-glucoside chloride. SPE was selected as the final extraction method for cyanidin-3-O-glucoside chloride and its internal standard.

Abstract

The oil palm frond (OPF) biomass contains chemical characteristics, which makes it a potential alternative adsorbent in wastewater treatment applications. In this study, the OPF sample was produced as biochar by using a top-lit updraft (TLUD) gasifier. The maximum temperature of this process was 750ºC and it yielded 20% w/w of biochar. The Brunauer–Emmett–Teller (BET) surface area for the OPF biochar was 248.08 m^2/g with an average pore size of 4.3 nm and categorised as mesoporous adsorbent. The OPF biochar had a high carbon content of more than 70%, which was desirable for the alternative adsorbent. It was discovered that the aromatic ring and aliphatic functional group was detected in the biochar based on the Fourier Transform Infrared (FTIR) analysis which was commonly found in biochar produced at temperatures above 500°C. Based on the result obtained from the adsorption test, the OPT biochar could provide a maximum removal of 64.65% of COD, with an initial COD of 3960 mg/L. This study has found that the OPF biochar is suitable to be used as an alternative adsorbent for wastewater applications.

Keywords: biochar, oil palm frond, adsorption, palm oil mill effluent

Abstrak

Pelepah kelapa sawit (OPF) mempunyai sifat kimia yang berpotensi sebagai bahan penjerap alternatif dalam aplikasi rawatan air sisa. Dalam kajian ini, sampel OPF digunakan sebagai bahan mentah untuk menghasilkan biochar dengan menggunakan *gasifier top-lit updraft* (TLUD). Suhu maksimum process ini adalah 750ºC dan 20% *w/w* biochar telah dihasilkan. Luas permukaan Brunauer–Emmett–Teller (BET) untuk biochar OPF adalah 248.08 m^2/g dengan ukuran purata saiz pori 4.3 nm dan diketagorikan sebagai penjerap mesoporos. Biochar OPF mempunyai kandungan karbon yang tinggi melebihi daripada 70%, yang merupakan ciri-ciri yang dikehendaki untuk penjerap alternatif. Berdasarkan analisis spektroskopi inframerah transformasi Fourier (FTIR), kumpulan organik alifatik dan cincin aromatik dikesan didalam bahan ini. Kumpulan organik ini biasanya ditemui dalam biochar yang dihasilkan pada suhu melebihi 500°C. Berdasarkan hasil kajian yang diperolehi daripada ujian penjerapan, biochar OPT mampu memberikan menyingkirkan 64.65% COD daripada air sisa kilang kelapa sawit yang mempunyai COD awal sebanyak 3650 mg/L. Kajian ini mendapati bahawa biochar OPF wajar digunakan sebagai penjerap altenatif untuk rawatan sisa pepejal.

Kata kunci: biochar, pelepah kelapa sawit, penjerapan, sisa efluen kilang kelapa sawit

Introduction

Crude palm oil (CPO), palm kernel oil (PKO), and palm kernel cake (PKC) are the primary interests in palm oil industry. In 2020, there were 5.87 million hectares of palm oil plantations in Malaysia. The production of crude palm oil (CPO) in the same year was 19.14 million tonnes [1]. A total of 80 million tonnes of biomass are generated annually in Malaysia, with the majority from the palm oil industry [2, 3]. Biomass generated by the palm oil industry are mainly produced from the harvesting of fresh fruit bunch (FFB) at the plantation, and the processing of FFB in mills. These biomasses include mesocarp fibre (MF), empty fruit bunch (EFB), palm shell (PS), oil palm fronds (OPF), oil palm leaflet (OPL), oil palm trunk (OPT), and palm mill effluent (POME). The presence of wastes creates a disposal problem, which requires the implementation of a robust management strategy.

POME is one of the wastes generated from the palm oil industry. POME is brownish wastewater generated from the processing of FFB; it has a high amount of organic contaminants and requires proper treatment before it can be discharged into any water body. Anaerobic and aerobic digestion treatments are the common treatments used to remove the organic contaminants in the wastewater, but both treatments are not sufficient to comply with the standard set by the Department of Environment (DOE) Malaysia, as shown in Table 1 [4]. The final discharge of POME from the biological treatment or palm oil secondary effluent (POMSE) usually remains high in chemical oxygen demand (COD) and biochemical oxygen demand (BOD), with an average of 800 mg/L and 200 mg/L respectively. Furthermore, it is also dark in colour, which is higher than the standard set by the DOE [5]. This is due to the presence of lignin, carotene, humic acids and other organic compounds that are recalcitrant to biological treatments [6]. Another treatment that should be implemented to polish the biologically treated POME, ensuring that it complies with environmental legislation, is the adsorption technique, a technology that can be applied to biologically treat POME as a polishing method. The key benefits of this technology are that it is easy to design, and it has a minimal initial investment. Natural resources such as biomass, silica, and zeolite can be used to make the adsorbent [7, 8].

Table 1. Environmental Quality (Industrial Effluent) Regulation 2009

Parameter	Unit	Standard	
		A	B
COD	mg/L	80	200
BOD_5	mg/L	20	50
Colour	ADMI	100	200
TSS	mg/L	50	100

The biomass from this industry has the potentials to be converted into valuable products. The potentials include using OPT as building materials, OPF as the precursor for ethanol production, OPS as an aggregate in lightweight cement, MF as a growing media for tissue culture, POME as a substrate for methane generation, and OPL and EFB as mulch in plantation [3, 9]. Some biomass, such as PKS and EFB, have critical functions as fuel sources for mills and to maintain soil conditions [10, 11]. However, there is still a significant amount of biomass that are unutilised, and measures should be taken to improve its functionalities. In recent years, there is an increasing amount of literature on the conversion of palm oil biomass into biochar. Biochar is a carbon-rich material produced from the thermochemical process. The pyrolysis process is the common thermochemical process utilised to produce biochar. However, scarce attention has been paid to gasification as a thermochemical process to produce biochar.

Gasification is defined as a thermochemical process to convert carbonaceous feedstock into syngas (a mixture of hydrogen, carbon dioxide, and methane), tar, and

biochar at high temperatures (≥ 500°C) in oxygen-deficit conditions [12, 13]. So far, this method has only been applied for the generation of energy [14]. Most of the literature on the gasification process only focus on the optimisation of process parameters and the quality of gas produced from this process [15, 16]. The solid product of gasification, i.e., biochar, receives less attention. In general, biochar is known as an effective carbon sequestration strategy due to its recalcitrant properties. Therefore, biochar produced from the gasification process might have the same potentials as biochar produced from other thermochemical processes, i.e., fast pyrolysis, and hydrothermal process. The characteristics of biochar are dependent on the properties of biomass, the conditions of the process, and the type of reactor used for the thermochemical process.

Most literature on biochar are more focused on carbon sequestration and soil conditioner. The potential of biochar is not only limited to carbon sequestration and soil application, but it also has the potential to be used in other applications especially in water application. However, there are limited studies done on the application of biochar in water and wastewater treatment. In a study on the application of biochar as an alternative adsorbent, Huggins et al. [17] found that biochar from the gasification process could reduce phosphate, COD, and nitrogen ammonia in brewery wastewater. Kearn et al. [18] proved that biochar produced from the gasification process could remove trace organic contaminants from drinking water. Similarly, Kaetzl et al. [19] found that biochar was found to reduce both organic and inorganic contaminants from a municipal wastewater. Overall, many studies highlighted that biochar was effective in eliminating organic and inorganic pollutants from water and wastewater [16-23] This could be due to the high porosity of biochar or the presence of other chemical species that aids the adsorption process [12, 25].

The utilisation of biochar produced from the gasification process in wastewater application is an interesting topic to be studied. This paper will focus on biochar produced from gasification by using top-lit updraft (TLUD) gasifier and oil palm frond (OPF), which were used as the raw materials in this study. The characteristics of the biochar and its performance to treat biologically treated POME will be evaluated.

Materials and Methods

Source and preparation of biomass

The raw material used in this study was oil palm frond (OPF). The OPF was obtained from a local plantation located in Tampin, Negeri Sembilan. Figure 1 shows the structure of OPF. The structure of the OPF consists of the top section, middle section, and basal. Only the basal part of the frond was used in this study as it was easier for real-life application. The OPF was chopped using a mechanical chopper with the particle size ranging from 1–4 mm and rinsed with tap water to remove any impurities. The OPF was then dried in a vacuum oven for 24 hours to avoid rotting.

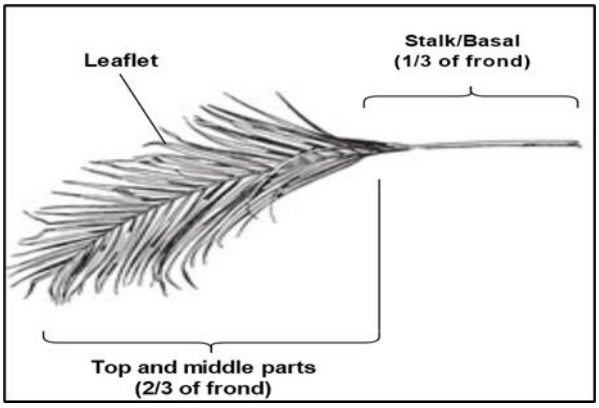

Figure 1. Structure of OPF

Gasification of oil palm frond

The top-lit updraft gasifier (TLUD) was used to produce OPF biochar, as illustrated in Figure 2. Before the gasification process, the raw OPF was sieved to ensure that the particle of the OPF was uniformed. The uniformity of the size of feedstock was vital to ensure that the feedstock was fully charred, and to achieve a good airflow through the reactor body. The dried OPF was weighed before it was filled into the gasifier. The dried OPF was then placed into the gasifier about ¾ of the reactor body (approximately 600 g of dried OPF). A small piece of paper or wood was used as rekindling. The kindling was lighted, and it would burn strongly.

The fan of the gasifier was turned on to provide air to assist the gasification process. The temperature of the process was monitored for quality control and assurance. The dried OPF was burnt from top to bottom until a bluish flame was formed. The blue flame was an indicator that the OPF was fully gasifier. The fan was then turned off and the gasifier was allowed to cool. The OPF biochar was then sprayed with some water to remove any ash and fine. The biochar was cooled until it was cool enough for handling.

The OPF biochar produced was weighted and the percentage of yield of the biochar was calculated using Equation 1.

$$\%\text{Yield} = \frac{W_1 - W_2}{W_1} \times 100 \quad (1)$$

where W_1 is a weight of biomass and W_2 is a weight of biochar.

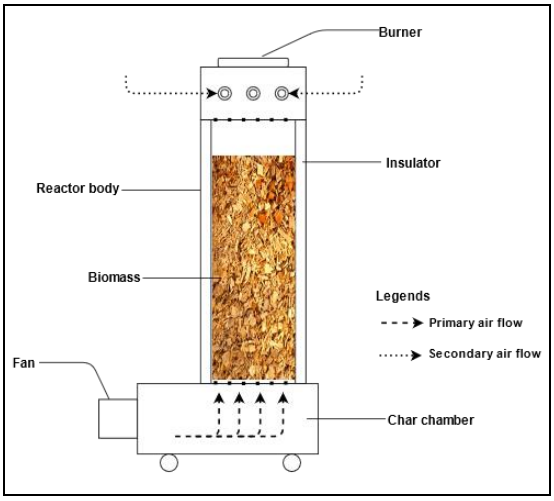

Figure 2. TLUD gasifier

Characterisation of OPF

pH of biochar

pH is an indicator of the acidity and basicity of the biochar. The pH of biochar can be a good indicator to understand the oxygen complexes and functional groups on the surface of biochar. The OPF biochar was soaked in the deionised water (ratio of 1:25% wt./v solid to water ratio) for one hour with agitation [26]. The pH of the slurry was then tested with a pH meter (Mettler Toledo).

Proximate analysis and ultimate analysis of raw material and biochar

There were three components of proximate analysis which were moisture content, ash content, and volatile matter. The proximate analysis of raw OPF was done using National Renewable Energy Laboratory (NREL) method for all three analyses. On the other hand, the proximate analysis of biochar was done using the ASTM method (ASTM D2867-09, ASTM D5832-98, and ASTM D2866-04).

The ultimate analysis of both raw OPF and OPF biochar was carried out using a CHNS analyser. This analysis was done to quantify the content of carbon, hydrogen, nitrogen, and sulphur in both samples. All four elements were analysed simultaneously.

Scanning electron microscopy analysis and Brunauer–Emmett–Teller surface area analysis

Scanning electron microscopy (SEM) analysis of raw OPF and OPF biochar was carried out using Scanning Electron Microscope SEM (FEI Quanta 450). BET analysis was used to determine the surface area of biochar in this study. The BET analysis was conducted using a BET Surface analyser (Micromeritic) with N_2 gas adsorption at 77 K in relative pressure from 0.05 to 0.2. The samples were degassed for 2 hours at 200 ºC.

Fourier transform infrared analysis

FTIR analysis was done to determine the functional groups of the biochar. This analysis is vital to gain an understanding of the chemical characteristic of biochar and the adsorption mechanism of biochar. Before conducting the FTIR analysis, the OPF biochar was ground into powder and dried in an oven overnight to remove any residual moisture in the biochar. The sample was then mixed with potassium bromide (KBr) with a ratio of 1:2000 (1 part sample: 2000-part KBr). The mixture was then pressed into a pellet form by using a hydraulic presser. The pellet was finally analysed using the FTIR analyser (Nicolet 5700, FTIR, Thermo Fisher Scientific, and Waltham, MA, USA).

Adsorption test

The batch adsorption test was conducted to determine the applicability of OPF biochar as an adsorbent for wastewater treatment. The adsorbate used in this study was palm oil mill secondary effluent (POMSE). POMSE is the effluent generated after the biological treatment of POME. It is high in chemical oxygen demand. (COD). Method No.8006 was used to measure the COD of POMSE before and after treatment. The measurement of COD was conducted using the APHA potassium dichromate method. The measurement was carried out in HACH COD high range vials by using DR900 spectrophotometer and HACH COD reactor (Model: 45600).

Next, the batch adsorption test was conducted using 100 ml of POMSE. The OPF biochar was added to the conical flask containing 100 ml of POMSE. The mixture of the OPF biochar and POMSE was then shaken for 24 hours at 150 rpm using an incubator shaker. The samples were withdrawn at a fixed time interval. The adsorbent was separated from samples by filtration. The filtrates were then analysed for COD. The number of COD adsorbed per unit mass of the adsorbent (qe) was calculated according to the following Equation 2 and the adsorption yield was calculated by using Equation 3.

$$q_e=(C_0-C)\times\frac{V}{m} \quad (2)$$

$$\%\text{COD removal} = \frac{C_0-C}{C_0}\times 100 \quad (3)$$

where, q_e is the number of COD adsorbed per gram of adsorbent (mg/g); C_0 and C are the initial and final COD concentrations (mg/L), respectively; V is the volume of POMSE (L); and m is the mass of biochar (g).

Results and Discussion

Gasification of OPF

The main products of the gasification process usually consist of syngas, bio-oil, and biochar. The quantity biochar product derived from the gasification process is usually lower compared to other types of thermochemical processes such as pyrolysis, hydrothermal and torrefaction. For this study, the yield of OPF biochar was 20%. The same yield of biochar was obtained by Nsamba et al.[26] using the same gasification system. The biochar obtained from the gasification process is usually lower than other thermochemical processes i.e., fast pyrolysis because of the partial oxidation of carbon into carbon monoxide and other flue gasses [27, 28]. Other than partial oxidation of carbon in the biomass, the release of volatile matter from the polymeric backbone of carbonaceous feedstock also contributed to the yield of the biochar. Apart from that, the temperature of the gasification that is usually ≥ 500 °C is good to produce high porosity biochar [29, 30]. In this study, the range of maximum temperature of the gasification process for OPF biochar was 750 °C by controlling the speed of the fan that improved the air supply. Studies on the effect of temperature on the properties of biochar in past studies found that the surface area of the biochar was increased as the temperature of the thermochemical increased [31, 32]. Increasing the surface area of the biochar contributed to better performance of biochar as an adsorbent as it can remove more pollutants from wastewater. This trend can be seen in earlier studies using orange peel biochar for removal of cadmium from aqueous solution; maximum removal of cadmium was obtained when the orange peel biochar was produced at a temperature of 700 °C, which was then used as an adsorbent [33]. Other studies showed a similar trend in the removal of chromium from aqueous solution [34, 35]. These findings suggest that gasification biochar has the potential to be used as an adsorbent.

Characterisation of OPF biochar

pH of biochar

The pH for OPF biochar in this study is alkaline (pH=8) which is similar to the literature where most biochar is best produced at temperatures higher than 400 °C [29, 30, 36, 37]. The alkaline pH of OPT biochar is correlated to the presence of basic functional groups on the surface of biochar, as shown in Figure 4. Generally, raw biomass has a high number of acidic functional groups. Figure 4 illustrates the presence of acidic functional group in the raw OPF that corresponded to the carboxylic acid functional group. However, the band of the functional group diminished

after the gasification process. The reduction of the acidic functional groups was aligned to the reduction of volatile matter of biomass as the temperature of the process increased.

Apart from the reduction of acidic functional groups, the alkalinity of OPF biochar was contributed by the formation of the aromatic and aliphatic functional group. The peak of the functional groups can be seen at the band of 1200–1600 cm^{-1}. The same findings can be seen in a study conducted by Usman et al. [38] on the production of biochar from the date palm waste. Other studies had established that the pH of biochar increased when the temperature of thermochemical increased [38-40]. The presence of alkaline metal contributed to the alkalinity of biochar [12, 42].

Proximate analysis and ultimate analysis

Table 2 shows the proximate analysis and ultimate analysis for both raw material and biochar. Generally, the value of each component changed after the gasification process. Table 2 shows that the volatile matter decreased sharply from 86.49% in raw OPF to 15.57%. This was due to the conversion of volatile matter into more condensed aromatic structures and/or may burn out which might help in the development of the porous structure of biochar [43]. The raw OPF had high volatile matter (86.49%), which was a good indicator that the biomass is suitable to be used as a feedstock for the thermochemical process. The percentage of volatile matter obtained in this study is closed to those obtained from other studies [11, 31, 11, 31].

Ash content is a vital indicator to determine the suitability of the biomass as feedstock for the thermochemical process. The ash content of the raw OPF in this study is 0.92%, which aligned with previous studies [11, 31, 44]. The ash content of the biochar is higher than the raw OPF due to the accumulation of inorganic material in the biomass after the volatilisation of carbon, oxygen, and hydrogen [45]. The fixed carbon content is significantly increased from 12.59% in raw OPF to 68.34% in OPF biochar. The ash content of OPF biochar is 13 times greater than raw OPF; similar trend can be observed in other studies [28, 36, 38, 46].

Table 2 provides the Carbon (C), Hydrogen (H), Nitrogen (N), Sulphur (S) and Oxygen (O) content of both raw OPF and OPF biochar. The C and N content of the OPF biochar was significantly higher compared to its original biomass. On the other hand, the O and H content of the biochar is lower than its original biomass. This may be due to the breakdown of carbon and functional groups of the biomass during the gasification which led to the formation of aromatic functional groups [47]. The O/C and H/C ratio of the biochar is found to be lower than the biomass, which indicated the formation of aromatic functional and reduction of hydrophilicity of the biochar [47], [48].

Table 2. Proximate analysis and ultimate analysis

Proximate Analysis (%w/w)	**Raw OPF**	**OPF Biochar**
Moisture content	9.95	3.71
Ash content	0.92	12.38
Volatile matter	86.49	15.57
Fixed carbon	12.59	68.34
Ultimate analysis (%w/w)		
Carbon (C)	41.87	76.97

Table 3 (cont'd). Proximate analysis and ultimate analysis

Proximate Analysis (%w/w)	**Raw OPF**	**OPF Biochar**
Hydrogen (H)	6.00	2.50
Nitrogen (N)	0.33	0.76
Sulphur (S)	0.70	0.39
Oxygen (O)	51.10	19.38
O/C ratio	0.92	0.19
H/C ratio	1.72	0.39
pH	-	8
Porous characteristics		
BET surface area, m^2/g	-	248.08
Pore Volume, cm^2/g	-	0.23
Average pore size, nm	-	4.3

Scanning electron microscopy analysis and Brunauer–Emmett–Teller surface area analysis

SEM analysis was performed to analyse the morphology of raw biomass and biochar. Figure 3 shows the morphology of raw material and biochar. Figure 3 demonstrates a significant change in the surface of OPF and OPL before and after the gasification process. In Figure 3 (a), the surface of OPF is very rough and less pore is visible whereas in Figure 3 (b) the surface of the OPF biochar is smoother than raw OPF. More pores were visible for OPF biochar. The formation of pores in the biochar are caused by the release of volatile matter, decomposition of cellulose and hemicellulose, which resulted in the complex structure of biochar with multiple diameters of pore [47, 49].

BET and BJH analysis were done on the OPF biochar to analyse its surface area and characteristics of pores. Table 2 provides the BET surface area, pore volume and average pore size of OPF biochar. The BET surface area of OPT biochar was 248.08 m^2/g with an average pore size of 4.3 nm. The OPF biochar can be classified in the mesopore category as the average pore size of OPF biochar fell within the range of 2–50 nm. When compared to other studies, the surface area and pore volume of OPF biochar found to be higher than other studies which, on average pores, are lower than 150 m^2/g [44, 50, 51]. Compared to commercial activated carbon (AC), the AC has a larger surface area and smaller average pore size which leads to high affinity to low molecular weight compound but is less efficient in the removal of high molecular weight compound. The high molecular weight compounds are commonly present in wastewater after biological treatments as refractory pollutants. A study conducted by An et al. [52] proved that a mesoporous lignite adsorbent was effective in removing refractory pollutants from biologically treated coal gasification wastewater. The result of this study is aligned to the findings from other studies using the same type of wastewater, similar to the research by Gai et al. [53] and Xu et al. [54]. The OPF biochar appears to have the potential to be used as alternative adsorbent to improve the characteristics of biologically treated wastewater.

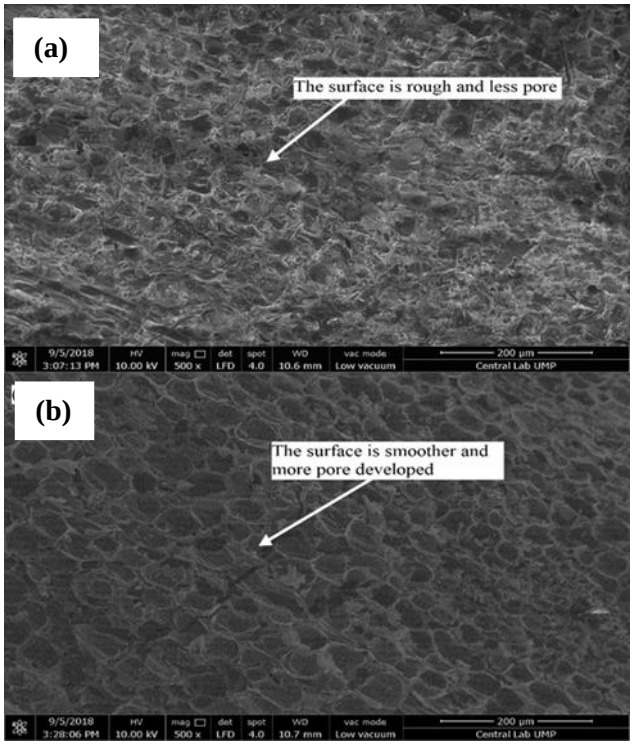

Figure 3. (a) raw OPF (b) OPF biochar

Fourier transform infrared analysis

FTIR analysis was done to determine the functional group of the biochar's. Figure 4 compares the FTIR spectra of both raw materials and biochar produced in the gasification process. Overall, the spectra between raw OPF and OPF biochar is different. In Figure 4, the peak between 3200-3600 cm^{-1} corresponded to the –OH group with stretch vibration and carboxylic acid functional group. The presence of broad –OH in the raw OPF which attributed to the moisture content and hydroxyl functional group found in lignin, hemicellulose, and cellulose [54], [55]. The intensity of the peak decreased after the gasification process. The reduction of the intensity of the peak indicated that the removal of moisture and volatile matter contributed to the porous structure of the biochar [39], [56].

There is a peak within the band of 2800-3000 cm^{-1} which corresponded to the saturated aliphatic C–H functional group. This functional group is associated with the methylene functional group in cellulose [54, 56]. The peak within the band of 1700-1800 cm^{-1} represents the C=O acetyl group associated with the ester functional group in hemicellulose [55, 57]. This band diminished after the gasification process due to the integration of cellulose and hemicellulose. There are some peaks within the band of 1600-1700 cm^{-1} in both biomass and biochar. These bands correlated with the carboxylic acid functional group. However, the peaks diminished after the gasification process is aligned with the alkaline pH of the biochar.

The intensity of the peak within the band of 1500-1600 cm^{-1} is abated. The peaks within this band correlated to the aromatic hydrocarbon functional group of lignin

C-C stretching vibration in the aromatic ring [55, 56]. The peaks within the band of 1000-1500 cm^{-1} corresponded to the aliphatic and aromatic functional groups. The intensity of the peaks was reduced in the OPF biochar. This might be due to the partial decomposition of lignin in the raw biomass. The presence of aromatic aliphatic functional groups in the biochar will provide the active sites to assist the adsorption process and contributes to the hydrophobicity of the biochar. This can be seen in the study conducted by Liu et al. [57] on the role of functional groups in the adsorption of bisphenol A (BPA) on activated carbon. The study revealed that the modified AC provided 10% higher removal of BPA compared to commercial AC. This was due to the decrease of acidic functional groups in the modified AC and stronger hydrophobicity than commercial AC which leads to better BPA adsorption and more water molecule exchange, which aligns with the findings by Sidik et al. [58] on the OPL adsorbent with enhanced hydrophobicity.

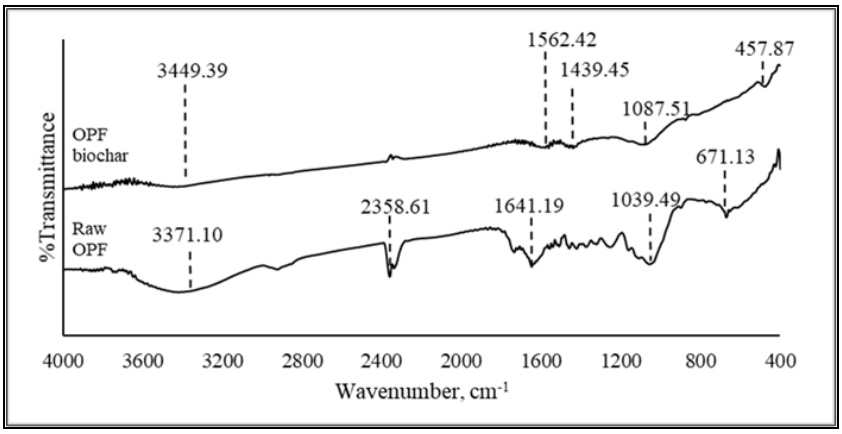

Figure 4. FTIR spectra of raw OPF and OPF biochar

Adsorption test

The wastewater used in this study was palm oil secondary effluent (POMSE) obtained from a local palm mill in Selangor. The POMSE is the effluent generated from the biological treatment of raw POME and it was still high in COD. This is a common problem faced by palm oil mill operators [59]. The high COD in the POMSE was contributed by the presence of macromolecules, such as fulvic acid and humic acid [60]. The initial concentration of COD is 3960 mg/L and the experiment was conducted in batch modes. Figure 5 and Figure 6 show the reduction of COD from POMSE by using OPF biochar as an adsorbent. As shown in Figure 5, there is a significant reduction of COD from POMSE. After 30 minutes of contact time with OPF biochar, the COD of POMSE is reduced from 3960 mg/L to 2100 mg/L. The COD of POMSE continuously reduced as the contact time with the OPF biochar increased.

From Figure 6, the maximum removal of COD is 64%, in which it is achieved after 24 hours of contact time. When compared to other studies, the biochar produced in this study can provide better removal of pollutants than other alternative adsorbent which on average can only provide 55% removal of pollutants [44]. Other than that, the performance of the OPF biochar in this study was comparable to the coconut-based activated carbon produced in the study conducted by Parveen et al. [61]. After 24 hours of contact time, the removal of COD from POMSE is constant. This is due to the unavailability of active adsorption sites on the OPF biochar [62], [63]. By comparing to the research conducted by Razali et al. [64] using oil palm trunk (OPT) biochar, the OPF biochar provided better removal of COD than OPT biochar. This might be due to the differences in characteristics of the biochar. In comparison, the surface area of the OPF biochar is

higher than the OPT biochar. Other than the surface area, the OPF biochar has a higher pore volume compared to OPT biochar which is in line with the surface area of the biochar.

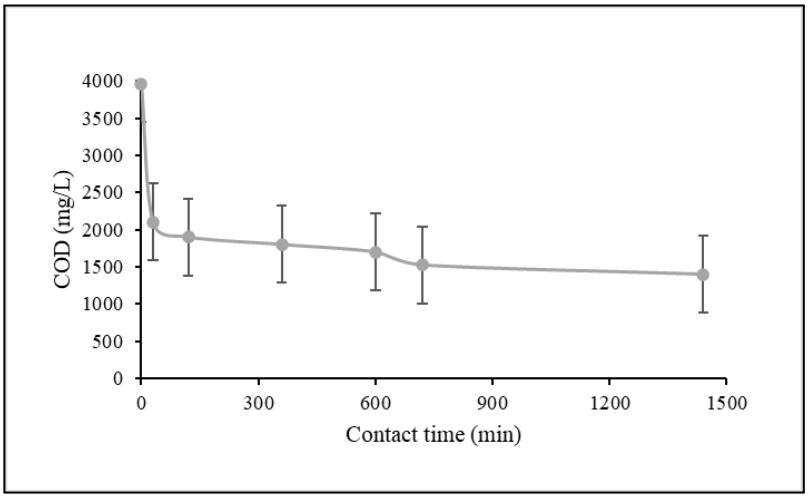

Figure 5. COD removal POMSE

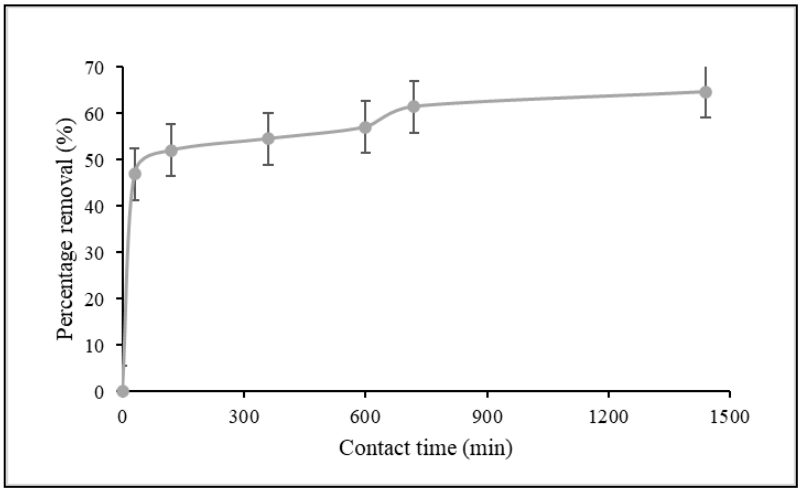

Figure 6. Percentage removal of COD from POMSE

Conclusion

The gasification process proves that other valuable and functional products (biochar) can be produced by using OPF, which is currently used as mulching and fertiliser. This study discovered that gasification biochar that was specifically produced from raw OPF has the potential to be used as adsorbents in wastewater application treatment. The biochar from the gasification process can be used as soil conditioning and in wastewater treatment as an adsorbent due to its unique characteristic, low moisture content, low ash content and high fixed carbon content. The OPF biochar produced from this study has a large surface area and high total pore volume which can be potentially used as alternative adsorbent in the adsorption process. The high carbon content and the

presence of carbonyl compound and aromatic rings in the biochar provide active sites that aid the adsorption process. It was proven that OPF biochar can provide more than 50% removal of pollutants from the wastewater tested in this study compared to other biochar produced in other studies.

A further study should be done on the application of biochar as an adsorbent for wastewater application. Further research on the factors and the kinetic of adsorption using this gasification biochar should be conducted to gain more understanding on the mechanism involved in the adsorption process by using gasification biochar.

Abstract

In this study, the banana trunk-derived activated carbon (BTAC) used was prepared via zinc chloride ($ZnCl_2$) activation. BTAC is used as an adsorbent to remove methylene blue (MB) from the aqueous solutions. The BET surface area, total pore volume and pore diameters of the BTAC were 1329.5 m^2/g, 1.16 cm^3/g and 3.8 nm, respectively. The effect of adsorbent dosage, initial concentration, contact time and solution pH were studied in batch experiments. The experimental data were analyzed by Langmuir, Freundlich, Temkin, and Dubinin-Radushkevich (D-R) adsorption isotherms model. Data analysis study via RMSE and χ^2 analyses suggested that Temkin isotherm model was the best fitted with the adsorption of MB on BTAC. The maximum monolayer adsorption of MB onto BTAC was calculated to be 217 mg/g. Kinetic parameters were evaluated based on pseudo-first-order (PFO), pseudo-second-order (PSO) and Weber–Morris intraparticle diffusion (IPD) kinetic models. The regression results showed that a PSO model is more accurately representing the adsorption kinetics. While the plot of q_t versus $t^{1/2}$ for the IPD model represented multi-linearity and proved that the adsorption processes occurred more than one step. Thermodynamics parameters were determined between temperatures of 25 to 40 °C. The $\Delta G°$ and $\Delta H°$ values were negative and the overall adsorption process was determined as spontaneous and exothermic. While the positive value of $\Delta S°$ proposed good affinity of the MB molecules toward the BTAC. The results from this study suggested that BTAC could be a viable adsorbent in managing higher concentrations of dyes from water and wastewater.

Abstrak

Dalam kajian ini, karbon teraktif daripada batang pisang (BTAC) yang digunakan telah disediakan melalui pengaktifan zink klorida ($ZnCl_2$). BTAC telah digunakan sebagai penjerap untuk menyingkirkan metilena biru (MB) daripada larutan akueus. Keluasan permukakaan BET, jumlah isipadu dan diameter liang pori bagi BTAC masing-masing adalah 1329.5 m^2/g, 1.16 cm^3/g

dan 3.8 nm. Kesan dos penjerap, kepekatan permulaan, masa kontak dan pH larutan dilakukan secara eksperimen kelompok. Data ekperimen telah dianalisa menggunakan model Langmuir, Freundlich, Temkin dan Dubinin–Radushkevich. Analisa data kajian melalui RMSE dan χ^2 mencadangkan bahawa model isoterma Temkin adalah yang paling sesuai dengan penjerapan MB pada BTAC. Penjerapan lapisan-mono maksima MB kepada BTAC dikira sebagai 217 mg/g. Parameter kinetik telah dinilai berdasarkan model kinetik pseudo-pertama (PFO), pseudo-kedua (PSO) dan resapan intrazarah (IPD) Weber–Morris. Hasil regresi menunjukkan bahawa model PSO lebih tepat mewakili kinetik penjerapan. Sementara plot q_t melawan $t^{1/2}$ untuk model IPD menunjukkan garisan linear yang pelbagai dan membuktikan bahawa proses penjerapan berlaku lebih daripada satu langkah. Parameter termodinamik telah ditentukan di antara suhu 25 hingga 40 °C. Nilai ΔG° dan ΔH° adalah negatif, maka keseluruhan proses penjerapan telah ditentukan sebagai spontan dan eksotermik. Sementara itu, nilai positif bagi ΔS° mencadangkan bahawa pertalian yang baik diantara molekul MB terhadap BTAC. Keputusan dari kajian ini mencadangkan bahawa BTAC mampu menjadi penjerap yang berkesan dalam menguruskan kepekatan pewarna yang lebih tinggi dari air dan air sisa.

Kata kunci: penjerapan, karbon teraktif, metilena biru, isoterma, kinetik

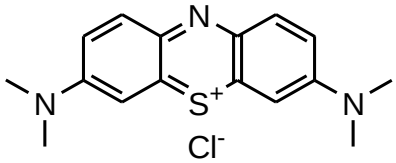
Introduction

Wastewater effluent that contains dyes is a typical and one of the major causes of environmental pollution. The presence of dyes in the industries effluent poses the most prominent problem since they are toxic and the recalcitrant nature of dyes [1]. Typical biological wastewater treatment plants cannot eliminate toxic pollutants such as dyes since they were purposely designed for organic and nutrient removal. Methylene blue (MB) is an example of dye that is commonly used in industry. MB is a heterocyclic aromatic chemical compound. Thus, MB is highly toxic, carcinogenic and its degradation process is difficult [2]. Therefore, MB containing effluent must be treated appropriately before discharge. Previously, various advanced oxidation methods have been introduced to treat dyes polluted water, such as ozonation [3], photocatalyst [4] and electrochemical treatment [5]. However, oxidation or degradation of dyes might contribute to the secondary pollutants. The other methods that have been employed include reverse osmosis [6], coagulation-flocculation [7], membrane filtration [8], ion exchange[9] and adsorption [10]. Among these methods, adsorption is a well-known and applicable method of removing dyes contaminant water. In addition, the adsorption process has emerged as a cost-effective, efficient, and environmentally friendly method of dye removal [11].

Recently, there are a variety of absorbents have been introduced to treat dyes such as bio-composite [12], nanoparticles [13], graphene oxide [14], forest wastes [15], polystyrene foam [16] agriculture waste [17]. Based on the current scenario, activated carbon (AC) is the best adsorbent to treat textile effluent. Previously, the preparation of AC by using low-cost precursor from agriculture waste such as dates stone [18], ashitaba waste [19], banana peel [20], almond and walnut shells [21] have been employed extensively as a new precursor in the production of AC. Most of the mentioned researchers claimed that abundance and continuous availability of the agriculture biomass are the key motivation of their precursor selection. In addition, the treatment and reuse of agriculture waste should be implemented efficiently to obtain its valorization and achieve sustainable waste management [22].

In Malaysia, biomass derived from agriculture such as banana plantation is gaining increasing attention. Banana widely planted in tropical country such as Malaysia, thus it is not surprising that it is the major biomass source. Instead of burning and disposing naturally as an organic fertilizer, a better way would be converting them into AC. Thus, this study used banana trunk as a precursor to prepare AC. During preparation of AC via chemical activation, the lignocellulosic precursor is treated primarily with a chemical agent, such as H_3PO_4, H_2SO_4, HNO_3, NaOH, KOH, or $ZnCl_2$. According to Lewoyehu [23], during the activation with $ZnCl_2$ the cellulosic material will be degraded, results in charring and aromatization of the carbon skeleton and creation of the pore structure. Hence,

produced AC with high surface area and good adsorption capacity.



However, in order to treat water-containing dye via adsorption requires a deeper understanding especially on the effectiveness of the adsorbent towards the adsorbate. Therefore, the objective of the present work is to introduce BTAC as an adsorbent and to examine its effectiveness in removing MB from aqueous solutions. The effect of adsorbent dosage, initial concentration, contact time and solution pH were studied in batch experiments. The experimental were analyzed by Langmuir, Freundlich, Temkin, and Dubinin-Radushkevich (D-R) adsorption isotherms model. Kinetic parameters, rate constants, equilibrium adsorption capacities, and related correlation coefficients were evaluated based on pseudo-first-order (PFO), pseudo-second-order (PSO) and Weber–Morris intraparticle diffusion (IPD) kinetic models. Thermodynamics parameters such as ΔG°, ΔH°, and ΔS° have also were evaluated.

Materials and Methods

Materials

In this study, the adsorbent used was BTAC with particle size <215 um, which was obtained from our previous study [24]. The BTAC was prepared from the banana trunk and activated with $ZnCl_2$ at a temperature of 640 °C. All the chemicals used in this study were of analytical reagent grade unless otherwise stated. The adsorbate used is a cationic dye, namely methylene blue (Sigma Aldrich, Germany). The physicochemical information of BTAC and MB were shown in Table 1. MB adsorption data was used to obtain adsorption isotherms, kinetic and thermodynamic study. Stock solution of MB (1000 mg/L = 1000 ppm) was prepared by dissolving 1 g of MB into 1 L distilled water. The stock solution was further diluted with distilled water to obtain the desired concentrations of MB in the range of 75 to 125 mg/L.

Table 1. Physicochemical information of BTAC and MB[20]

Banana trunk derived activated carbon (BTAC)			
Textural properties		**Ultimate analysis (wt.% dry basis)**	
BET surface area (m^2/g)	1329.5	Carbon (wt%)	84.1
Mesopore surface area (m^2/g)	1152.6	Hydrogen (wt%)	2.1
Micropore surface area (m^2/g)	176.9	Nitrogen (wt%)	3.7
Total pore volume (cm^3/g)	1.16	Sulfur (wt%)	0.2
Pore diameter (nm)	3.83	Oxygen (wt%)	9.9
Physicochemical properties		**Proximate analysis (wt.% dry basis)**	
Bulk density (g/cm^3)	0.6	Volatile matter (wt%)	25.1
Iodine number (mg/g)	819.03	Fixed carbon (wt%)	74.7
pH_{pzc}	3.7	Ash (wt%)	0.2
Methylene blue (MB)			
 Structure formula of MB		Commercial name	Methylene blue
		Chemical name	Methylthioninium chloride
		Empirical formula	$C_{16}H_{18}ClN_3S$
		Molar mass	319.85 g/mol
		CAS number	61-73-4
		λ_{max}	664 nm

Batch adsorption study

The batch adsorption procedure was utilized to investigate the uptake of MB from aqueous solution onto BTAC. For the effect of adsorbent dosage, various dosage of BTAC ranging from 0.01 to 0.13 g was added into 250 mL Erlenmeyer flasks containing 100 mL of 150 mg/L MB concentration. The influence of initial concentration was explored using seven different concentrations from 50 to 150 mg/L MB solution. While the effect of contact time was determined from initial until equilibrium contact time is reached (5 to 360 min). The solution pH was varied from 5.0 to 8.0 with constant another adsorption parameter. The samples were then shaken at isothermal temperature (25 ±2 °C) at 125 rpm in an incubator shaker. Each experiment was conducted with two replications. Then, the samples were taken out and filtered through a 0.45 µm nylon membrane before analysis to minimize the adsorbent's interference. After that, the filtered solutions were analyzed for MB uptake analysis by UV-visible spectrophotometer at 664 nm, which is the maximum absorption peak of MB. The adsorption capacity of MB in the aqueous solution was calculated by using Eq. (1) as follows:

$$q_e = [(C_o - C_e)V] / M \quad (1)$$

where C_e (mg/L) and C_o (mg/L) respectively represent the equilibrium and initial concentration of adsorbate, adsorbent mass is denoted by M (g), and solution volume is V (L). The isotherm parameters of the Langmuir and Freundlich, Temkin and Dubinin-Radushkevich models were investigated using batch experimental adsorption data at various C_o studied. For the kinetic studies, the experiments were carried out similarly as described above. Approximately 2 mL of MB solution was withdrawn at specific time intervals using a plastic syringe. The MB concentration in the liquid phase (C_t, mg/g) was analysed as a function of contact time (t). The adsorption capacity (q_e) was calculated using Eq. (2):

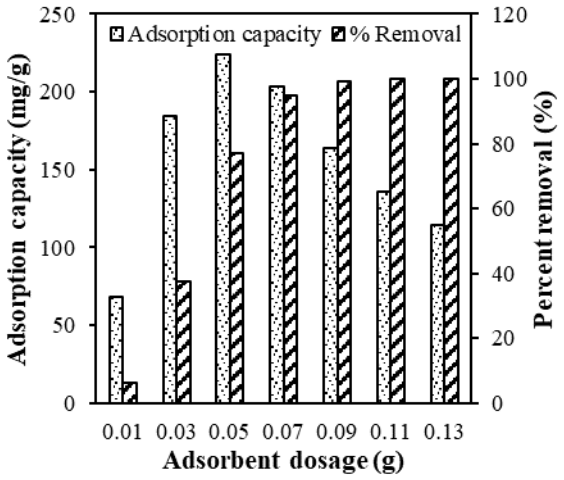
$$q_t = [(C_o - C_t)V] / M \quad (2)$$

where q_t is the amount of MB adsorbed per unit weight of adsorbent at any time t (mg/g); C_o and C_t are the initial and liquid-phase concentrations of the adsorbate solution at any time t (mg/L), respectively; V is the volume of the solution (L); and M is the weight of the sorbent used (g).

The thermodynamic studies were performed similarly as adsorption equilibrium study. The adsorption temperatures were varied from 25, 30, 35 and 40 °C (±2 °C). These experiments were carried out in incubator shaker at shaking rate of 125 rpm. The BTAC dosage and MB concentration was fixed at 0.05 g and 125 mg/L, respectively. The adsorption capacity of MB in the aqueous solutions was calculated by using Eq. (1). All isotherm, kinetic and thermodynamic studies were fitted with the experimental data using their linear equations which were shown in Table 2.

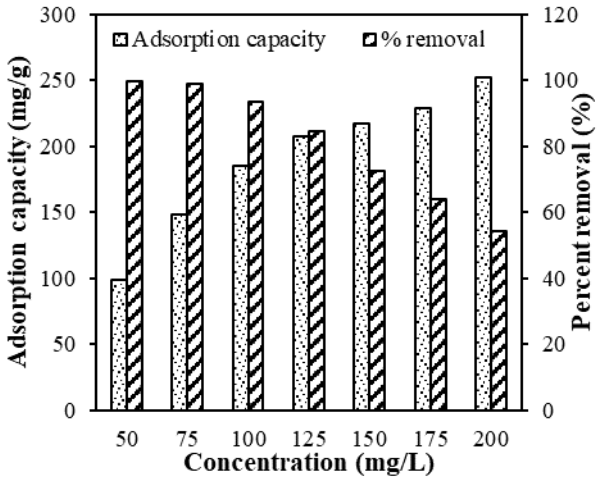
Table 2. The equations of isotherm, kinetic and thermodynamic studies

Parameters	Equation		Nomenclature
Langmuir	$C_e/q_e = 1/K_L q_m + C_e/q_m$; $R_L = 1/(1 + K_L C_o)$	(3)	q_e = amount adsorbate quilibrium (mg/g) q_t = amount adsorbate retained at time (mg/g) q_m = monolayer adsorption capacity (mg/g) t = time (min) k_1 = PFO rate constant (1/min) k_2 = PSO rate constant (g/mg.min) k_{ID} = IPD rate constant (mg/g/min$^{0.5}$) C_i = thickness of the boundary layer (mg/g)
Freundlich	$\ln(q_e) = \ln(K_F) + 1/n \ln(C_e)$	(4)	
Temkin	$q_e = B \ln(K_T) + B \ln(C_e)$; $B = RT/b_T$	(5)	
Dubinin-Radushkevich	$\ln(q_e) = \ln(q_s) - \beta\varepsilon^2$; $\varepsilon = RT \ln[1 + 1/C_e]$; $E = 1/\sqrt{2\beta}$	(6)	
Pseudo first order (PFO)	$\ln(q_e - q_t) = \ln(q_e) - k_1 t$	(7)	
Pseudo second order (PSO)	$t/q_t = (1/k_2 q_e^2) + (1/q_e)t$	(8)	
Intraparticle diffusion (IPD)	$q_t = k_{ID} t^{0.5} + C_i$	(9)	
Thermodynamic	$\ln K_D = -\Delta G°/RT$; $\ln K_D = (\Delta S°/R) - (\Delta H°/RT)$; $\Delta G° = \Delta H° - T\Delta S°$	(10)	



Results and Discussion

Effect of adsorption parameters on MB removal



In this study, the preliminary experiments to explore the effect of several adsorption parameters were done by batch adsorption technique. For batch adsorption, the BTAC is mixed with the MB solution in an agitated vessel for specific time. The effects of adsorbent dosage, initial concentration, contact time and solution pH on adsorption efficiency were presented and described in the following subsections.

Effect of adsorbent dosage

Adsorbent dosage is an important parameter that affects the adsorption performance. This parameter is essential to observe the maximum adsorption with the minimum promising amount of adsorbent [25]. The effect of adsorbent dosage was studied by added different adsorbent dosage (0.01 to 0.13 g) into 100 mL of 150 mg/L MB concentrations under. Figure 1(a) shows the adsorption capacity and percentage removal of MB as a function of the BTAC dose. Adsorption capacity and percent removal of MB increased sharply as the BTAC dose increased from 0.01 to 0.05 g. However, an opposite trend was observed with the additional increased of BTAC dosage beyond 0.05 g. It was noticed that the adsorption capacity of MB start to reduce gradually from 224 to 115 mg/g. Similar trend reduction of adsorption capacity with additional increased in adsorbent dosage were observed by Xue, et al. [19], Muniyandi, et al. [10] and Fan, et al. [26]. While the percentage removal was further increased and reached approximately 100% and did not show any significant MB removal as the BTAC dosage beyond 0.09 g. The opposite relationship between adsorbent dosage and removal of the MB was explained by the existence of a greater number of available sorption sites on adsorbent surface as described by Saif Ur Rehman, et al. [27]. They claimed that the concentration of adsorbate is fixed against an increasing adsorbent dose. Thus, the MB per unit mass of BTAC decreased leaving a number of active sites uncovered at high dosage, subsequently leads to a low adsorption capacity. Hence, considering minimal dosage with the highest adsorption capacity, 0.05 g BTAC dosage was selected as the optimum adsorbent dosage and used for subsequent experiments to study the influence of initial concentration, contact time and solution pH.

(a)

(b)

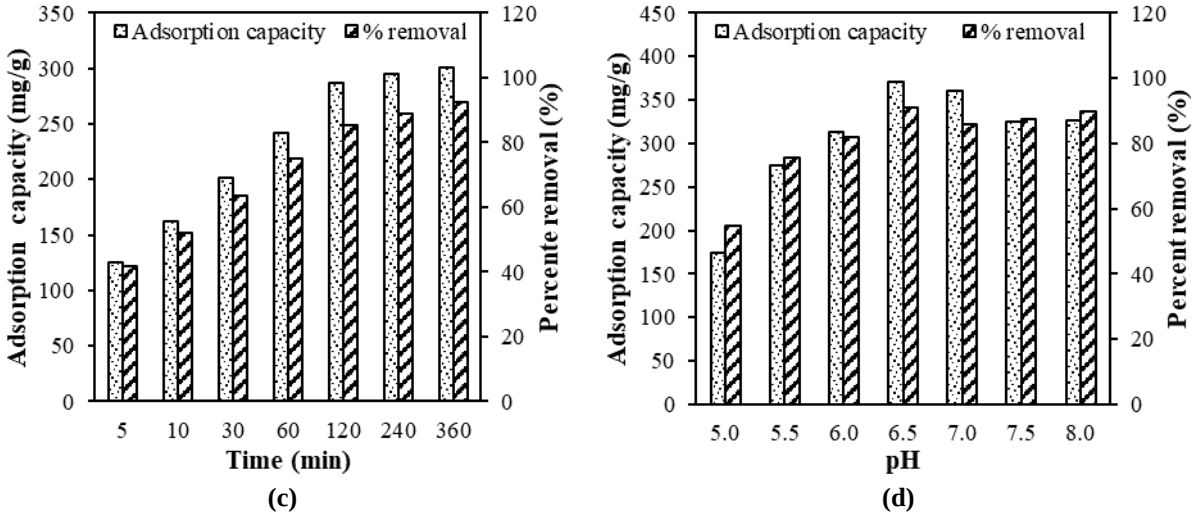


Figure 1. (a) effect of adsorbent dosage (b) effect of initial concentration, (c) effect of contact time and (d) effect of solution pH on the adsorption of MB dye

Effect of initial adsorbate concentration

Initial adsorbate concentration is another important parameter for adsorption study. Figure 1(b) shows an opposite trend of the adsorption capacity and percentage removal of MB as a function of initial MB concentration. Similar observation was reported previously for MB removal by using different type of adsorbent including modified lignocellulosic materials [28]. As per Figure 1(b), the adsorption capacity increased from 98 to 252 mg/g when the initial MB concentration increased from 50 to 200 mg/L. Higher adsorption capacity at high initial concentration is due to the generation of significant driving forces caused by a pressure gradient as explained by Benhouria et al. [29]. However, the percent MB removal gradually decreased from 99 to 54% for a similar increase in MB concentration. This observation related to the at low concentration [30]. This results clearly indicated that the adsorption process is highly dependent on the initial concentration of the solution. Based on the results, MB concentration of 125 mg/L was selected as an optimum concentration as the adsorption capacity was 207 mg/L with the percent removal of 83%, located in the middle of the graph. Thus, this initial concentration was adopted for the next experiment.

Effect of contact time

The influence of contact time (5 to 360 min) on adsorption capacity and MB percent removal is presented in Figure 1(c). Both adsorption capacity and percent removal increased as the function of contact time. When the contact time was approximately 360 min (6 h), the adsorption efficiency reached 92% with 301 mg/g adsorption capacity. It was noticed that the adsorptive removal of MB underwent two stages. During the first stage (within 60 min), the adsorption of MB increased quickly, followed by a slow adsorption stage during which adsorption capacity increased gradually. No further changed observed after 360 min which can be related to adsorption process reached the state of adsorbent–adsorbate equilibrium. This findings suggesting that high attraction existed between MB and the surface of the BTAC and the MB adsorption occurred mainly on the surface at the beginning as described by Li et al. [31]. However, with further extended the contact time, limited surface-active sites were accessible. Therefore, only a minor increase in the adsorption capacity and MB percent removal were observed and this finding mostly due to internal surface adsorption Maneerung et al. [32]. This finding suggested that significant contact time was needed for the adsorbate to diffuse into adsorption sites surface and internal pores of the adsorbent as mentioned by

Jawad et al. [33]. As no further improvement in term of adsorption capacity and MB percent removal were noticed after 360 min, therefore it was determined as an equilibrium contact time between MB and BTAC and was used as a contact time for isotherm study.

Effect of solution pH

The effect of pH on the removal of MB has been investigated. Solution pH was a key factor affecting ionic dyes (anionic or cationic) adsorption because the pH primarily influenced the surface charge on the adsorbent [34]. The adsorption experiment of MB onto BTAC was performed in 5.0 to 8.0 pH range, at controlled temperature of 30 °C for 360 min. Figure 1(d) shows the adsorption capacity and removal efficiency of MB by BTAC under different pH. It was notice that the adsorption capacity was lowest at pH 5.0 (174 mg/g) and the maximum adsorption capacity of the dye was achieved at pH 6.5 (371 mg/g). Similar trend was observed for percentage removal of MB. At the lowest pH (at pH 5.0) the MB removal efficiency was less than 60%. It showed that lower pH does not favour the uptake of cationic dye from the system and leads to electrostatic repulsion. This can be explained as dissolving MB in water results in having positively charged ions in the solution, thereby the positively charged surface of the adsorbent tends toward competing with the adsorption of the MB [35]. However, when the pH increased to 6.5, the MB removal efficiency increased up to 91% due to the decrease in electrostatic repulsion between the positively charged MB and the surface of the BTAC. While with further increase of pH to 7.0, removal efficiency reduced to 85% and no significant changes noticed as the pH increased from 7.0 to 8.0. According to Banerjee and Chattopadhyaya [36], change in pH affects the adsorptive process through the dissociation of functional groups on the adsorbent surface that tends to shift in equilibrium characteristics of the adsorption process. The present findings were supported by earlier reteaches who have reported the removal of MB onto waste carpets derived AC [34] and . Thus, the solution pH of 6.5 was selected as the optimum conditions for adsorption of MB on the surface of the investigated adsorbents.

Isotherm study

In order to study the adsorption behavior of MB in detail, the data for equilibrium adsorption isotherms were fitted into several isotherm models such as Langmuir, Freundlich, Temkin and Dubinin-Raduskevich. The parameters obtained in the isotherm equation and a determination coefficient (R^2) were listed in Table 3. According to the linear regression (R^2) analysis method, it was observed that the values of the correlation coefficients were slightly high (≥ 0.9300). Thus, it showed that the results fit these four models very well. Based on the value of R^2, the Langmuir isotherm model was the best fit with the adsorption equilibrium data with R^2=0.9998. However, according to Misran et al. [2], R^2 is not adequate to depict the applicability of the models to the experimental data. Hence, a comparison was exhibited between the calculated adsorption capacities at equilibrium (q_e) from the applied models and the experimental values. Further analysis of the isotherm data based on root-mean-square error (RMSE) and chi-square (χ^2) analysis showed that the Temkin isotherm model given the lowest values for RMSE and χ^2 analyses. Therefore, Temkin isotherm model was selected as the best fits with the adsorption of MB onto BTAC since it demonstrates better agreement with the experimental data.

Based on the Langmuir isotherm model on the linear Eq. (3), the isotherm parameters, K_L and maximum adsorption capacity, q_m can be determined from the slope of the plot C_e/q_e vs. C_e. In the conditions studied, the maximum adsorption capacity at monolayer coverage (q_m) was 217.4 mg/g. While the calculated R_L values for the selected range of concentration studied were in the range of 0.0045 to 0.0133. These values were greater than zero showing favorable adsorption of MB onto BTAC. Previous study, Ezechi et al. [37] and Fan et al. [26] claimed that for favorable adsorption, $0 < R_L < 1$; unfavorable adsorption, $R_L > 1$; linear adsorption, $R_L = 1$; and adsorption process is irreversible if $R_L = 0$. For the Freundlich isotherm model, the values of n and K_F can be calculated from the plot of ln q_e vs. ln C_e using Eq. (4). Based on the equation, the values of n and K_F were 6.9396 and 134.8

L/g, respectively, with R^2 =0.9797. Temkin isotherm represents the quantity of heat needed for the adsorption by one layer of adsorbate on the surface of the adsorbent [38]. Temkin isotherm constants were determined from the slope and intercept from the plot q_e vs. ln C_e based on the linear Eq. (5). The value of the Temkin constant (B) was calculated to be 22.13 J/mol. The value of B was greater than 1 indicates an exothermic process [39]. While b_T and K_T were calculated to be 111.9 mg/L and 569.2 L/g, respectively. The positive value of b_T proved that the adsorption process was exothermic [35]. Ahmad et al. [40] also observed comparable results for the adsorption study of synthetic dyes removal using pomegranate peel AC. The Dubinin-Radushkevich adsorption isotherm is generally applied to express the adsorption mechanism with a Gaussian energy distribution onto a heterogeneous surface. Based on the Eq. (6), the theoretical saturation adsorption capacity (q_s) and k_{ad} values were calculated to be 172.2 mg/g and 4×10^{-8} mol^2/J^2, respectively. While the value of adsorption energy (E) was determined as 3.53 kJ/mol. The value of E was noticed less than 8 kJ/mol implying that removal of MB by BTAC involves physical adsorption as reported by Xue, et al. [19]. Magnitude of E is useful for estimating the mechanism of the adsorption reaction [38]. Based on the result, it can be concluded that strong physical interactions are the driving force of MB adsorption onto BTAC, an assumption supported as well by the great value of saturation adsorption capacity.

The q_m value of MB onto BTAC was then compared with the adsorption capacities of ACs as prepared by various agriculture waste as listed in Table 4. This comparison data clarified that the BTAC is a highly effective adsorbent due to its high surface area and good adsorption capacity for MB dye removal from aqueous solution.

Table 3. Langmuir, Freundlich, Temkin and Dubinin–Radushkevich constants for MB adsorption

Langmuir		**Freundlich**		**Temkin**		**Dubinin-Radushkevich**	
q_m (mg/g)	217.4	n	6.9396	B (J/mol)	22.13	q_s (mg/g)	197.2

Kinetic study

In this study, pseudo-first order (PFO) and pseudo-second order (PSO) were used to examine the experimental adsorption data, such as the examination of the controlling mechanisms of the adsorption process (chemical reaction, diffusion control, and mass transfer). The parameter data of the PFO and PSO can be determined from the slope and intercept of plot ln ($q_e - q_t$) against t and plot t/q_t against t by the linear Eq. (7) and (8), respectively. The parameters obtained in the PFO and PSO equations, together with their R^2 and $q_{e,cal}$ is listed in Table 3. It was found that the plots ln ($q_e - q_t$) against t (Figure 2(a)) give a less linear relationship and subsequently contribute to the low R^2 values. In addition, the experimental and calculated values of q_e showed a significant difference. These results indicate that the experimental data do not agree with PFO kinetic model.

On the other hand, plot t/q_t against t (Figure 2(b)) showed a linear relationship. The R^2 value (~0.999) for the PSO kinetic model was relatively higher than the PFO. Moreover, the $q_{e,cal}$ values derived from the PSO model were slightly close to the $q_{e,exp}$ value. Thus, these results suggest that the PSO model provided a good correlation for the adsorption of MB onto BTAC. Most previous studies also report PSO kinetics for adsorption, such as the adsorption of MB onto forest wastes [15], methyl orange onto pumpkin seed powder [43], and adsorption of reactive orange by iron oxide nanospheres [44]. The PSO kinetic model also verified that the chemisorption was the rate-controlling step over the whole adsorption process [45].

The IPD model was also tested because the PFO and PSO kinetic models cannot identify a diffusion mechanism [46]. Intraparticle models parameters (k_{ID} and C) were calculated from the slope and intercept of plot q_t vs. $t^{1/2}$ and summarized in Table 5. As shown in Figure 2(c), plots of q_t vs. $t^{1/2}$ present multi-linearity, thus indicating that more than one step occurs during the adsorption of MB onto BTAC. Similar patterns have also been obtained by Kumar and Jena [42] and Bedin et al. [47] . According to Shin and Kim [46], the first portion is the fast adsorption or external surface adsorption stage, where adsorbate (MB molecules) migrates through the solution to the exterior surface of the adsorbent (BTAC) particles (Stage I). This portion was attributed to bulk diffusion. The second portion is the gradual adsorption stage, where MB molecules move within the particles (Stage II). This portion is due to intraparticle diffusion. The third portion is the final equilibrium stage, where the MB molecules are adsorbed at sites on the interior surface of BTAC (Stage III). Moreover, the observed multi-linearity also suggests that intraparticle diffusion is not the rate-limiting step [48]. It was observed from Table 5, the value of k_{ID1} and k_{ID2} increase with increasing MB concentration from 75 to 125 mg/L. In addition, at constant MB concentration, the values of k_{ID1} were found larger than k_{ID2}. In other words, the adsorption was rapidly at the initial stage and became slower beyond this stage and no more adsorption occurred when achieving the equilibrium. The magnitude in the C_1 pattern with the changes of adsorbate concentrations was not clearly observed. However, at the second stage, C_2 values were noticed to decrease as the adsorbate concentration increase. The reason behind this due that higher adsorbent dosage will weaker the boundary layer effect.

Thermodynamic study

The slope and the intercept of the plots of ln K_D versus 1/T using the Van't Hoff plot (figure not shown) are used to determine the ΔH° and ΔS° values. From the values of ΔH° and ΔS°, ΔG° can be calculated using Eq. 10. According to the data presented in Table 6, Gibbs free energy (ΔG°) values for MB were in between -25.83 and -26.34 kJ/mol as the temperature rose from 25 to 40 °C. These negative ΔG° values indicate that spontaneous sorption takes place. In addition, the value of ΔG° was observed to increase (less negative) with decreasing temperature, suggesting rapid and more spontaneous adsorption at lower temperatures. In addition, the calculated ΔH° value was -15.57 kJ/mol. The negative value of ΔH° for the adsorption process indicates that the adsorption was an exothermic process [15]. Furthermore, these results indicate weak attraction forces between the adsorbate and the BTAC. The low value of ΔH° (less than 40 kJ/mol) implies loose bonding between the adsorbate molecules and the adsorbent surface. In the case of entropy (ΔS°), it was found to be 33.87 J/mol.K. The positive value of ΔS° resulted from the increased randomness due to the adsorption of MB, which suggested good affinity of the solute molecules toward the BTAC and increased randomness at the solid-solution interface during the fixation of MB molecules on the active site of the BTAC. A similar finding was also reported by Alver et al. [12] for the adsorption of methylene blue on magnetic alginate/rice husk bio-composite.

Table 6. Thermodynamic study for adsorption of MB

Temperature °C	k_{ad} (L/g)	ΔG° (kJ/mol)	ΔH° (kJ/mol)	ΔS° (J/mol.K)
25	28.48	-25.83	-15.57	33.87
30	25.51	-26.00		
35	23.54	-26.17		
40	21.16	-26.34		

Conclusion

The present investigation revealed that BTAC is a promising adsorbent to remove MB from aqueous solutions. The equilibrium data fitted well to Langmuir, Freundlich, Temkin and Dubinin-Radushkevich isotherm models. Based on error analysis study via RMSE and χ^2 analyses, Temkin isotherm model was the best fitted with the adsorption of MB on BTAC. Maximum monolayer adsorption based on Langmuir was calculated to be 217.4 mg/g. Thermodynamic parameters such as free energy changes (ΔG°), enthalpy (ΔH°) and entropy (ΔS°) were evaluated between temperatures of 25 °C and 40 °C. The ΔG° was noticed progressively decrease from -25.83 to -26.34 kJ/mol as the temperature increase. The ΔH° and ΔS° values were found to be -15.57 kJ/mol and 33.87 J/mol.K respectively. The results showed that the overall adsorption process was exothermic and spontaneous. The findings from this study suggested that BTAC could be a viable adsorbent in managing higher dye problems associated with textiles industries effluent.

Abstract

This review explores the contributions of natural resources with diverse disciplines which offers the insights into the design of greener chemical analysis. The discussion was focused on the published works in our group where a diverse range of natural reagents used in the determination of various environmental analytes has been highlighted, aiming to discuss the initiatives and applicability of the usage of alternative natural reagents and substitute synthetic methods in optimizing analytical processes, which in turn would lead to cost-effective and time-efficient in handling analytes assay. By exploring the potential of natural reagents, the sustainability in green chemical analysis could be promised in coming near future, especially in convincing for the talent and challenge for ASEAN in this new normal chemical analysis.

Keywords: green analytical chemistry, natural reagent, natural material, local wisdom, sustainable chemistry

Abstrak

Ulasan ini membincangkan sumbangan reagen semula jadi dalam pelbagai disiplin ilmu yang dapat memberikan gambaran mengenai analisis kimia hijau. Perbincangan in fokus kepada penerbitan yang telah diterbitkan oleh kumpulan kami di mana beberapa jenis reagen semula jadi yang digunakan dalam penentuan pelbagai analit persekitaran akan diutamakan, bagi membincangkan inisiatif dan penerapan penggunaan reagen semulajadi alternatif dan kaedah sintetik gantian dalam mengoptimumkan proses analisis, supaya analisis dapat dikendalikan secara kos efektif dan cekap masa. Dengan menerokai potensi reagen semula jadi, kesinambungan dalam analisis kimia hijau akan dapat dijanjikan dalam masa terdekat terutamanya dapat memberikan keyakinan dalam bakat dan cabaran di ASEAN dari segi analisis kimia di norma baru ini.

Kata kunci: kimia analisis hijau, reagen semula jadi, bahan semula jadi, kebijaksaan tempatan, kimia kelestarian

Introduction

Green chemistry concept was first devised in the early of 1990s, which is practically about 30 years ago [1, 2]. This concept is laid on the foundation of twelve principles for green chemistry which can be described as ecological approaches in molecules and materials making, reactions, and processes that are meant to provide a safer human health with the effort in minimizing or removing the use and production of harmful constituents. Evolving from here, green analytical chemistry has adopted the green chemistry's twelve principles to focus on the development of analytical methodologies and techniques with greater commitment in preservation of the environment and safety of operators. These two concepts, the green chemistry, and the green analytical chemistry, are closely associated with sustainable chemistry, which is the scientific notion that strive for efficiency improvement in natural resources utilization as to fulfill the human needs and requirement for chemical products and services. Sustainable chemistry encompasses the design, manufacture and use of efficient, effective, and more environmentally benign and friendly on chemical products and processes. This also serves the United Nations Sustainable Development Goals (UN SDGs) on the universal call to act in protecting the planet by integrating balance in between development involving social, economic, and environmental sustainability [3].

Having said that, a global consensus on how to assess and appraise the greenness of an analytical method has not yet been achieved, but several green metric tools have been proposed towards this goal [4]. Apart from the development in experimental techniques and instrumentation designs, which both are crucial for quality improvements in chemical analyses; efforts and attempts are being made to reduce or minimizing the undesirable impact of chemical analyses on the environment, and to enable sustainable development principles being embedded and implemented within analytical laboratories. As shown in Figure 1, the current trend in analytical practices is depending on high-performance instruments which emphasize on sensitivity, selectivity, and precision. Such laboratory design and set-up always required skillful human resource, and utilize enormous amounts of chemicals, solvents, as well as energy [5]. The similar practice was applied in almost all academia institutions in developed countries as well as for the laboratories setting in industry, where most of them rely on high-end instruments to generate most of the analytical information which applicable for process control, or environmental conditions assessment and evaluation [6]. Nevertheless, despite the capability of such designed-laboratories, there is an urgent need for simple indicator-type sensors in market that able to offer adequate precision and specificity, easy to handle thus do not require trained personnel, and while during operation, little or no waste generation thanks to volume minimization, which in return consume negligible amounts of energy or none, and still capable to obtain chemical information from the point-of-care, including on-site process analysis for the widest use. Such sensor characteristics would also link to cost-effective operation.

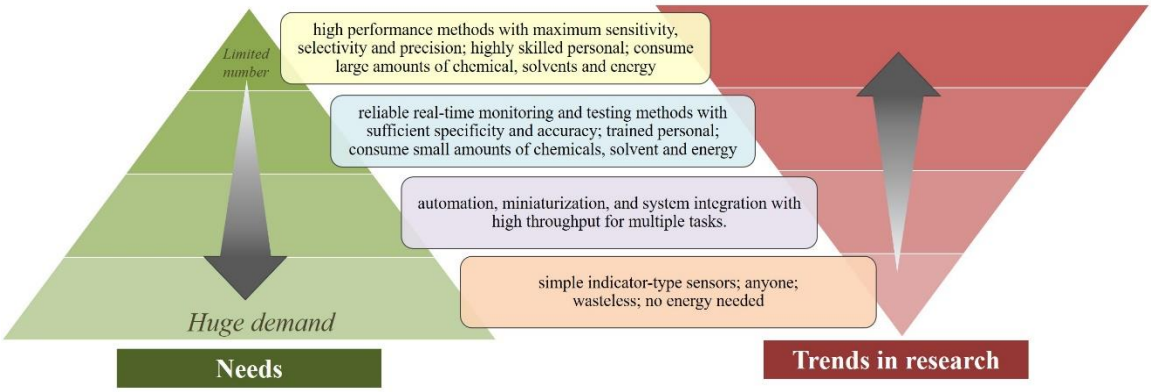

Figure 1. Comparison of the needs and trends in analytical chemistry. Reproduced with adaptation from [5]

Thus, one of the purposes of green analytical chemistry is to discover alternative reagents or substitutive synthetic methods which can reduce or minimize the usage of hazardous or poisonous chemicals. This suggestion may at first seem to be counteract to one of the best adhered principles of analytical chemistry, in which typically reagents of the highest purity grade are accounted for minimization of reagent blanks and impurities interferences. Nevertheless, in some cases there may be the possibility in replacing or substituting this highly purified reagents (which contributing to the costing in analysis) without compromising or bargaining the success of the assay determination. Under the typical condition of analytical experiments, a reagent is normally required in a small amount, or a crude extract which contains the essential active reagent are sufficient to get the analysis done. This is where the use of such natural reagents is highly desirable attributed to its simplicity in their preparation as well as the inherent or zero energy and chemical waste prevention. The ASEAN countries including Thailand and Malaysia are rich in natural resources. Utilizing a variety of natural resources existing in this region for health, chemicals, nutrient tests, and as natural dyes have been exercised as one of local wisdoms. Such wisdoms have long been employed in local peoples for improvement of life quality, for example using the fermented tea leaf like *Miang* as health supplement and snacks [7], which in return becomes the major source of income and tourism activities for one of the village in northern Thailand. Natural dyeing craftsmanship in textile industry has been kept alive thanks to discovery of various extracts from local plant such as mangosteen tree (*Garcinia dulcis*) [8] which offers bright yellow color, indigo leaves (*Indigofera tinctoria*) which contributes the blue color and coconut barks which attributed to pinkish brown color [9]. A team of chemists, focusing on the development of green chemical analysis techniques, has adapted the wisdoms in modern chemical analyses. In many parts of Thailand alone, there has been some regional handling of guava leaves as the sign or as an indicator towards the presence of iron in ground water. The appearance of darker color of water upon contacts with the guava leaves helps local villagers in making some decisions (or "screening test", as for today term), such as whether the water is suitable for cloth washing, due to the strain that tends to deposited on the cloth, attributed to the iron presence in the water source; or it can lead to pre-treatment decisions such as applying alum into the ground water prior consumed for drinking or cooking use. This example of local wisdom has never been published nor any scientific explanation is available until Settheeworrarit et al. reported the investigation of natural guava (*Psidium guajava L.*, Myrtaceae family) leaf extract as an alternative natural indicator for quantification of iron using the flow injection technique [10]. This is just one of the many examples which showcase on how the natural resources can work perfectly in applying chemical analysis in such green analytical approach.

From the Scopus database, trends in research works based on keywords "natural reagent" in "chemistry" have shown an increasing pattern as displays in Figure 2. This indicates an encouraging direction among analytical chemist in effort towards green analytical chemistry which adopted natural reagents as the active materials in performing assay testing. It is worth to notice that scientific articles contribution from our group are sharing the similar development. Different examples of the use of natural reagents for derivatization have been published as indicated by the used database. Natural reagents are consisted of extracts from various sources including the vegetables, plant-based, bacteria, or animals that required minimal treatment (extraction process) and among them, natural compounds contained in plants were able to distinguish themselves as the imperative key to green analytical chemistry initiatives.

Herein in this review, we have pin-pointed the published works done on natural reagents and materials, particularly in green analytical chemistry by our group to discuss its scientific potential as part of the ASEAN consortium efforts. The scope of discussion was designed to fortify the geographical advantages in this southern Asia region where each country is sharing the similar bioresources that could be explored further in various scientific exploration as well as collaboration and networking. One of the advantages of the reported works here is that it could help in shorten the needs of screening a vast range of natural compounds, hence open the opportunity to adopt the similar plant species for further exploration. A diverse range of natural reagents used for the determination of various environmental analytes has been highlighted, aiming to critically discussed the initiatives and applicability of the use of such alternative reagents and alternative synthetic methods in optimizing analytical processes, as a way to provide the required information in a manner that is environmentally friendly, prioritize sustainability with the least possible consumption of materials, energy, and generating less or zero waste along the way.

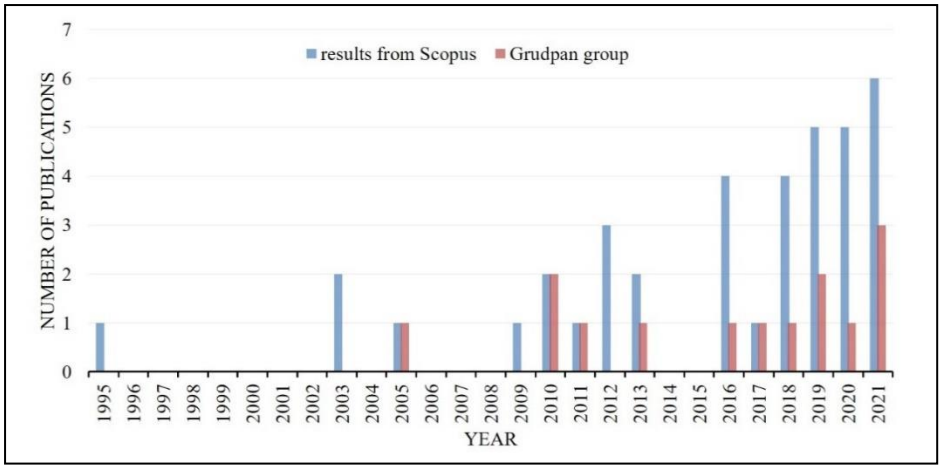

Figure 2. Number of publications obtained from Scopus database using the keywords of "natural reagent" (■) in chemistry and with "Grudpan" (■) (searched on 31 August 2021)

Natural reagents used in chemical analysis

Table 1 represents some natural reagents extracts which can be found in plants that grew in ASEAN countries. The tropical forests in this region offer a unique natural heritage which has been evolved for over a hundred million years, resulting in rich flora and fauna with spectacular biodiversity. Currently, these are in much demand due to their efficacy, safety, and minimal side effects. Sample treatment which involves both the extraction of the analytes and the purification of the sample extract obtained, is still considered the bottleneck of the entire analytical procedure, despite

much progress on automation and miniaturization has been accomplished. It is still the most labor-intensive and time-consuming analytical step, accounting for 60–80% of the total analysis time. These steps can affect both, the accuracy and precision, and green analytical features of analytical methods. Extraction of plant materials can be done by various conventional and nonconventional extraction procedures including maceration, infusion, percolation, digestion, decoction, Soxhlet extraction, ultrasound-assisted extraction, turbo-extraction, countercurrent extraction, microwave-assisted extraction, ultrasound extraction, supercritical fluid extraction, solid-phase extraction, and column chromatography. Considering the aforementioned information, it is easy to imagine that substantial efforts have been made in recent years to simplify the overall sample preparation steps and to tailor it to the green analytical chemistry principles. Major efforts of scientists have been devoted to miniaturization of the extraction device; development of new sorbent materials with advanced properties; reduction and replacement or elimination of toxic and hazardous organic solvents; reduction of sample volume and extraction time, and maximizing extraction efficiency and selectivity, among others. The natural reagents reported here can be obtained in a greener approach of extraction which only involving the use of water and ethanol as the organic solvent. The extracted chemical species have shelf-life of up for weeks provided with proper storage in fridge, thus allowing repeatability of experiments easily without restriction in chemical stocks.

Based on previous reported works, the chemical species which are active to certain analytes are listed. These active compounds are operating on the principle of colorimetric, where upon interacts with target analyte, the color changes will provide information on types of analytes as well as its concentration range, by performing the image analyzing via open source (free) color applications such as ImageJ and Color Grab. It should be noticed that for an analyte detection, the coloration visualization may be attributed to presence of different ligands from the reagents active compounds that forming chelation or binding with the analyte itself. This explains the versatility of various active compounds as they may obtain from different plants as of same species or family, yet capable to provide the equal analyte quantification. For instance, the anthocyanins species that active towards acidity measurement, can be obtained from butterfly pea, orchid and beetroot [11, 12]; iron can be quantified using phenolic compounds from green tea and guava leave [13, 14]. It is then of interest to explore which local plants would be use of in each analyte detection. By combining the efforts and intellectual of analytical chemists, natural products expertise, biologist, computational modeling, along with the advantages of ASEAN geographical, many plant species as natural reagents could be explored further. Such strategy one day may offer benefits in the possibility where we would be on self-reliance in using the reagents from the bioresources in our region, and with less dependent from the big chemical companies, thus affording the cost-effective in handling analytes assay; and time-efficiency where chemical delays arise from delivery would no longer be an issue.

Despite the detection limits and linear ranges are probably constrained by higher blank values originating from the reagents themselves, and the limitation of the detection systems used, yet the assay determination in analytical chemistry does not restrict to maximum sensitivity, rather to the applicability towards the targeted detection range. The trend of having high precision and sensitivity which restricted to advance instrument and highly trained personnel is not able to support the demand in analytical testing especially in those resources-limited countries. While most of these examples focus on agricultural, clinical or wastewater samples, which have higher analyte concentrations, the use of natural reagents for trace analytical purposes, e.g., in environmental waters, are possible to accomplish when the enhanced analytical control of flow injection-based or sequential injection analysis is utilized in combination with intrinsically sensitive detection methods such as chemiluminescence. Thus, when applied with recognition of their limitations, natural reagents, especially when used in combination with flow-based systems, can offer an alternative approach to sustainable and greener analytical measurement.

Table 1. Natural regents obtained from plants used in chemical analysis

Analyte	Active Species	Common Name	Scientific Name	Ref.	Photo of the Plant	Availability
Acidity and iron	Anthocyanins	Butterfly pea flower	*Clitoria ternatea* L.	[11]		Introduced into: Cambodia, Laos, Myanmar, Thailand, Vietnam, Brunei Darussalam, Philippines, Singapore, Indonesia, commercial hybrid
	Anthocyanins	Orchid flower	*Dendrobium* Sonia			Commercial hybrid
	Anthocyanins	Beet root	*Beta vulgaris subsp. Vulgaris*			Introduced into: Vietnam, Thailand

Natural reagents for green analytical procedures

Pertaining to the effective experimental measurement stage, greener analytical procedures and experimental setup are inherent to automated flow-based instrument setup, owing to their capability in reducing the consumption and needs of reagent and solvent and to the possibility of incorporating decontamination of wastes on-line. The development of flow-analysis-based techniques best suited in realizing such ideology. The flow analysis approach offers a feasible means of employing natural reagents for green chemical analysis.

Guava leaf extract is one of the widely studied natural reagent where its chemical compounds may serve as whitening essence, anti-bacterial, anti-pigmentation, and in diabetes prevention. Besides, guava leaf extract is an alternative natural compound used to identify ferrous (Fe^{2+}) metal through flow injection method. In one of the reported works by Hartwell and her co-workers, by using a simple flow injection system, the scientific explanation behind the use of guava leaf extract as an alternative reagent to quantify iron(II) in water samples has been revealed. Chemical and physical properties of the extract, including its stability and ability to form chelation complexes with iron(II) and (III), respectively, spectroscopic characteristics, the appropriate solvent medium used for extraction, and its potential to be used for quantification of iron in water samples were tabulated in detail. Minimization on guava leaf extract consumption was achieved via using the modified reverse flow injection manifold with two lines, where the reagent was injected into the buffer solution which was later mixed with the flow of sample solution. Such in-situ design displayed a better sensitivity and detection limit as compared to the conventional flow system. This is presumably attributed to higher amount and a concentrated iron solution are being introduced via pumping as compared to injection along the line. [10]

Some of the works discussed as follows, although were not registered in the above search (Table 1), they engaged with the deployment of natural reagent. A simple simultaneous quantification of two metals-iron and manganese in ground water via sequential injection spectrophotometry was reported by utilizing the astilbin crude which extracted from *Smilax china L. root*. This natural reagent can be found easily in one of those common plants that grown in many tropics and subtropics worldwide. The extraction was done with methanol solvent at room temperature and the solid astilbin was obtained after evaporation and recrystallization steps. By dissolving the natural reagent with buffer solution, the mixtures were sequentially aspirated into the holding coil and the reactions with iron(III), manganese(II) and astilbin which took place in the flow cell was monitored by measuring absorbance change at the visible light wavelength. The applicability and simplicity setup which demonstrated in this work indicates that the proposed system and the easily obtained reagent are useful for ground water analysis. [23].

A simple and cost-effective analytical device for determination of ammonia which based on gas pervaporation and diffusion method is proposed [24]. This user-friendly device is consisted of a well microplate as a donor chamber and the butterfly pea flower extract was applied as natural indicator. The

butterfly pea flower which having an intense blue color flower is easily grown in the ASEAN region. In this reported work, the flower extract was immobilized on the paper as the acceptor sensor. The anthocyanin color pigments from this flower extract are strongly influenced by the degree of acidity upon contact which changed the structure of the pigment and displaying color changes accordingly to different pH values. Using the reagent immobilization method on paper allows the microliter-scale solution handling. Such principle can reduce the consumption of reagent and the analyte itself. On the reported work, the sample preparation started by converting the ammonium ion into ammonia by using the solution in alkalinity range. The next procedure is allowing the ammonia gas pervaporation and diffusion across the PTFE membrane into the natural indicator which has been pre-immobilized on the filter paper. The colorimetric change (color appearance) on the paper was then detected by either a smartphone camera or naked eye which offer the quantitative or semi-quantitative analysis, respectively. Such simple paper sensor was successfully applied for real samples in ammonia detection that are widely found in the swine farming wastewater and chemical fertilizer samples. On top of that, the developed ammonia sensor could concurrently perform triplicate runs of 18 samples in just 15 minutes, which in return can generate 72 samples in one-hour timeframe. This proposed device with pervaporation and diffusion method offers on-site assay and green chemical analysis with relatively high throughput while at the same time display the example of cost-efficiency.

Several extracts from natural sources- vegetables and plant-based, namely carrots, leaves and flowers of peacock plants (*Caesalpinia pulcherrima*) were acquired through maceration and boiling procedures by using ethanol and water as solvents. Such extracts are being tested to detect lead(II), the poison heavy metal which mainly found in agriculture or industrial ecosystem. After performing the screening using the reagents which have been prepared, the researchers from Indonesia discovered those which can form complexes between ligand compounds of plant extract with lead(II), via the observation of color change, were only the flowers of the peacock plant (*Caesalpinia pulcherrima*). As such, the sequential injection analysis (SIA) system for determination of lead(II) in this work by employing the peacock flower extract as the natural reagent was developed. The discovery of using such natural reagent offers the advantages, once again, cost-effective and feasibility due to the easily available plant itself, inexpensive experimental setup, environmentally friendly, and the reagent can form the stable complex with the target lead ion [25].

In the recent published work, phenolic species of the guava leaf extract was used as natural reagent which responsible for chelation with the ferrous metal ions and leads to color formation. Such observation serves as a detection tool for the small and portable paper-based analytical devices (PADs) which can operate without any complicate supporting equipment, thus it is well-suited for point of care applications in places especially where budget is limited. The novel PAD reported here has been fabricated using a home-based printer with the design that able to complete replication test of iron analysis via a single run which in turn offers the versatility of having standards for calibration and duplicate or triplicate of sample analysis; concurrently under one analysis. Calibration plot in the concentration range from 0 to 20 ppm iron(III) was plotted based on the gray color intensity against iron concentration [26].

Natural materials used in chemical analysis

Various natural materials have been proposed for the use in chemical analysis, as represented in Table 2. They serve as platforms in colorimetric assays, in combining with the use of information technology (IT) devices including smartphone, webcam camera, and scanner, or via naked eyes, to perform the images analysis as the mode of detection. Such arrangements offer the benefits, such as easily accessible to local available materials, biodegradable, portable in terms of smartphones, and with simple fabrication (using home-based printer to complete the process). All the listed pros eventually will lead to cost-effective and user-friendly analytical applications.

Table 2. Natural materials used in chemical analysis

Material	**Analyte**	**Reagent**	**Detection Principle**	**Detection Device**	**Advantages**	**Ref.**
Paper	Ammonium	Alkaline solution and butterfly pea flower extract	Gas pervaporation, diffusion method and acid –base equilibrium	Smartphone	High sample through put, local available materials, biodegradable materials, portable	[24]
Paper and cotton cloth	Acidity	Red maple leaf extract	Acid-base equilibrium	Smartphone	Local available materials, biodegradable materials, portable	[27]
Paper	Iron, phosphate, water hardness	Iron: 1,10-phenanthroline/guava leaf extract phosphate: molybdenum blue water hardness: Eriochrome black T and EDTA	Iron: complex formation reaction phosphate: complex formation reaction water hardness: complexometric titration	Smartphone	Replication analysis of a sample within a single run, local available materials, biodegradable materials, portable	[26]
Cotton thread	Anionic surfactant	Methylene blue	Ion association	Smartphone	Local available materials, biodegradable materials, portable	[28]
Cotton thread	Total phenolic content and antioxidant capacity	Total phenolic content: Folin-ciocalteu antioxidant capacity : 2, 2-diphenyl-1-picryhydrazyl (DPPH)	Redox reaction	Smartphone	Local available materials, biodegradable materials, portable	[29]

Table 2 (cont'd). Natural materials used in chemical analysis

Material	Analyte	Reagent	Detection Principle	Detection Device	Advantages	Ref.
Noodle	Acidity and copper	Acidity: bromothymol blue/ butterfly pea flower extract copper: starch and potassium iodide	Acidity: acid-base equilibrium copper: redox reaction and complex formation	Webcam camera/ scanner	Local available materials, biodegradable materials, self-indicating platform	[18]
Kaolin clay	Acidity	Phenolphthalein/ thymol blue/ butterfly pea flower extract	Acid-base titration	Naked eye	Reusable, local available, materials, biodegradable materials	[12]

Natural reagents with synthetic materials

From the green analytical perspective, new analytical tools can be obtained via modification or combination of conventional molecules with synthetic materials and forming a kind of hybrid system. Such tactics set off a promising strategic way in getting synergistic and additive effect achieved from either the natural reagents or the synthetic materials. In the work reported by Rujiwatra et al., [22] *miang* (*Camellia sinensis var. assamica*) leaves from northern Thailand are being fermented and blended with silver (Ag) nanoparticles (NPs) which can be applied as colorimetric agents for nitrite determination. The working principle behind this work is depends on employing *p*-aminobenzoic acid as aiding reagent, and a camera phone as a detector to capture the color changes upon interaction of Ag-*miang* NPs with the target analyte. As an effort to design the synthesis route become more environmentally benign, crude water extracts of *miang* leaves, which are abundantly available locally throughout the year in two forms, i.e., non-fermented and fermented *miang*, were used as natural reagents. Unique color of AgNPs can be obtained via controlling the morphology and sizes of AgNPs itself. Thus, the Ag-*miang* nanocomposites in turn providing the rapid, simple, and selective tool for the determination of nitrite.

On another reported work by Rujiwatra et al., [30], the team has demonstrated a sustainable way of reducing the waste generation, which in turn offers the potential in minimizing the impact on the environment. Such approach is achieved via the consumption of crude water extract from the ground longan (*Dimocarpus longan Lour*) seeds industry in northern Thailand, which annually discarded in large amount. This untreated wastewater was being used as the natural reagent, serving as the starting material for the green synthesis of ZnO photocatalyst. By using the simple and rapid microwave synthesis, phytochemicals from longan seeds such as flavonoids, catechins, vitamins, proteins, and sugars can be employed as either the capping or reducing agents, or both at same time which driven the ZnO nanoparticles synthesis. Such green synthesis of ZnO nanoparticles can be employed further for wastewater treatment of the local textile dyeing industry and contributing to the circular economy in the region.

Natural reagents in new normal chemistry education

Covid-19 has deeply affected the education sector globally as it forced many schools and colleges to remain closed temporarily. For most science students, their hands-on experience working as a real scientist in school and university laboratory are limited during this lockdown period, whereas in some region, certain students are inaccessible to fully stocked and supported teaching lab owing to limited funding. Despite such scenarios have created many problems; one can harness it as an opportunity for profound changes in our practical education approach that will align our teaching laboratories with those where we conduct our research, by adopting green chemistry principles to the practice of science education lab work. We live in a golden age of easy-to-access instrumentation thanks to smartphones which can be used as detector in chemical analysis. The difficulties of having to set up a measurement almost from scratch, without technicians to prepare equipment and solutions, could help inculcate a spirit of improvisation. By combining these factors, lab-at-home teaching is ready in action. Some of the examples using natural reagents extracted from plants as alternative low-cost tools in teaching chemical analysis, especially in school laboratories that ought to operate within a stiff budget. In some of the universities in Thailand, the ready-to-use natural reagents were introduced in the academic year of 2019 in science and pharmaceutical science courses. They were also employed in lab-at-home sessions and E-workshops. One of the examples was using the natural reagent kit for iron assay in water quality testing which adapted from Thai local wisdom using guava leaves. The kit was equipped with dry guava leaf powder that served as natural reagent in the assay, iron(III) standard and buffer solutions, sample vials, 96-wells microplate as reaction platform and a manual. The camera from smartphone was used as the detector to monitor the difference in color intensity of the reaction product which attributed by the reaction in between iron(III) and phenolic compounds in the natural reagent. Students from six different universities have received the kit via postage during the pandemic lock-down period and had benefits from this lab-at-home practice [31]. The initiative of using modern green chemical analysis in the online classroom setting received great feedback from teachers and learners as the chemicals involved utilized locally available bioresource as the natural reagent for green analysis in chemistry education which supports the sustainable education in Thailand. The method is now being employed by an increasing number of institutions. The team has demonstrated that their experience in conducting this green analytical research can be incorporated into the new normal style of teaching [32].

Challenges in natural reagents application

Natural reagents hold great promise for addressing global humanitarian needs including the goals of sustainable development. The sources of natural reagents and their applications are numerous, yet they are still largely an untapped resource. Use of natural reagents as a source of greener and cheaper reagents for a range of analytical tasks should not be seen as an option just for the developing world, but as something that is equally applicable worldwide. Opportunity should be valued when a natural reagent can be legitimately substituted for a purified or synthetic material, without compromising the viability or quality of the analytical process. Despite not explored here, there is also great potential to utilize food grade or domestic chemicals in a range of analytical procedures, again without prejudice to analytical quality. However, most current developments are not immediately translatable to outside-the-lab scenarios which differ in terms of resource-accessible and resource-limited aspects. Resource-accessible settings include scenarios whereby technology is deployed with essentially unlimited access to resources and experienced personnel. Resource-limited settings refer to situations marked by limited or no access to resources and expertise, which unfortunately most part of ASEAN fall in this category. Such challenges necessitate the time constraints in accessing commercially available chemicals especially when dealing with the long duration of waiting period for procurement. The increasing prices of reagent grade chemicals may restrict the accessibility as well. For instance, when students extract an indicator from plant tissue, and applied in an acid base titration or extracting the acid phosphatase from potatoes and used in the study of

enzyme behavior and kinetics, costing of such experiments can be varied by 30 times as compared to procuring of 50 units acid phosphatase from a major US supplier which costs about $60 dollar with ca. $2 for a sack of potatoes. Students studying such fundamental analytical and biochemical behavior would gain an appreciation for the important role of natural product chemistry.

Conclusion

This mini review discusses the simple natural reagents and natural materials which were developed from a century-old local knowledge in the rural area, and through the combining with today technology, such phenomenon contributes to green chemistry, principally in green analytical chemistry aspect, leading to sustainable chemistry which could serves many goals of the United Nation Sustainable Development Goals (UN SDGs). Research of such direction has gained of interest as indicated by the increasing trends in publications. ASEAN is rich in bioresources, there are talent and challenges in development of utilizing natural reagents and natural materials for chemical analysis in new normal chemical analysis. To meet the talent and challenge, works across disciplines with networking would enhance the targets. Apart from analytical scientists, researchers in the other fields including, natural product, computational chemistry, chemometrics, other fields of chemistry, computer scientists etc. should work together. The work would reflect: Local issue- Global impact- Sustainable world.

Abstract

Christia vespertilionis (L. f.) Bakh. f. is well-known for treating various contagious diseases. This plant has been recognised among researchers and locals to have anti-inflammatory properties and has thus become popular for treating cancer. Two types of *C. vespertilionis* are acknowledged which are green and red. The green *C. vespertilionis* has been widely studied by many researchers, however just a few have studied the red type. This study was carried out to optimise the extraction method of red *C. vespertilionis* leaves by different extraction techniques (maceration and Soxhlet extraction) and solvents (methanol and ethanol) to yield bioactive phytochemicals using gas chromatography-mass spectrometry (GC-MS). The components were identified through GC-MS via comparisons as guided by the National Institute of Standards and Technology Mass Spectral Library 2011 (NIST 11, version 2.0g). According to the four (4) samples of red *C. vespertilionis* leaves using maceration of methanol (RMM), maceration of ethanol (RME), Soxhlet extraction of methanol (RSM), and Soxhlet extraction of ethanol (RSE), seventy-one (71) bioactive phytochemicals were identified. Eleven (11) major bioactive phytochemicals (abundance of > 4%) were identified namely, acetic acid, butyl ester; 1-butanol, 3-methyl-, acetate; heptanoic acid, propyl ester; hexanoic acid, 3-oxo-, ethyl ester; phenol, 3,5-bis(1,1-dimethylethyl)-; 1-octadecene; 4-O-methylmannose; .alpha.-d-mannofuranoside, methyl; 2-undecene, 9-methyl-, (E)-; n-hexadecanoic acid; and 1-octadecanol. Only seven (7) out of eleven (11) compounds were reported to have biological activities. Among those samples, RSM was the most effective using correlation coefficient between abundance (%) and retention time (minute(s)) with a significant difference at $P < 0.05$.

Keywords: *Christia vespertilionis*, gas chromatography-mass spectrometry, phytochemicals, maceration, Soxhlet extraction

Abstrak

Christia vespertilionis (L. f.) Bakh. f. dikenali secara meluas dalam merawat pelbagai penyakit berjangkit. Tumbuhan ini diakui di kalangan penyelidik dan penduduk tempatan tentang kelebihannya sebagai salah satu ubat tradisional yang mempunyai sifat

anti-radang serta digunakan secara meluas dalam merawat barah. Terdapat dua jenis *C. vespertilionis* iaitu jenis hijau dan merah. *C. vespertilionis* hijau telah banyak dikaji oleh penyelidik dan hanya sedikit yang dikaji untuk jenis merah. Kajian ini dijalankan untuk mengoptimumkan kaedah pengekstrakan daun *C. vespertilionis* merah dengan teknik pengekstrakan yang berbeza (pengekstrakan maserasi dan Soxhlet) dan pelarut (metanol dan etanol) untuk menentukan fitokimia bioaktif melalui kromatografi gas-spektrometri jisim (GC-MS). Komponen tersebut dikenal pasti melalui GC-MS dengan membuat perbandingan dari data rujukan Institut Piawaian dan Teknologi Nasional 2011 (NIST11-MS, version 2.0g). Berdasarkan 4 sampel daun merah *C. vespertilionis* melalui maserasi metanol (RMM), maserasi etanol (RME), pengekstrakan Soxhlet methanol (RSM) dan pengekstrakan Soxhlet etanol (RSE), tujuh puluh satu (71) sebatian fitokimia dikenal pasti. Sebelas (11) sebatian fitokimia utama (> 4 % kawasan puncak) juga dikenalpasti seperti asid asetik, butil ester; 1-butanol, 3-metil-, asetat; asid heptanoik, propil ester; asid heksanoik, 3-okso-, etil ester; fenol, 3,5-bis (1,1-dimetiletil)-; 1-oktadekena; 4-O-metilmanos; .alpha.-d-manofurosida, metil; 2-undekena, 9-metil-, (E)-; asid n-heksadekanoik dan 1-oktadekanol. Hanya tujuh (7) daripada sebelas (11) sebatian yang dilaporkan mempunyai aktiviti biologi. Di antara sampel tersebut, RSM adalah yang paling berkesan dengan menggunakan pekali korelasi antara kebanyakan (%) dan masa pengekalan (min) dengan perbezaan yang signifikan pada $P < 0.05$.

Introduction

Christia vespertilionis (L. f.) Bakh. f. is a family of Fabaceae that is known as butterfly wing because of its shape, which is similar to that of a butterfly wing. This plant possesses the ability to cure several diseases due to it having various biological activities such as anti-cancer, anti-inflammatory, anti-proliferative and anti-plasmodial properties [1, 2, 3]. In Malaysia, *C. vespertilionis* leaves are consumed by cancer patients and have gained great popularity among Malaysians, including researchers who are keen to explore and discover the real potential of this plant.

C. vespertilionis is known to potentially exhibit various bioactive secondary compounds that can be used in food and pharmaceutical areas [4]. Previous studies revealed the presence of bioactive secondary compounds in *C. vespertilionis* such as alkaloid, phenol, fatty acid, triterpene and alcohol [2]. The aerial part of *C. vespertilionis* is revealed to contain corynoxidine and palmitine [2]. *C. vespertilionis* also possesses great anti-proliferative activities in MTC cells and is excellent in anti-plasmodial activities using aqueous-methanol extracts [1,2]. Other studies showed that *C. vespertilionis* extract has a high inhibition on cancer cells such as human medullary thyroid carcinoma and human intestinal neuroendocrine tumours [5]. In addition, *C. vespertilionis* exhibits moderately as an anti-malaria which is against the 3D7 malaria parasite and literally can be used for malaria treatment [6].

Today, people have developed high interest in traditional plants, as a substitute for synthetic drugs. Plant comes from nature and safe to use. It is also low cost and has less negative side effects [7]. However, the World Health Organization (WHO) has noted that inappropriate practices of using traditional plants for treatment can have dangerous effects. Therefore, further study is necessary to ascertain the efficacy and safety of plants for human consumption. While many studies of *C. vespertilionis* have been conducted, there is no study available on bioactive phytochemicals of red *C. vespertilionis* leaves using gas chromatography-mass spectrometry (GC-MS). GC-MS is one of the techniques that separates individual compounds in the form of a mass spectrum and measurement of the abundance of chromatography [8]. Identification of compounds in GC-MS is achieved by comparing mass spectrum of sample with the reference National Institute of Standards and Technology Mass Spectral Library 2011 (NIST11-MS) based on matching system.

Prior to that, before GC-MS, red *C. vespertilionis* leaves need to undergo extraction to separate the target products from the raw materials. Currently, solvent extraction is widely used in natural plants and herb medicines. Selection of solvent is also a crucial part for solvent extraction. The solvent with a shorter differences of polarity value to the polarity of the solute, is expected to perform better. As regarding the technique of extraction, there are two commonly used methods namely as maceration and Soxhlet extraction.

These methods were most of the time given acceptable results, however Soxhlet can be time-consuming although requires a small amount of sample compared to maceration. Therefore, this research aims to optimise the extraction method of red *C. vespertilionis* leaves in different extraction techniques (maceration and Soxhlet extraction) and solvents (methanol and ethanol) to yield bioactive phytochemicals using GC-MS.

Materials and Methods

Plant material

Red *C. vespertilionis* was collected from Floranika Nursery Sungai Buloh, Selangor (Malaysia), located at a latitude and longitude of 3° 13' 6.7764" N, 101° 34' 18.1704" E, respectively. The voucher specimen was authenticated by Dr Yong Kien Thai from Plant Taxonomy, Rimba Ilmu, University of Malaya. The voucher specimen of red *C. vespertilionis* (KLU 50025) was placed at the herbarium of the University of Malaya, and left to air-dry for 7 to 8 days. Leaves were ground with a blender to obtain coarse powder for extraction and were kept in a closed jar until further use.

Maceration

1 g of dried leaves powder of red *C. vespertilionis* was immersed into a 100 ml of methanol, MeOH (Merck, Germany), and absolute ethanol, EtOH (VWR Chemicals, American) in a 250 ml conical flask, separately. The samples were left in a water bath at 40 °C for 48 hours. The extracts were filtered and evaporated with rotary evaporator at 45 °C until they were concentrated. The extracts were filtered again to remove any solid particles and kept tightly closed in a microcentrifuge tube at 4 °C until further use.

Soxhlet extraction

1 g of dried leaves powder of red *C. vespertilionis* was extracted with 200 ml of MeOH (Merck, Germany), and absolute EtOH (VWR Chemicals, American) using a Soxhlet apparatus, separately. The samples were left in a water bath at 40 °C for 48 hours. The extracts were filtered and evaporated using a rotary evaporator at 45 °C until they were concentrated. The extracts were filtered again to remove any solid particles and kept tightly closed in a microcentrifuge tube at 4 °C until further use.

Gas chromatography-mass spectrometry analysis

Samples were diluted to 500 ppm with the respective solvents into 1.5 ml vials. The GC-MS analysis was done at the IPPP Central Laboratory Facilities, University Malaya, Kuala Lumpur, Malaysia. Model of GCMS-QP2010 Ultra (Shimadzu, Tokyo, Japan) was used for the GC-MS analysis. This model is a single quadrupole gas chromatograph-mass spectrometer that produces stable and affordable analyses for complex compounds. 0.5 µl of the sample was auto-injected into the system. The system was supplied with a capillary column of RTX5MS with length x diameter of 30.0 m × 0.25 mm and a 0.25 µm of thickness. The injection temperature was set to 200 °C which possessed a splitless injection mode. The initial temperature was 50 °C (3 minutes) with an accelerating rate of 10 °C (1 minute) to 300 °C (10 minutes). Helium gas was used with 47.8 cm/second of linear velocity. Electron ionisation (EI) mode at 70 eV with a spectral range of 35 m/z-500 m/z was performed for mass spectra results. The ion source temperature was fixed at 150 °C and the interface temperature was at 230 °C with a solvent cut-off time of 3 minutes. The start time was set at 3.0 minutes and the final time was adjusted at 33 minutes. The total flow programmed was 21.6 ml/minute with a column flow of 1.69 ml/minute. The compounds were determined based on the interpretation of mass spectrum with standard reference spectral using the National Institute of Standards and Technology Mass Spectral Library 2011 (NIST11) version 2.0g databases.

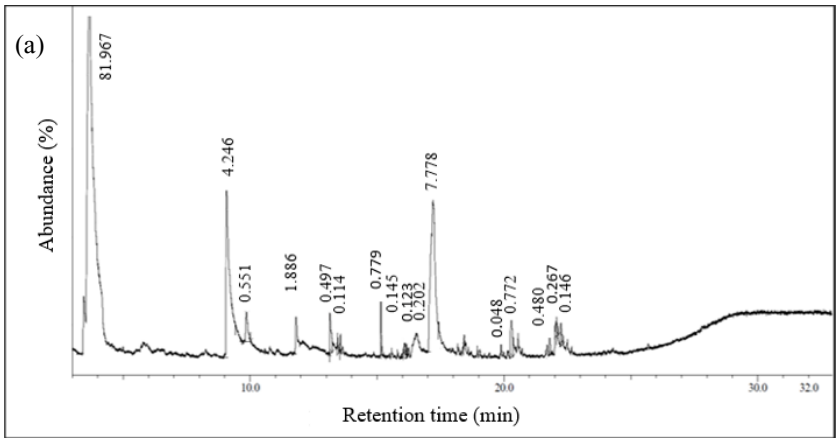
Statistical analysis

The correlation between abundance and retention time of the sample was determined using GraphPad Prism 8.0.2, where Pearson's correlation coefficient test was conducted and the difference was considered statistically significant when $P < 0.05$. Chemical structure drawing was applied on the website: https://chemwriter.com/.

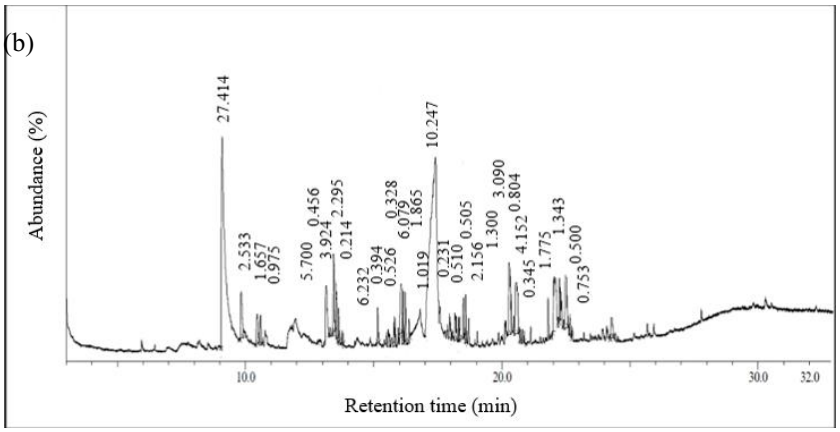
Results and Discussion

GC-MS chromatogram and bioactive phytochemicals

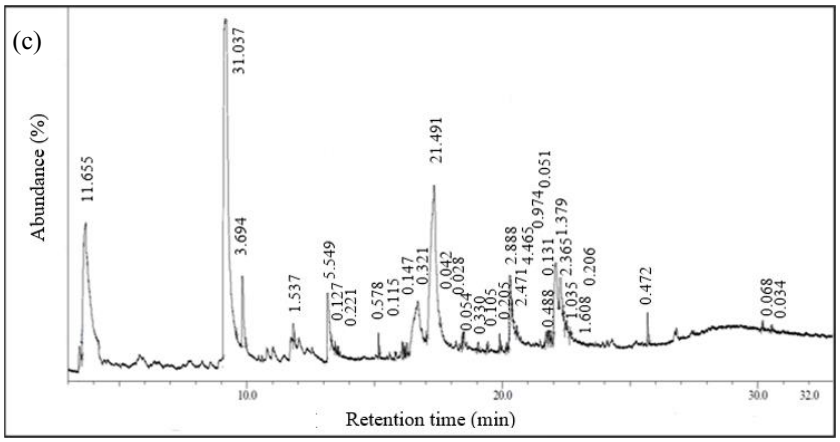
GC-MS is important to identify bioactive phytochemicals in a complex compound using a technique of separation in a GC system and measuring on a mass spectrometer that comes with an electron ionisation (EI) ion source. There are two electron ionisation (EI) main spectrum library: main and replicate with a total of 212,961 and 30,932 mass spectra, respectively. NIST11-MS library has a total of 346,757 retention index for 70,835 compounds that were extracted based on column type, column class, data type and program type [9]. Through GC-MS analysis showed seventy-one (71) phytochemicals from four (4) samples that consist of major and minor compounds. Major compounds consisted of an abundance larger than 4% [10] as shown in Table 3. The conditions of the samples were shown in Table 1.



Bioactive phytochemicals of the samples were presented in Table 2 and the GC-MS chromatogram of the abundance of samples shown in Figure 1. GC-MS analysis for RMM resulted in a total of sixteen (16) peaks (according to Figure 1(a) and Table 2). There are three (3) major compounds, namely: acetic acid, butyl ester (81.967%); 1-butanol, 3-methyl-, acetate (4.246%) and 4-O-methylmannose (7.778%). RME resulted in a total of thirty (30) peaks (according to Figure 1(b) and Table 2). There were seven (7) major compounds, namely: 1-butanol, 3-methyl-, acetate (27.414%); heptanoic acid, propyl ester (5.700%); phenol, 3,5-bis(1,1-dimethylethyl)- (6.232%); 1-octadecene (6.079%); .alpha.-d-mannofuranoside, methyl (10.247%); 2-undecene, 9-methyl-, (E)- (5.505%) and 1-octadecanol (4.152%).



Furthermore, RSM resulted in a total of thirty-three (33) peaks (according to Figure 1(c) and Table 2). Five (5) major compounds were identified, namely: acetic acid, butyl ester (11.655%); 1-butanol, 3-methyl-, acetate (31.037%); hexanoic acid, 3-oxo-, ethyl ester (5.549%); 4-O-methylmannose (21.491%) and n-hexadecanoic acid (4.465%). Lastly, RSE resulted in a total of thirty-seven (37) peaks (according to Figure 1(d) and Table 2). Four (4) major compounds comprised: 1-butanol, 3-methyl-, acetate (6.414%); phenol, 3,5-bis(1,1-dimethylethyl)- (5.950%); 4-O-methylmannose (4.085%) and n-hexadecanoic acid (8.733%).



Previous study found other major compounds on red *C. vespertilionis* leaves extract such as 10-undecenoic acid (5.00%), 6-methylheptyl-2-propenoate (4.96%), 2-(2-benzothiazolylthio)-1-(3,5-dimethylpyrazolyl)-ethanone (2.70%), tetrahydro-2-methyl-thiophene (61.77%) and phytol (8.59%) [11]. Another study also found that *C. vespertilionis* leaves methanolic extract exhibited hexadecanoic acid (4.87 %), 9,12,15-octadecatrienoic acid (7.82%), phytol (6.97%), 2-propenoic acid (8.75%) and cyclododecane (7.04%) [12]. These previous study outcomes also can be found in Table 2 such as 9,12,15-octadecatrienoic acid, phytol and hexadecanoic acid.

Optimisation of extraction

Correlation was used between abundance and retention time of the sample in GC-MS for all compounds found. Maceration using MeOH (RMM) was significantly high at $P < 0.011$ (Figure 2). When using EtOH (RME), the significant difference was at $P < 0.049$. In Soxhlet, the significant difference was high in MeOH (RSM) with $P < 0.009$ and there was no significant difference in (RSE) which was at $P < 0.104$. The smaller the P value, the more significant it is. A total of seventy-one (71) abundance were analysed for each sample. The results indicated that significant difference between abundance and retention time increased when using Soxhlet extraction particularly in MeOH.

Extraction methods using different solvents play an important role to exhibit bioactive phytochemicals. Based on Figure 2, abundances of compounds are exhibited more when using Soxhlet extraction and MeOH. A previous study stated that the polarity of MeOH could be the reason for the high exhibition of

compounds [13]. Other study stated that using MeOH produces high bioactive phytochemicals particularly compounds that cure inflammation which is extracted from the branches of *S. buxifolia* [14]. It was also revealed that MeOH is a solvent that is more effective in extracting secondary metabolite compounds from *M. viridis* than any other plants in the Lamiaceae family [15].

The technique of extraction is also one of the factors that contribute to the effectiveness of bioactive phytochemicals attribution. Based on Figure 2, more compounds were exhibited using Soxhlet extraction as compared to maceration. Soxhlet extraction offered more efficiency and was less time-consuming as compared to maceration. Other researches obtained similar results in *Nepeta leucophylla* and *Potentilla atrosanguinea* aerial parts when using Soxhlet extraction where it exhibited significantly higher, and attained maximum percentage yields than maceration [4, 16]. Therefore, for red *C. vespertilionis* leaves, Soxhlet extraction obtained highest compounds attribution as compared to the maceration technique. Overall, red *C. vespertilionis* leaves work efficiently using Soxhlet extraction and MeOH as a solvent.

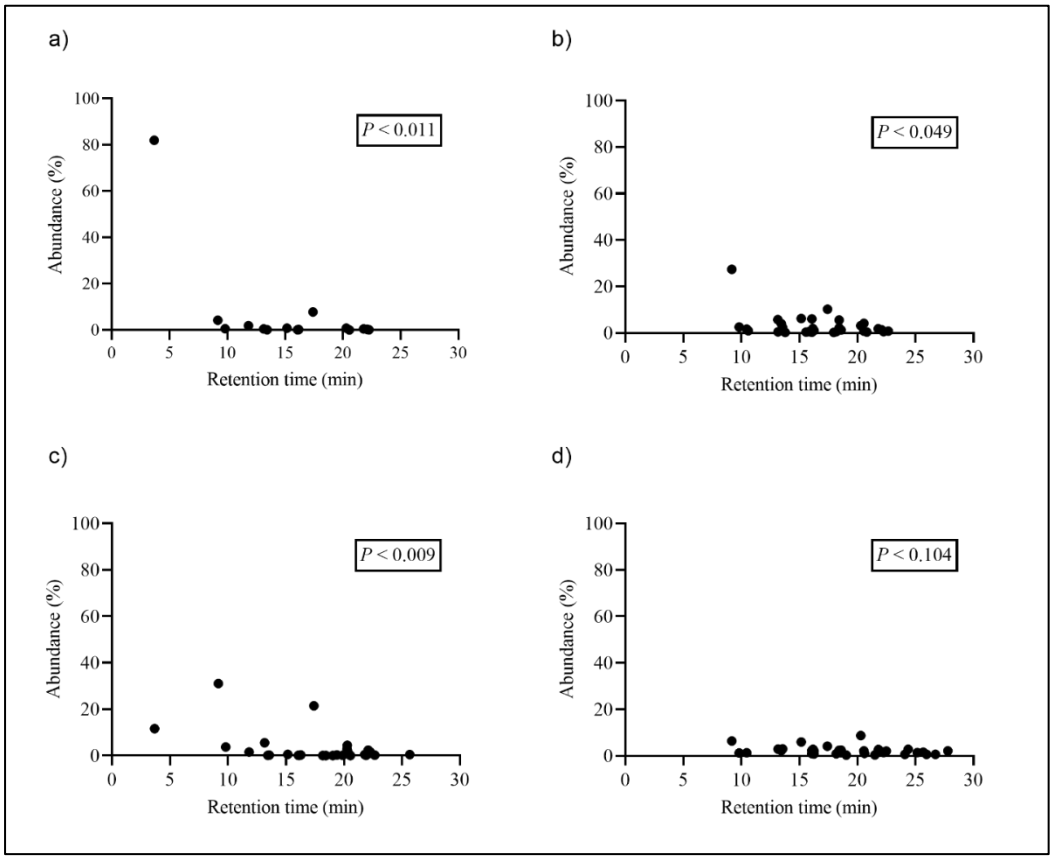

Figure 2. Correlation between abundance (%) versus retention time (min) of a) RMM b) RME c) RSM and d) RSE

Major bioactive phytochemicals

Four (4) samples (RMM, RME, RSM and RSE) of *C. vespertilionis* leaves extract, detected seventy-one (71) bioactive phytochemicals, which consisted of major and minor compounds using GC-MS, as presented in Table 2. The abundance presented for each sample is shown in Figure 1. Through this analysis, it was found that eleven (11) major compounds achieved higher than

4 % of the abundance from all of samples as presented in Table 3.

The eleven (11) major bioactive phytochemicals were acetic acid, butyl ester (81.967%), 1-butanol, 3-methyl-, acetate (31.037%), heptanoic acid, propyl ester (5.700%), hexanoic acid, 3-oxo-, ethyl ester (5.549%), phenol, 3,5-bis(1,1-dimethylethyl)- (6.232%), 1-octadecene (6.079%), 4-O-methylmannose (21.491%), .alpha.-d-mannofuranoside, methyl (10.247%), 2-undecene, 9-methyl-, (E)- (5.505 %), n-hexadecanoic acid (8.733%), and 1-octadecanol (4.152%).

The n-hexadecanoic acid and 1-octadecanol possessed anti-inflammatory activities [17,18]. The antimicrobial agent was revealed by 1-butanol, 3-methyl-, acetate, [19]. Ethyl acetate root extract of *C. vespertilionis* showed the highest total phenolic content that is responsible for good anti-inflammatory and anti-microbial properties [20,21]. Meanwhile, 1-octadecene possessed anti-cancer property [22, 23]. Based on the previous study, *C. vespertilionis* extract has viability against various cell lines such as WRL68 (normal liver), CRL 2522 (fibroblast), HepG2 (liver carcinoma), MCF-7 (breast cancer) and HaCaT (keratinocyte) with the IC50 values of 1.93, 1.51, 1.63, 1.74 and 1.22 mg/ml, respectively [24]. Four (4) compounds had antibacterial activities that included n-hexadecanoic acid, 4-O-methylmannose, 1-octadecene and phenol, 3,5-bis(1,1-dimethylethyl)- [23, 24, 26-30].

Most of the compounds possessed anti-oxidants, including 1-octadecanol, n-hexadecanoic acid and 1-octadecene [18, 23, 26, 31]. *C. vespertilionis* ethyl acetate: methanol extract has significantly exhibited the highest DPPH scavenging activity with the IC50 value of 0.549 ± 0.02 mg/mL [32]. Acetic acid, butyl ester was the most abundant compounds that is beneficial as an antifungal and antitumour [33]. *C. vespertilionis* inhibited tumour growth and increase survival time of mice induced with S180 AND H22 tumour cells [34]. Another known compound was phenol, 3,5-bis(1,1-dimethylethyl)- which acts as an antiseptic, disinfectant and flavourant [24, 29]. No biological activity was reported for heptanoic acid, propyl ester; hexanoic acid, 3-oxo-, ethyl ester; .alpha.-d-mannofuranoside, methyl and 2-undecene, 9-methyl-, (E)-. Therefore, only seven (7) out of eleven (11) major compounds were reported their biological activities.

Table 3. Major bioactive phytochemicals of red *C. vespertilionis* leaves

	Name of Compound/ Chemical Classes	Rt (Min)	Abundance (%) Maceration		Soxhlet		Formula	MW	Structure	Biological Properties
			MeOH (RMM)	EtOH (RME)	MeOH (RSM)	EtOH (RSE)				
1	Acetic acid, butyl ester (Carboxylic acid ester)	3.683	+ 81.967	-	+ 11.655	-	$C_{16}H_{12}O_2$	116		Antifungal, Antitumor [33]
2	1-butanol, 3-methyl-, acetate (Carboxylic acid ester)	9.179	+ 4.246	+ 27.414	+ 31.037	+ 6.414	$C_7H_{14}O_2$	130		Antimicrobia [19]
3	Heptanoic acid, propyl ester (fatty acid ester)	13.140	-	+ 5.700	-	-	$C_{10}H_{20}O_2$	172		No activity reported

Table 3 (cont'd). Major bioactive phytochemicals of red *C. vespertilionis* leaves

	Name of Compound/ Chemical Classes	Rt (Min)	Abundance (%) Maceration		Soxhlet		Formula	MW	Structure	Biological Properties
			MeOH (RMM)	EtOH (RME)	MeOH (RSM)	EtOH (RSE)

	Total of major compounds		3	7	5	4				

Conclusion

This study revealed that red *C. vespertilionis* leaves have various bioactive compounds that has high potential to treat diseases. Red *C. vespertilionis* leaves possessed biological activities of anti-inflammatory, antitumour, anticancer, antibacterial, antimicrobial, antioxidant and antifungal properties. The compounds were greatly exhibited from Soxhlet extraction and MeOH as a solvent. Conclusively, this study achieved success in identifying bioactive phytochemicals of red *C. vespertilionis* leaves in different techniques and solvents. Further study needs to be done to isolate bioactive phytochemicals and investigate its biological activities. A comparison to green *C. vespertilionis* needs to be analysed to observe the differences in terms of bioactive phytochemicals and biological activities.

Abstract

Penang Assam Laksa is a sour, fish-based soup popular in Malaysian street food. The content of heavy metals (Cd, Hg, and Pb) as well as essential minerals (Fe, Ca, Na, and K) in ready-to-eat Penang Assam Laksa food samples collected from five stalls over three different days was determined using flame atomic absorption spectrometry (FAAS), a Flow Injection Mercury System (FIMS), and inductively coupled plasma optical emission spectrometry (ICP-OES) after a wet-digestion procedure. Statistical analyses such as Student's *t*-test and an inter-day precision study were conducted on the obtained results. The wet-digestion procedure was found to be effective, with recoveries above 85%. Meanwhile, an inconsistency in element content was observed for food samples collected on different days. Based on Student's *t*-test, both FAAS and ICP-OES were suitable for detecting and quantifying heavy metals and essential minerals in the food samples.

Keywords: Penang Assam Laksa, heavy metal, essential minerals, street food

Abstrak

Asam Laksa Pulau Pinang adalah sup masam yang berasaskan ikan. Kandungan logam berat (Cd, Hg, Pb) serta mineral penting (Fe, Ca, Na, K) dalam Asam Laksa Pulau Pinang (makanan sedia dimakan) yang dikumpul dari lima gerai terpilih pada tiga hari berbeza telah ditentukan menggunakan FAAS (spektrometri penyerapan atom nyalaan), FIMS (sistem merkuri suntikan aliran) dan ICP-OES (spektrometri pancaran optik induktif gabungan plasma) selepas prosedur pencernaan basah. Analisis statistik seperti *Ujian-t* pelajar dan kajian ketepatan antara hari telah dijalankan ke atas keputusan yang diperolehi. Prosedur pencernaan

basah didapati merupakan kaedah yang berkesan dalam mencerna sampel makanan dengan pemulihan lebih daripada 85%. Sementara itu, ketidakselarasan kandungan unsur diperhatikan daripada sampel makanan yang dikumpul pada hari yang berbeza. Berdasarkan *Ujian-t* pelajar, kedua-dua FAAS dan ICP-OES sesuai untuk pengesanan dan penentuan logam berat dan mineral penting dalam sampel makanan.

Kata kunci: Asam Laksa Pulau Pinang, logam berat, mineral penting, makanan jalanan

Introduction

Food is a fundamental requirement for sustaining life. The rapid acceleration of the human population has led to the creation of various kinds of foods, including street foods, which are defined as ready-to-eat foods and beverages that are prepared and/or sold by street vendors [1]. Generally, street foods are rich in macro- and micro-nutrients. Macro-nutrients such as carbohydrates, fats, and proteins are needed in relatively large amounts, as they provide energy to the human body, while micro-nutrients in food comprise vitamins and inorganic minerals such as calcium (Ca), potassium (K), and iron (Fe). Essential minerals are present in small quantities but play significant roles in human biology, especially as catalysts for enzymatic activities [2-5]. For example, sodium (Na) and K are common electrolytes that drive the transmission of signals along nerves as well as maintain water balance, while Fe is a principal component in hemoglobin production, which is responsible for oxygen transportation [6-8] in blood. Either inadequate or excessive intake of essential minerals will adversely affect human health. Hypocalcemia, also known as low blood calcium levels may result in tetany, whereas hypercalcemia may lead to kidney-stone formation (nephrolithiasis) [7].

Street foods can readily become contaminated with heavy metals such as cadmium (Cd), lead (Pb), and mercury (Hg) due to environmental pollution, which is all the more common in modern times [9]. Heavy metals are substances that occur naturally and are often present in the environment at trace levels [10]. Heavy metals have caused widespread concern due to their tendency to accumulate in selective human tissues (liver, brain, and kidney) and not decay over time. These characteristics will eventually lead to various types of disorders, such as peripheral neuropathy and different cancers9. Previous studies have shown that humans are exposed to heavy metals via the ingestion of contaminated food and beverages [3, 9, 10]. Hence, is has become necessary to perform food analysis in order to assess food quality and safety.

Food analysis is a challenging task in analytical chemistry; the presence of heavy metals and essential minerals in trace quantities, as well as the complex nature of food matrices, have only increased its difficulty. Proper and efficient sample preparation followed by a highly sensitive instrumental analysis is often required to obtain quality element-content data in food [11]. There are numerous types of sample digestion methods that have been successfully employed in determining element content in diverse food samples. Dry-ashing and wet-digestion procedures are well established methods, and their efficiency has been reported in previous studies. Dry ashing is known to be effective in digesting organic materials in food samples, but it is time-consuming and prone to losses due to volatilization and/or retention problems [9, 12, 13]. Wet digestion is relatively simple, rapid, and inexpensive compared to dry ashing. This procedure benefits from small sample quantities and greater flexibility, as the sample weight and digestion conditions can be changed accordingly.

In recent years, numerous analytical techniques have been developed for determining element content in food samples. These techniques include neutron activation analysis (NAA), voltammetry, atomic absorption spectrometry (AAS), inductively coupled plasma optical emission spectrometry (ICP-OES), and inductively coupled plasma mass spectrometry (ICP-MS) [4, 9, 10, 14, 15, 16]. Among these techniques, AAS (including flame atomic absorption spectrometry, FAAS, and graphite furnace atomic absorption spectrometry, GFAAS), ICP-OES, and ICP-MS [4, 15] are well established as mainstays in food analysis

because of their rapidity and effectiveness in detecting and quantifying elements in samples at extremely low concentrations [4, 10, 11, 16]. In addition, flow injection analysis (FIA) using devices such as the Flow Injection Mercury System (FIMS) is also employed, as it combines the advantages of flow injection and atomic absorption measurement into a compact Hg analyzer [17].

In Malaysia, Penang is well known as a food paradise due to its wide variety of street foods. These foods reflect the multicultural makeup of the state, which has citizens of Chinese, Malay, and Indian descent. One of the most famous Penang street foods is Penang Assam Laksa, which is a broth made of shredded fish (*Kembung* fish or mackerel) and finely sliced vegetables [cucumber, onions, red chilies, pineapples, lettuce, fresh mint, and torch ginger (in Malay: *bunga kantan*)][18]. An increased interest in street foods has led to public concern about their safety and quality, owing to their socioeconomic importance as well as nutritional value. However, there is a paucity of proper studies and data on this kind of fresh, ready-to-eat food, as most studies focus on raw, uncooked foods or commercialized food products. Thus, there is a need to perform a proper scientific study to obtain a general picture of the nutritional content of Penang Assam Laksa. Such information can help prove the safety of the food and increase confidence among consumers.

This study mainly aimed to detect the essential minerals (Ca, Fe, Na, and K) and heavy metals (Hg, Cd, and Pb) in Penang Assam Laksa by using FAAS, FIMS, and ICP-OES. The safety of the food was further assessed by comparing the element content obtained from collected food samples to the permissible levels stated in Malaysia Food Act 1983 and Food Regulations 1985 [19], as well as the recommended dietary allowance (RDA) from U.S. Dietary Guideline 2010 [18]. Finally, a simple comparative study was performed to evaluate the agreement between the results provided by these two different groups of techniques.

Materials and Methods

Chemicals and Standards

Concentrated nitric acid (HNO_3, 65%, Merck, USA) and hydrogen peroxide (H_2O_2, 35%, Hmbg, India) were purchased from local chemical suppliers. Commercial 1000-ppm standard stock solutions (Perkin Elmer Laboratory preparation, USA) containing elements of interest were used to prepare working standard solutions, all of which were freshly prepared prior to analysis. Ultrapure water was produced by a Milli-Q System (Millipore, Bedford, MA, USA) and used for solution preparation as well as sample digestion.

Sample Collection and Handling

Fifteen food samples (Penang Assam Laksa) were purchased from five selected areas throughout Penang Island on three different days, all of which were cooked and ready-to-eat. Upon purchasing, the solid ingredients (sliced vegetables and noodles) and the broth of the samples were packed separately with leak-proof nylon bags. During sample preparation, the solid ingredients were soaked in the broth and left for 20 min. After that, the mixture was filtered, and the broth was collected for further treatment.

Wet Digestion of Samples

The wet-digestion procedure performed in this work was adopted from a study by Salau and Hassan [5]. Three 5-mL aliquots of previously filtered broth samples were transferred to three conical flasks. Ten mL of HNO_3 was added to the sample and left overnight (24 h) in a fume hood. The following day, further digestion was carried out by adding a mixture of HNO_3 and H_2O_2. Details about the procedure and its steps are summarized in Table 1. The solutions were filtered with white filter papers (WHATMAN, qualitative filter papers, 125-mm diameter) and then re-filtered with a syringe filter. Then, the filtered solutions were diluted with ultrapure water to 100 mL and transferred into polyethylene sample bottles and kept in a refrigerator.

Table 1. Wet digestion procedure for samples

Step	Ultrapure water added (mL)	HNO_3 added (mL)	H_2O_2 added (mL)	Heating (°C)	Time (min)
1	-	10	-	-	Overnight
2	-	5	2	100	30
3	-	10	4	100	30
4	30	5	2	100	30
5	30	10	2	100	20

Recovery Study

Standard solutions containing the elements of interest were prepared at three different concentrations: 6.00, 8.00, and 10.00 ppm, except for those of Hg, which were prepared at 0.10, 0.15, and 0.20 ppm. Five-mL samples of the prepared food were spiked with 0.5 mL of the standard solutions. The spiked samples were prepared in triplicate at each concentration. Simultaneously, unspiked blank solutions containing 5 mL of food sample and 0.5 mL of ultrapure water were prepared as well. These spiked and unspiked samples then went through the digestion procedure as described above before subsequent instrumental analysis.

Instrumental Analysis

A Perkin Elmer AAnalyst 400, a Perkin Elmer FIMS 100, and a Perkin Elmer Optima 8000 were used for FASS, FIMS, and ICP-OES analyses of the target elements, respectively. All the instruments were equipped with WinLab 32 computer software for data acquisition. For every target element, calibration was performed prior to instrumental analysis. The calibration curves for all elements were plotted as absorbance intensity against concentration in ppm (with the exception of ppb for Hg analysis) using Microsoft Excel, and correlation coefficients, R^2, for all curves were determined. Working standard solutions of certain concentrations were prepared accordingly by diluting the 1000-ppm standard stock solutions. The standard stock solutions were drawn by using micropipette. Samples collected on Days 1 and 2 were run on instruments at the same time, while samples collected on Day 3 were run separately with a new calibration cycle. The concentrations of the working standards for each element remained unchanged for the first and second runs.

Statistical Analysis

Student's *t*-test was performed by means of Excel in order to determine whether the two methods (FAAS/FIMS and ICP-OES) gave significantly different results. Meanwhile, an inter-day precision study was conducted for the samples collected on different days by expressing the repeatability in terms of relative standard deviation (RSD).

Results and Discussion

Recovery and Efficiency of Wet Digestion Procedure

The accuracy and efficiency of the wet digestion procedure performed on the spiked samples at three different concentration levels were evaluated in triplicate. The average recovery (%) of all target elements is presented in Table 2, which shows that the recoveries for all the target elements were satisfactory - more than 85% of the elements were recovered from the spiked samples. In FAAS, the highest digestion efficiency was achieved for Cd at 96.1%, whereas Pb exhibited the lowest efficiency at 86.3%. In contrast, Hg exhibited the highest average recovery percentage in ICP-OES (94.5%). Based on this recovery assay, the efficiency of the digestion procedure used in this work was confirmed.

Table 2. Average recovery for all targeted elements

Elements	Average Recovery (%)	
	FAAS/FIMS	ICP-OES
Hg	91.6	94.5
Cd	96.1	85.8
Pb	86.3	91.7
Fe	94.0	90.3
Ca	91.7	91.1
Na	93.5	93.5
K	94.1	86.9

Instrumental Analysis of Studied Foods

Linearity of Analysis: Every elemental analysis carried out via FAAS, FIMS, and ICP-OES consisted of two calibration cycles, as the food samples were run in two batches. All the calibration curves exhibited linearity, with R^2 values greater than 0.99, except for Hg via ICP-OES, as well as K and Na via FAAS, which gave slightly lower R^2 values. As an overall observation, all the calibration curves demonstrated a linear response within a particular range. It was noted that both calibration cycles for the elements generated different regression equations and R^2 values, but these differences were quite small and negligible, as they did not possess any significant meaning.

Detection of Essential Minerals in Studied Food Samples: The mineral-content ranges of the food samples were compared to the RDA for minerals according to U.S. Dietary Guideline 2010, as shown in Table 3. Since the RDA values stated in the guideline are in units of mg/day, for ease of comparison, an assumption was made wherein the mineral content presented in the Tables 3 and 4 under this section is normalized as that in 250-mL samples. Adequate Fe intake is crucial to prevent anaemia [2]. It was noted that the order of Fe content for each sample collected at different locations showed the same pattern for the three different collection days. The highest detected Fe content was 1.98 mg/L by FAAS and 1.51 mg/L ICP-OES. According to U.S. Dietary Guideline 2010 [8], adult females and males are recommended to take approximately 18.00 mg and 8.00 mg of Fe per day, respectively. In general, all the studied food samples were considered to have adequate levels of Fe for an adult male older than 19 years. However, the Fe content was insufficient for an adult female because they experience the Fe losses associated with physiological processes (menstruation) [8].

Calcium is the most abundant cation in the human body. According to U.S. Dietary Guideline 2010 [8], an adult is recommended to take 1.00×10^3 mg of Ca daily as an upper intake level (UL). From Table 3, the highest detected Ca content was 3.25×10^2 mg/L (FAAS) and 2.61×10^2 mg/L (ICP-OES). The high Ca content in the studied food samples was most probably due to mackerel, the main ingredient of the food samples, since it was reported in a previous study that mackerel contains high levels of Ca, ranging from 1.60×10^3 to 1.80×10^3 mg/L [20]. All the studied food samples were considered to have adequate Ca levels for an adult older than 19 years.

For Na, adequate intake (AI) levels are used instead of RDA, since the latter could not be determined. The determined Na concentration of all the studied food samples approached the AI level and was less than the UL. The highest Na levels were 1.23×10^3 mg/L (FAAS) and 1.44×10^3 mg/L (ICP-OES). The Na content in the studied food samples was most likely due to salt (sodium chloride), which is added to enhance taste. Based on the obtained results, the

studied food samples were considered to have adequate Na levels. However, the consumption of Penang Assam Laksa is advised to be reduced in order to avoid excessive Na intake.

Potassium is important for building muscle as well as metabolizing proteins and carbohydrates [8]. The highest concentration of K was detected at 1.52×10^3 mg/L and 6.67×10^2 mg/L for FAAS and ICP-OES, respectively. The AI level for K established by U.S. Dietary Guideline 2010 is approximately 4.70×10^3 mg/day; all the studied samples were considered to have sufficient K, most likely because of the mackerel - the main ingredient of the broth [21].

Table 3. Ranges of Fe, Ca, Na, and K contents in the studied food samples detected by FAAS and ICP-OES (assuming 250 mL of broth per serving unit)

Element	Range of Concentration Detected (mg/L)		Recommended Dietary Allowance
	FAAS	ICP-OES	
Fe	5.48×10^{-1} to 1.98	5.57×10^{-1} to 1.51	18.00 mg per day (female above 19 y.o.) 8.00 mg per day (male above 19 y.o.)
Ca	3.96×10 to 3.25×10^2	1.18×10^2 to 2.61×10^2	1.00×10^3 mg per day (male and female above 19 y.o.) Adequate Intakes
Na	7.32×10^2 to 1.23×10^3	6.87×10^2 to 1.44×10^3	1.50×10^3 mg per day (male and female above 19 y.o.)
K	1.92×10^2 to 1.52×10^3	1.44×10^2 to 6.67×10^2	4.70×10^3 mg per day (male and female above 19 y.o.)

*All values are expressed as a mean in ppm or mg/L

* y.o. = years old

* Recommended dietary allowance and adequate intakes (Source: US DA & US DHS 2010)[8]

Detection of Heavy-Metal Contents in Studied Food Samples: The concentration of heavy metals detected in all food samples was tabulated and compared to the permissible levels stated in Malaysia Food Act 1983 and Food Regulations 1985 [19], as seen in Table 4.

Cadmium affects cell proliferation, differentiation, and apoptosis; it also inhibits both cellular respiration and oxidative phosphorylation at low concentrations [22]. In this study, Cd was not detectable via ICP-OES for all samples, while it was detectable via FAAS. This observation does not lead to the conclusion that the samples were free of Cd. Instead, the results only suggest that Cd was undetectable in ICP-OES, as FAAS was able to give readings. Basically, the Cd content in the studied food samples ranged from 7.80×10^{-2} to 2.85×10^{-1} mg/L (in FAAS determination). This concentration level was relatively low and did not exceed the permissible level stated in Malaysia Food Act 1983 and Food Regulations 1985 [19], which is 1.00 mg/L.

The FIMS used in this study was a dedicated Hg system coupled with a high-sensitivity Hg detector [17]. This instrument was designed purposely for Hg quantification with an extremely low detection limit (as suggested by the user manual of the instrument) of less than 5.00×10^{-6} mg/L, as compared to the much higher 5.10×10^{-3} mg/L for ICP-OES. In other words, ICP-OES is not sensitive enough to detect Hg at trace

levels; thus, it yielded no readings or measurements in this study. The Hg detected in most of the food samples was present at trace amounts ranging from 9.00×10^{-4} to 8.10×10^{-3} mg/L, lower than the permissible level of 5.00×10^{-2} mg/L as stated in Malaysian Food Act 1985 [12]. Meanwhile, Hg was undetectable in a few samples.

The Pb levels in the food samples were significantly higher than those of Cd and Hg. According to Malaysia Food Act 1983 and Food Regulations 1985 [19], the permissible level of Pb in food is 2.00 mg/L. Unfortunately, the majority of the samples contained excessive Pb levels, which possibly originated from the raw ingredients used to prepare the foods, such as fish, spices, and vegetables. This finding is of great concern, as Pb was classified as a "human carcinogen" by International Agency for Research on Cancer (IARC) in 1993 [23]. Excessive Pb intake can cause severe brain and kidney damage. Moreover, a high intake of (or exposure to) Pb may cause miscarriages in pregnant women [10, 24].

Table 4. Ranges of Cd, Hg, and Pb contents in the studied food samples detected by FAAS/FIMS and ICP-OES (assuming 250 mL of broth per serving unit)

Elements	Range of Concentration Detected (mg/L)		Permissible Level in Malaysia
	FAAS/FIMS	ICP-OES	
Cd	7.80×10^{-2} to 2.85×10^{-1}	n.d.	1.00 mg/L
Hg	9.00×10^{-4} to 8.10×10^{-3}	n.d.	5.00×10^{-2} mg/L
Pb	2.87 to 5.26	1.27 to 5.04	2.0 mg/L

*All values are expressed as a mean in ppm or mg/L

*n.d = non-detectable

*Permissible Level in Malaysia (Source: Malaysia Food Act 1983 and Food Regulations 1985, 2017 [19]

Statistical Testing

Student's *t*-test: The results provided (Table 5) by the two types of analytical instruments, FAAS/FIMS and ICP-OES, were compared using Student's *t*-test. There was no significant difference (at a confidence level of 95%) in the results of essential minerals as determined by FAAS and ICP-OES. However, there was a significant difference found in the heavy-metal results. This indicated that both FAAS and ICP-OES were suitable for the detection and quantification of essential minerals in food samples. For heavy metals, both analytical instruments failed to show a good correlation between the obtained results. Perhaps this was associated with the trace levels of heavy metals in the food samples and the sensitivities of the instruments. Thus, the suitability of an instrument in detecting and quantifying heavy metals in food samples is dependent upon its detection limit.

Table 5. Summary of Student's *t*-test for all targeted elements

Elements	*t*-calculated	*t*-critical	Result
Fe	1.24		No Significant difference
Ca	1.67		No Significant difference
Na	1.91		No Significant difference
K	1.25	2.15	No Significant difference
Cd	11.2		Significant difference
Hg	3.18		Significant difference
Pb	8.11		Significant difference

*Student's *t*-test performed at a 95% confidence interval

Inter-day Precision Study

An inter-day precision study was performed in order to assess the consistency of the determined content of minerals and heavy metals in the studied food samples. Sample collection was repeated on three different days at selected locations. The precision of repeatability is expressed as %RSD. In general, the acceptable level for %RSD is less than 10%[8]. Overall, almost all the elements exhibited a %RSD value above 10%, which suggests the inconsistency of the content of heavy metals and minerals for samples collected on different days. The variability of the element content is most likely a result of the ingredients comprising the food samples. However, it is difficult to ascertain the exact cause for such variation, as there are a wide variety of factors involved.

Conclusion

The heavy metals (Cd, Hg, and Pb) and essential minerals (Fe, Ca, Na, and K) present in Penang Assam Laksa collected from different areas were successfully characterized by using both FAAS/FIMS and ICP-OES. Cadmium and mercury were detected in Penang Assam Laksa at trace levels, whereas lead was found at levels higher than those permitted by Malaysian Food Act 1983 and Food Regulations 1985. Most of the Penang Assam Laksa contained adequate levels of iron, calcium, potassium, and sodium. As determined by Student's *t*-test, both FAAS and ICP-OES can be satisfactorily used in the detection and quantification of minerals, while an inter-day precision test showed variability of the element content in food samples collected on different days. Moreover, the wet-digestion procedure was efficient and suitable for digesting the food samples. In general, this work represents the first scientific study on the element content in Penang Assam Laksa, one of the most famous street foods in Penang. However, the findings stated above cannot be generalized to all Penang Assam Laksa samples, as this study just focused on five selected locations. Instead, this work serves as valuable direction for other researchers in the field. Further studies are needed in order to provide a full picture of the nutritional content in Penang Assam Laksa.

Abstract

Avocado seed is the residue from direct food consumption and fruit processing industry, which is rich in phytochemicals. Ultrasound-assisted extraction (UAE) has been proposed as a cost-effective technique to recover the phytochemicals from plant fractions. Sonication time is one of the parameters that may influence the quantity and quality of phytochemicals isolated from the plant fractions when using UAE. Hence, this study aimed to investigate the effect of different sonication times (0, 20, 40 and 60 min) used in the UAE on the phytochemicals and antioxidant capacity of methanolic avocado seed extract. Results indicated the total phenolic, flavonoid and anthocyanin content of the seed extracts were in the range of 31.90-41.62 mg GAE/100 g, 8.25-12.51 mg RE/100 g, and 8.02-24.57 mg CGE/100 g, respectively. UAE for 60 mins generated the significant highest (p<0.05) amount of phenolic, flavonoid and anthocyanin content. Based on the antioxidant capacity tests, UAE for 60 mins resulted in the highest antioxidant activity.

Keywords: avocado seed, sonication time, phytochemicals, ultrasound-assisted extraction

Abstrak

Biji alpukat merupakan bahan sisa daripada penggunaan secara langsung dan/atau industri pemprosesan buah-buahan, yang kaya dengan fitokimia. Pengekstrakan berbantukan ultrabunyi (UAE) merupakan kos efektif teknologi untuk mengisolasi fitokimia daripada sumber tumbuh-tumbuhan. Dalam kaedah UAE, masa sonikasi adalah salah satu faktor yang mempengaruhi kuantiti dan kualiti fitokimia yang diisolasi daripada sumber tumbuh-tumbuhan. Kajian ini bertujuan untuk analisa kesan masa sonikasi yang berbeza (0, 20, 40 dan 60 minit) dalam UAE terhadap fitokimia dan kapasiti antioksidan ekstrak biji alpukat metanol. Hasil kajian menunjukkan jumlah kandungan fenolik, flavonoid dan antosianin dalam ekstrak biji alpukat adalah dalam lingkungan 31.90-41.62 mg GAE/100 g, 8.25-12.51 mg RE/100 g dan 8.02-24.57 mg CGE/100 g. Penggunaan masa sonikasi 60 minit dalam UAE dapat menghasilkan kandungan fenolik, flavonoid dan antosianin yang paling signifikan banyak (p <0.05). Berdasarkan

ujian kapasiti antioksidan, pengunaan masa sonikasi 60 minit dalam UAE dapat menghasilkan aktiviti antioksidan yang paling tinggi.

Kata kunci: biji alpukat, masa sonikasi, fitokimia, pengekstrakan berbantukan ultrabunyi

Introduction

Avocado, also known as *Persea americana* Mill. or alligator pear, is a tropical and subtropical fruit that has been gaining increasing worldwide demand in recent years due to its relevant nutritional values and health benefits. There are over 100 varieties of avocado fruits have been recorded in the database of California Avocado Society [1]. Hass variety avocado is one of the most widely sought for commercialization [2]. A major portion of Hass avocado is constituted by the pulp (65%) whereas the seed (20%) and peel (15%) make up the rest [3].

Avocado fruits have been primarily used for human consumption, and to a lesser extent, as raw material in the pharmaceutical and cosmetic industries [4]. However, only the pulp of avocado is valued for commercial usance while other fruit fractions such as the seed and peel are considered obsolete and usually throw away as waste products. Hass avocado seed is ovoid shaped with a length of 5 to 6.4 cm. The ivory-colored avocado seed is covered with a thin, brown-colored seed coat that adheres to the flesh cavity when ripe [5].

Proximate analysis done by Saavedra [6] revealed that the Hass avocado seed contained 52.7% of moisture, 2.51% of protein, 1.15% of ash, 1.11% of lipids, and 42.5% of nitrogen-free extract. The seed was also rich in phytochemicals such as phenolic acids, flavonoids and condensed tannins [7]. Based on current findings with regards to the biological effects of avocado seed extracts, they are known to have various ethnopharmacological properties for health-related conditions including anti-cancer, anti-inflammatory, anti-diabetic, anti-hypertensive, hypercholesterolemic, anti-microbial and the application in dermatological [8]. Hence, there has been a growing interest in the extraction of phytochemicals from avocado seeds to be utilized in the food and pharmaceutical industries.

Techniques such as maceration, infusion, heat extraction, enzyme-assisted extraction and Soxhlet extraction are commonly used to extract bioactive compounds from plants [9]. These techniques, however, have numerous limitations including the requirement of high extraction times, solvents and/or temperatures. Although advanced techniques like supercritical fluid extraction, microwave-assisted extraction and accelerated solvent extraction have demonstrated their efficiency in the recovery of phytochemicals, but these techniques are complex in operation and/or not cost-effective.

Ultrasound-assisted extraction (UAE) has been noted as one of the most effective techniques for the isolation of phytochemicals from plant materials [1, 9]. It utilizes acoustic waves to induce cavitation force to disrupt the plant cell wall, consequently enhancing the extraction rate of phytochemicals. Sonication time, solvent composition, sonication temperature, solid-solvent ratio and sonication frequency are the parameters that may influence the quantity and quality of phytochemicals isolated from the plant materials when using UAE [1, 9]. Among these parameters, sonication time was reported to have the greatest influence on the quality of plant extracts [10].

Industrial processing of avocado fruits produces a large number of seeds as wastes. Exploiting the phytochemicals of avocado seed waste may lead to new products and add value to the food industry. Therefore, this study aimed to investigate the effect of different sonication times on the UAE of phytochemicals and antioxidant activity of avocado seed extract.

Materials and Methods

Sample preparation

Hass variety avocado fruits were purchased from a local retailer in 2019. The fruits were kept at room temperature (25 ± 5°C) until ripe. Ripe avocado fruit,

as indicated by changes in peel color (from green to purplish-black) and gentle pressure felt when held in the palm, were manually separated into seed, peel, and pulp. The outer coat layer of the seed was peeled off before being cut into slices with an average thickness of 5 mm [6], followed by drying in a lab-scale freeze dryer (Liobras L101, Brazil). The lyophilized seeds were milled into fine powder by using an electrical blender (Panasonic MX-799S, Malaysia) and sieved through a 250 µm stainless steel sieve. The powdered sample was kept in an air-tight container at -5°C until use.

Chemicals and reagents

Analytical reagent grade of methanol, glacial acetic acid, hydrochloric acid (37%) was purchased from Fisher Scientific (Massachusetts, U.S.). Folin-Ciocalteu reagent, sodium carbonate, gallic acid, sodium nitrite, aluminium chloride hexahydrate, sodium hydroxide, rutin, 2,4,6-Tripyridyl-S-triazine (TPTZ), 2,2-diphenyl-1-picrylhydrazyl (DPPH), iron (III) chloride and iron (II) sulphate were purchased from Sigma–Aldrich (St. Louis, USA).

Ultrasound-assisted extraction

Approximately 1 g of avocado seed powder was mixed with 15 mL of 80% methanol in a 50 mL dark reagent bottle. The mixture was subjected to different sonication times (0, 20, 40 and 60 mins) in an ultrasonic bath [Elmasonic 100 H, Germany; 37 kHz ultrasonic frequency; 600 W ultrasonic output power; 11.8″ x 9.4″ x 5.9″ (L x W x H) internal dimensions] operated at a constant temperature of 30°C. Extraction time and ultrasonic temperature were regulated from the panel of the instrument. A centrifuge set at 4,000 rpm for 10 mins at room temperature was used to separate the methanolic seed extract from the powdered sediment. The extract was then transferred into a dark bottle using a pipette and kept at 4°C until use.

Phytochemicals

Determination of total phenolic content

The TPC was determined by the Folin-Ciocalteu method described by Tan and Azrina [11]. Briefly, 600 µL of methanolic seed extract was diluted with the same amount of distilled water in a test tube and subsequently added with 300 µL of 1 N Folin-Ciocalteu reagent and 600 µL of 2.0% Sodium carbonate. The mixture was incubated in the dark for 30 min. The absorbance was measured at 750 nm using a spectrophotometer (DLAB Scientific SP V1000, China) against a blank. A standard curve was plotted by using different gallic acid concentrations (0.20, 0.70 and 0.90 mg/mL) for TPC calculation. The results were expressed as mg gallic acid equivalent (GAE) per 100 g of samples on the basis of fresh weight (mg GAE/100 g).

Determination of total flavonoid content

The TFC was determined by the aluminium chloride colorimetric method described by Sharma and Agarwal [12]. Exactly 100 µL of methanolic seed extract was pipetted into a test tube containing 4 mL of distilled water and 0.15 mL of 5% sodium nitrite solution. After 6 min of incubation at room temperature, 0.15 mL of 10% aluminium chloride solution, 2 mL of 4% sodium hydroxide solution and 0.2 mL of distilled water were added into the mixture and vortexed. The mixture was allowed to stand for 15 mins. The absorbance was recorded at 510 nm using a spectrophotometer (DLAB Scientific SP V1000, China) against a blank. A standard curve was plotted by using different rutin concentrations (7.0, 9.0, 11.0, 13.0 and 15.0 mg/mL) for TFC calculation. The results were expressed as mg rutin equivalent (RE) per 100 g of samples on the basis of fresh weight (mg RE/100 g).

Determination of total anthocyanin content

The TAC was determined according to the method of Granato et al. [13]. Exactly 1000 µL of methanolic seed extract was pipetted into a 25 mL volumetric flask and diluted with distilled water to volume. The absorbance of the mixture was measured at 535 nm using a spectrophotometer (DLAB Scientific SP V1000, China) against a blank. The results were expressed as mg cyanidin-3-glucoside equivalent (CGE) per 100 g of samples on the basis of fresh weight (mg CGE/100 g).

Antioxidant activity

Determination of ferric ion reducing antioxidant power

The FRAP was determined according to the method of Bagheri et al. [14]. Freshly prepared FRAP reagent was obtained by mixing 2.5 mL of 10 mM TPTZ in 40 mM hydrochloric acid, 2.5 mL of 20 mM ferric chloride solution and 24 mL of 300 mM acetate buffer (pH 3.6). Then, 40 µL of methanolic seed extract was pipetted into 1.2 mL of the FRAP reagent and incubated at 37°C for 10 mins. The absorbance of the mixture was measured at 593 nm using a spectrophotometer (DLAB Scientific SP V1000, China) against a blank. A standard curve was plotted by using different concentrations of iron (II) sulfate solution (0.01, 0.03 and 0.06 mg/mL) for FRAP calculation. The results were expressed as mmol Fe^{2+} per kg of samples on the basis of fresh weight (mmol Fe^{2+}/kg).

Determination of DPPH radical scavenging activity

The DPPH radical scavenging activity was determined according to the method of Ghafoor et al. [15]. Briefly, 0.25 mL of methanolic seed extract was mixed with 2 mL of 30 mg/L freshly prepared DPPH solution in methanol. The mixture was vigorously shaken and incubated at room temperature for 5 mins. A decline in absorbance was measured at 517 nm using a spectrophotometer (DLAB Scientific SP V1000, China) against a blank. Pure methanol was used as a negative control. The results were expressed as the percentage of antiradical activity (AA) of the extract on DPPH radicals relative to the control.

Statistical analysis

Statistical analyses were performed using IBM SPSS Statistic 26.0 for Windows (SPSS Inc., Chicago, USA). Data was summarized and expressed as mean ± standard deviation. Mean value refers to three analytical replicates. Comparison of mean differences among different sonication times (0, 20, 40 and 60 mins) was conducted using a one-way analysis of variance accompanied by Tukey's post hoc analysis. The association between bioactive compounds and antioxidant capacity was evaluated using Pearson correlation test. Statistical significance was set at $p < 0.05$.

Results and Discussion

Total phenolic, flavonoid and anthocyanin content

Various extraction media (methanol, ethanol, butanol, chloroform, ethyl acetate and water) have been utilized to extract the bioactive compounds from different fractions of fruits, either in pure form or in diluted form. In the present study, 80% methanol was selected as the media to prepare avocado seed extract. This is because 80% methanol has been deemed as a common medium to isolate the lipophilic and hydrophilic bioactive compounds of plant fractions [16].

The TPC, TFC and TAC of methanolic seed extracts sonicated at different times (0-60 mins) are shown in Table 1. Generally, increased sonication time enhanced the extraction of phenolics, flavonoids and anthocyanins from the avocado seed. This could be associated with the cavitation force produced by ultrasonic waves, which disrupt the integrity of plant cell walls and aid in the release of phytochemicals [9].

Phenolic compounds are secondary products produced by the metabolism of plants. They are widely recognized to have antioxidant characteristics, which could provide protection against oxidation induced by metal cations [7]. Avocado seed has been proposed as a potential food waste product for phenolic extraction [17]. It has been reported that the medicinal properties of avocado seed are attributed by its high phenolic compounds. As reported by Bahru et al. [18], the phenolic content of avocado seed (64%) was higher than its peel (23%) and pulp (13%). The TPC of methanolic seed extracts obtained from different sonication times was in the range of 31.90 to 41.62 mg GAE/100 g (Table 1). Application of UAE for 60 mins significantly increased ($p < 0.05$) the yield of phenolic content for 30%, as compared with the control without UAE at 0 min. Previously, the TPC of non-ultrasound assisted avocado seed extracts obtained from 70% methanol and 80% methanol were reported to be 2.92 mg GAE/100 g and 0.09-0.13 mg catechin equivalent (CE)/100 g, respectively [19, 20]. These values were much lower than the present study, possibly due to the different experimental protocols used in TPC analysis. As stated by Singh et al. [21], there are no standard method to determine phenolic compounds of plant seed

extracts and the parameters used (e.g. solute to solvent ratio, particle size of the seed samples and agitation rate) in the preparation of seed extract could affect the yield of TPC.

Flavonoid compounds are secondary metabolites corresponding to phenolics and are one of the most studied bioactive compounds due to their diverse benefits in human health. The TFC is analyzed based on color change due to the reaction between aluminium chloride and flavonoid compounds in the methanolic seed extract. Previous study reported the TFC of water and ethanolic avocado seed extract were 3.72 and 4.96 mg RE/100 mL, respectively [22]. These values were comparable with the results of the present study. In Table 1, application of UAE for 60 mins significantly increased (p <0.05) the yield of flavonoid content for 52%, as compared with the control without UAE at 0 min. A similar observation was reported by Ramić et al. [23], in which the TFC of ethanolic chokeberries extract was highest when sonicated for 60 min.

Anthocyanins are naturally occurring pigments that belong to the group of flavonoids. The flavylium cation form of anthocyanins requires a sufficiently acidic medium to maintain its stability, but not to the extent that can cause acyl moieties in acylated anthocyanins to be hydrolyzed [24]. It is difficult to achieve optimal protocol of extraction due to the diversity of anthocyanins structure and their sensitivity to heat, metal complexes, pH, and co-pigmentation. Hence, this study utilizes a method that quantifies TAC without requiring the use of chemical standards to plot a calibration curve. In Table 1, the application of UAE for 60 mins significantly increased (p <0.05) the yield of anthocyanin content for 102%, as compared with the control without UAE at 0 min. This may be due to the simultaneous enhancement of fragmentation and hydration from acoustic cavitation of UAE improves the mass transfer of anthocyanin compounds into the extraction solvent [9]. There has been limited data on the anthocyanin content of avocado seed extract documented thus far. Our current study demonstrated the effectiveness of UAE application in enhancing the yield of anthocyanin in avocado seed extract. Further study on quantifying the individual anthocyanin compound of avocado seed extract following UAE of 60 mins could be conducted.

Table 1. Phenolic, flavonoid and anthocyanin content of methanolic avocado seed extract

Sonication Time (mins)	TPC (mg GAE/100 g)	TFC (mg RE/100 g)	TAC (mg CGE/100 g)
0	31.90 ± 0.09[a]	8.25 ± 0.03[a]	8.02 ± 0.38[a]
20	32.20 ± 0.09[b]	8.74 ± 0.01[b]	16.04 ± 0.38[b]
40	32.26 ± 0.09[b]	8.81 ± 0.02[c]	21.26 ± 0.22[c]
60	41.62 ± 0.09[c]	12.51 ± 0.02[d]	24.57 ± 1.59[d]

Mean values in the same column with different letters are significantly different at p <0.05

FRAP and DPPH radical scavenging activity

Antioxidant capacity of methanolic seed extract from UAE was determined using two different antioxidant capacity assays and the finding results are shown in Table 2. Both FRAP and DPPH assays involved scavenging free radicals through electron transfer mechanism. As can be seen in both antioxidant capacity methods used, application of UAE at 60 mins had the highest antioxidant capacity, followed by 40 and 20 mins, while the control had the lowest antioxidant capacity. This shows the longest sonication time, the highest antioxidant activity in the methanolic seed extract. A similar observation was reported by Gómez et al. [25]. Their study demonstrated that the antioxidant activity of ethanolic avocado seed extract, as measured by oxygen radical antioxidant capacity assay, was the highest (158.77 mg Trolox Equivalents/g) when the longest sonication time (55 mins) was used during UAE.

Table 2. Antioxidant activities of methanolic avocado seed extract

Sonication Time (mins)	FRAP (mmol Fe^{2+}/kg)	DPPH (%)
0	0.72 ± 0.00^{a}	28.20 ± 1.42^{a}
20	0.96 ± 0.00^{b}	36.54 ± 0.83^{b}
40	1.19 ± 0.02^{b}	83.47 ± 0.19^{c}
60	1.72 ± 0.00^{c}	84.96 ± 1.20^{c}

Mean values in the same column with different letters are significantly different at $p < 0.05$

Correlation between phytochemicals and antioxidant activity

Correlation between phytochemicals (TPC, TFC and TAC) and antioxidant activities (FRAP and DPPH) are shown in Table 3. Positive correlation ($p < 0.05$) was found between total phenolic, flavonoid and anthocyanin content and antioxidant activity measured by FRAP and DPPH, indicating these phytochemicals contribute high antioxidant activity in the extract. This observation is in agreement with Wang et al. [26], who reported the high antioxidant capacity in Hass avocado seed extract was due to the high concentration of flavonoid and phenolic content. Sonication time is a significant factor that influences the extraction of plant phytochemicals and their antioxidant activity. This may be contributed by the cavitation effect of the ultrasound improved the fragmentation, swelling, hydration and pore production of the plant tissue matrix where the phytochemicals are to be isolated [27]. This will enhance the exposure of the phytochemicals and the extraction medium and help their release into the solvent, thereby increasing the antioxidant activity.

Table 3. Correlation between phytochemicals and antioxidant activity of methanolic avocado seed extract

	TPC	TFC	TAC	FRAP	DPPH
TPC	1	0.995**	0.675*	0.908**	0.609*
TFC		1	0.738**	0.940**	0.657*
TAC			1	0.916**	0.916**
FRAP				1	0.859**
DPPH					1

** Correlation was significant at $p < 0.01$

* Correlation was significant at $p < 0.05$

Conclusion

Avocado seed is the by-product of direct food consumption and food processing industry which could be further utilized to develop nutraceutical products. The TPC, TFC and TAC of methanolic seed extract were in the range of 31.90-41.62 mg GAE/100 g, 8.25-12.51 mg RE/100 g and 8.02-24.57 mg CGE/100 g, respectively. All phytochemicals and antioxidant activity demonstrated a positive and significant correlation. Efficacy of the UAE in terms of sonication time was demonstrated in this study. Sonication for 60 mins leads to the highest extraction yield of phenolic, flavonoids and anthocyanin content in methanolic seed extract. Further study to quantify the individual bioactive compound of avocado seed extract following UAE application of 60 mins could be carried out.

Abstract

Kelulut honey (KH) is honey produced by stingless bees (Trigona spp.) found in Malaysia. This study investigated the difference inherent in the chemical composition of kelulut honey collected from the east coast, and the central and northern regions of Peninsular Malaysia. Total sugar content, individual sugar content, total phenolics, total flavonoids, ascorbic acid, ascorbic acid equivalent antioxidant content (AEAC), and proline content were determined. Sugar analysis revealed that kelulut honey contained 62.33-79.53 g/100g of total sugar, with maltose as the predominant sugar (15.85-37.74 g/100g), followed by fructose (9.91-53.64 g/100g), glucose (10.96-25.04 g/100g), and sucrose (0.54-3.48 g/100g). The results indicate that total flavonoids (78.95±0.70 mg QE/kg) and phenolics (1149.48±40.52 mg GAE/kg) were the highest in honey from the east coast region. The proline and ascorbic acid content were less likely to be affected by geographical factors. Kelulut honey possesses a unique sugar profile that may contribute to its unique taste. In conclusion, the geographical and floral origin of honey are the two most important factors that fundamentally affect the physical-chemical properties of honey samples.

Abstrak

Madu kelulut (KH) ialah madu yang dihasilkan oleh lebah tidak bersengat (Trigona spp.) yang terdapat di Malaysia. Kajian ini menyelidik perbezaan komposisi madu kelulut yang dikumpul dari pantai timur, tengah dan utara Semenanjung Malaysia. Jumlah dan gula individu, jumlah fenolik, jumlah flavonoid, asid askorbik, asid askorbik kandungan antioksidan setara (AEAC) dan kandungan prolin telah ditentukan. Analisis kandungan gula menunjukkan bahawa madu kelulut mengandungi 62.33-79.53 g/100g jumlah gula dengan maltosa sebagai gula utama (15.85-37.74 g/100g), diikuti oleh fruktosa (9.91-53.64 g/100g), glukosa (10.96-25. 100g) dan sukrosa (0.54-3.48 g/100g). Jumlah flavonoid (78.95±0.70 mg QE/kg) dan fenolik (1149.48±40.52 mg GAE/kg) adalah tertinggi dalam madu dari pantai timur. Prolin dan asid askorbik adalah kurang berkemungkinan dipengaruhi oleh faktor geografi. Madu kelulut mempunyai profil gula yang unik yang mungkin menyumbang kepada rasa unik madu

kelulut. Secara kesimpulannya, geografi dan floral madu adalah dua parameter kualiti penting yang pada asasnya mempengaruhi sifat fizikal-kimia sampel madu.

Introduction

Honey is a natural food consisting of about 200 different compounds including sugars, phenolics, amino acids, enzymes, organic acids, and aromatic compounds. Honey composition varies by bee species, nectar source, and geographic origin [1]. Honey is not only known for its nutritional benefit, but also as traditional medicine due to its healing properties. It has been proven that honey exert antioxidant, anti-inflammatory, anti-bacterial and anti-mutagenic properties. The antioxidant activity assay for any product is based on the capability of the compounds to inhibit oxidation. The DPPH and FRAP assays are typically chosen because they are simple and rapid methods for assessing a honey sample's antioxidant capacity. These two assays are based on different principles, and thus may be used to screen compounds that have different antioxidant mechanisms. Recently, there is an increase in the Malaysian consumer demand for honey, especially for health maintenance and promotion purposes. There has been a surge of interest in honey's capacity as an antioxidant and its protective effects on the brain and other organs [2]. *Kelulut* honey is produced by the stingless bees that are indigenous to Malaysia. A local study reported that a low dose of *Kelulut* honey taken orally could improve wound healing rate in epidermal keratinocyte *in vitro* wound healing model [3]. It has also been reported to have a potential in preventing damage to sperm and testes in diabetic rats [4]. *Kelulut* honey is a multifloral honey which does not have any predominant pollen present in it. The nutritional profile and composition of this honey is still understudied. Over the decades, research on Malaysian honey production has been focused on *Apis* spp. which left a gap to be bridged by research work on *kelulut* honey. The effect of different botanical and geographical environment on honey chemical composition could be studied by comparing the honey of a particular type produced in different localities. Previous studies indicated that the nectar source can affect the antioxidant content and the antibacterial and radical scavenging activities of the honey [5]. Bioactive compounds from the plant are secreted into the nectar, thereby impacting the quality of honey and its medicinal properties that are very dependent on its bioactive composition. The present study was undertaken to study the compositional variations of *kelulut* honey collected from different locations in peninsular Malaysia.

Materials and Methods

Sample collection

Kelulut honey from *Heterotrigona itama* species were collected from three peninsular Malaysia regions, namely the east coast region, the northern region, and the central region. The honey samples were collected from each region in two different batches. Each batch were analyzed in triplicates, and the results were expressed as an average ± standard deviation of six replicates from samples collected in two batches.

Individual and total sugar analysis using HPLC

The composition of individual sugars in *kelulut* honey samples was determined using high performance liquid chromatography (HPLC) [6]. About 1 g of honey sample was weighed and loaded into a 50 mL centrifuge tube. 25 mL of 50:50 acetonitrile/deionized water was added into the tube. The sample was then filtered using a 0.45 μM nylon filter. The purified sugar extract was analyzed using a HPLC Waters model 2707 with an XBridge Amide column (250 x 4.6mm, 3.5μM) coupled with Water RI-2414 refractive index detector. The mobile phase was acetonitrile/deionized water (75:25). The injection volume was 20 μL with flow rate of 1.0 mL/min. The retention time for each sugar was determined by comparing with a known standard sugar solution consisting of fructose, glucose, sucrose, and maltose with a concentration of 0.5 g/10 mL. The composition of the individual sugar was calculated using Empower 2 software.

Total sugar content using chemical analysis

Total sugar content in *kelulut* honey were also determined using the phenol-sulphuric acid method [7]. This analysis was performed in this study because honey also contains a small amount of oligosaccharides that the HPLC method could not detect. For this analysis, 0.1 g of honey sample was diluted 100-fold and the solution was homogenized, 1 mL of the new solution was 20-fold diluted. A 2 mL aliquot of the honey solution was combined with 1 mL of 5% aqueous phenol solution in a test tube. 5 mL of concentrated sulphuric acid was then added rapidly to the mixture. The mixture was allowed to stand for 10 min and subsequently vortexed for 30 seconds. The test tube was then placed in a water bath at room temperature for 20 minutes for color development. The absorbance was then recorded on a spectrophotometer (Secomam, France) at 490 nm. Glucose solutions 0f 0.0-0.1 g/L were used as standard.

Total phenolic content

The Folin-Ciocalteu assay [8] was used to determine the total phenolic content in *kelulut* honey. 0.5 mL of the 10% honey solution was mixed with 2.5 mL of 0.2 N Folin-Ciocalteu reagent, and the mixture was left to stand for 5 minutes. Then, 2 mL of 7.5% sodium carbonate solution was added. The mixture was allowed to stand at room temperature for 2 hours. The absorbance of the mixture was then measured at 760 nm using spectrophotometer (Secomam, France) against methanol as blank. Gallic acid (50-200 mg/L) was used to produce standard curve (R^2 = 0.987). The total phenolic content was expressed in mg of gallic acid equivalent (GAE)/kg honey.

Total flavonoid content

The total flavonoid content in the honey samples was analyzed using the method described by Zhishen et al. [9]. A 1 mL volume of 20% honey was mixed with 4 mL of distilled water and 0.3 mL of sodium nitrite. After 5 minutes, 0.3 mL of 10% aluminum chloride was added followed by 2 mL of 1 M sodium hydroxide six minutes later. The volume was made up to 10 mL by distilled water, and the mixture was shaken thoroughly. The absorbance was read using spectrophotometer (Secomam, France) at 510 nm wavelength. A standard curve was plotted using a quercetin solution with concentrations ranging between 25 - 100 µg/mL (R^2 = 0.987). The results were expressed as mg quercetin equivalent (QE)/kg honey.

Proline content

The proline content in the honey sample was determined using the method described by Bogdanov et al. [10]. A 0.5 mL sample of honey (0.05 g/mL) was mixed with 1 mL of formic acid (80%) and 1 mL of ninhydrin solution (3% in ethylene glycol monomethylether). The mixture was shaken vigorously for 15 minutes. The mixture was incubated in a boiling water bath for 14 minutes before being transferred to a 70 ºC water bath for 10 minutes. A 5 mL 50% propanol-water solution was added, and the mixture was allowed to cool for 45 minutes. Its absorbance at 510 nm was measured. Water was used as the blank and a 0.032 mg/mL proline solution was used as the standard. Proline content (mg/kg) was calculated as follow:

$$Proline = \frac{E_s}{E_a} X \frac{E_1}{E_2} X80 \quad (1)$$

where E_s is the absorbance of the sample solution; E_a is the absorbance of the proline solution; E_1 is the concentration of proline in mg used for the standard; E_2 is the weight of honey in g; 80 is the dilution factor.

Ascorbic acid content determination

The honey sample (100 mg) was extracted with 10 mL of metaphosphoric acid for 45 minutes at room temperature and the mixture was filtered through a filter paper. About 1 mL of the filtrate was mixed with 9 mL of 2,6-dichlorophenolindophenol and the absorbance was determined at 515 nm within 30 min. L-ascorbic acid (0.02-0.12 mg/mL) was used as standard [11].

Ascorbic acid equivalent antioxidant content

AEAC was performed according to the procedure described by Meda et al. [12]. A 0.75 mL samples of honey in methanol (0.04 g/mL) was mixed with 1.5 mL of 0.02 mg/mL methanolic DPPH radical solution. The mixture was left for 15 minutes at room temperature before its absorbance was measured using a spectrophotometer (Secomam, France) at 517 nm. The

blank sample was prepared from a mixture of 0.75 mL of honey solution and 1.5 mL of methanol.

Carotenoid content

The measurement of carotenoid in *kelulut* honey was performed based on the method described by Ferreira et al. [11]. A 100 mg honey sample was shaken with a 4:6 ratio mixture of acetone and hexane for 1 minute. The mixture was filtered with filter paper and the absorbance of the filtrate was measured using a spectrophotometer (Secomam, France) at 454 nm, 505 nm, and 663 nm. The content of β-carotene inside the sample was calculated using the equation $0.216A_{663} - 0.304A_{505} + 0.452A_{453}$ while the lycopene content was calculated using the equation $-0.0458A_{663} + 0.372\ A_{505} - 0.0806\ A_{453}$. The total carotenoid content is defined as the sum of β-carotene and lycopene, and all measurements were expressed in mg/100mL.

Anti-oxidative activities

The DPPH radical scavenging capacity of *kelulut* honey was investigated using the procedure described Ferreira et al. [11]. Approximately 0.5 mL of the 0.2 g/mL honey extract was mixed with 2.7 mL of methanolic 0.024 mg/mL DPPH radical solution. The mixture was vigorously shaken and incubated for 15 minutes, then its absorbance was measured at 517 nm. IC_{50} was defined as the concentration of a substance that would scavenge 50% of DPPH radicals, which means that a lower IC_{50} value corresponds to a stronger antioxidant property. The FRAP assay was performed using the procedure described by Benzie & Strain [13]. A 200 µL sample of 0.1 g/mL honey was mixed with 1.5 mL of the FRAP reagent prepared from acetate buffer (300 mM/L), 2,4,6-tris(2-pyridyl)-*s*-triazine (TPTZ) solution (10 mM in 40 mM/L HCl), and ferric chloride ($FeCl_3.6H_2O$) (20mM) in the ratio of 10:1:1. The mixture was pre-warmed at 37 °C for 4 minutes before its absorbance was measured at 593 nm using a spectrophotometer (Secomam, France). Ferrous sulfate ($FeSO_4.7H_2O$) solutions with concentrations between 250-1000 µM/L was used to construct the standard curve (R^2=0.991). The FRAP values were expressed as µM Fe (II) per kg honey.

Data analysis

IBM SPSS version 23 was employed for the statistical analyses. ANOVA with Tukey's Honest Significant Difference (HSD) test was used for the comparisons of the chemical compositions of *kelulut* honey from three different zones. Pearson correlation was used to establish correlation between bioactive compounds and anti-oxidative activities. The significant level was set as α=0.05.

Results and Discussion

The compositional analysis revealed that the *kelulut* honey samples from *Trigona* spp. Collected in this study contained fructose and glucose at the concentrations of 9.91-27.33 g/100g and 10.96-25.04 g/100g, respectively (Table 1). Maltose was the predominant sugar of *kelulut* honey from the east coast and central regions of Peninsular Malaysia. The total sugar content of *kelulut* honey was 62.3-79.53 g/100g. The honey also contained oligosaccharides as the minor sugar constituents. In this study, the oligosaccharide content of *kelulut* honey was estimated by subtracting the individual sugars analyzed using HPLC from the total sugars analyzed using the phenol-sulphuric acid method. The results showed that *kelulut* honey contained 3.84-14.68 g/100g of oligosaccharides.

The total phenolic content of the *kelulut* honey samples collected in the present study was in the range of 530.28-1166.77 mg GAE/kg while the total flavonoid content was in the range of 48.82-79.02 mg QE/kg (Table 2). *Kelulu*t honey samples collected from the east coast region contained the highest level of carotenoids at 1.52 ± 0.17 mg lycopene/kg and 3.09 ± 0.25 mg β-carotene/kg. The total carotenoid content of *kelulut* honey samples in this study ranged between 2.22-4.61 mg carotenoids/kg. The proline content of *kelulut* honey in the present study was 277.76-291.89 mg/kg. The ascorbic acid content of the *kelulut* honey was within the range of 75.71-95.85 mg/kg. The central region *kelulut* honey had a significantly higher (p<0.05) ascorbic acid content compared to the east coast and northern *kelulut* honey. Meanwhile, the AEAC of *kelulut* honey was 78.10-146.48 mg/kg. Ascorbic acid in the *kelulut* honey contributed 65.44-96.94% to AEAC.

Table 1. Types of sugar in *kelulut* honey

Sugars	**East Coast Region Honey (n=6)**	**Northern Region Honey (n=6)**	**Central Region Honey (n=6)**
Total sugars (g/ 100g)	62.33 ± 10.33^{a}	79.53 ± 13.22^{b}	64.28 ± 19.63^{ab}
Maltose (g/100g)	22.80 ± 1.74^{a}	15.85 ± 0.05^{b}	37.74 ± 8.57^{c}
Fructose (g/100g)	10.41 ± 0.18^{a}	27.33 ± 0.15^{b}	9.91 ± 3.99^{a}
Glucose (g/100g)	10.96 ± 0.18^{a}	25.04 ± 0.14^{b}	11.98 ± 1.68^{a}
Sucrose (g/100g)	3.48 ± 0.65^{a}	0.54 ± 0.01^{b}	0.81 ± 0.22^{c}

Total sugar was obtained from phenol-sulphuric acid method while individual sugars were analyzed using HPLC. Different superscripts across the same row indicates significant difference (p <0.05).

Table 2. Phenolic, flavonoid, proline, ascorbic acid content and AEAC of *kelulut* honey

Parameters	**East Coast Region Honey (n=6)**	**Northern Region Honey (n=6)**	**Central Region Honey (n=6)**
TPC (mg GAE/kg)	1166.77 ± 47.85^{a}	728.42 ± 58.06^{b}	530.28 ± 30.31^{c}
TFC (mg QE/kg)	7902 ± 0.59^{a}	48.82 ± 0.67^{b}	55.38 ± 0.37^{b}
AEAC (mg/kg)	146.48 ± 6.43^{a}	78.10 ± 3.75^{b}	96.92 ± 1.31^{c}
Ascorbic acid content (mg/kg)	95.85 ± 13.48^{a}	75.71 ± 12.69^{a}	92.79 ± 0.75^{a}
Proline (mg/kg)	277.76 ± 19.75^{ab}	291.89 ± 3.46^{a}	284.82 ± 10.72^{b}
Lycopene (mg/kg)	1.52 ± 0.17^{a}	0.64 ± 0.08^{b}	0.76 ± 0.08^{c}
β-carotene (mg/kg)	3.09 ± 0.25^{a}	1.58 ± 0.14^{b}	1.57 ± 0.05^{b}
IC_{50} (DPPH radical scavenging) (mg/mL)	15.17 ± 1.02^{a}	28.47 ± 2.03^{b}	24.27 ± 2.68^{c}
FRAP (μM Fe (II)/ kg)	7481.08 ± 57.57^{a}	4122.97 ± 424.44^{b}	3633.78 ± 127.21^{c}

Different superscripts across the same row indicates significant difference (p <0.05)

The DPPH and FRAP assays were chosen because they are simple and rapid methods for assessing the antioxidant capacity of honey. The FRAP assay measures the ferric-reducing capacity of antioxidants, whereas the DPPH assay measures the ability of antioxidants to scavenge the DPPH radical. These two assays are based on different principles, and thus may be used to screen compounds that have different antioxidant mechanisms. *Kelulut* honey exhibited IC_{50} values in the range of 15.17-28.46 mg/mL. The honey collected from the east coast region showed the strongest DPPH radical scavenging activity with the lowest IC_{50} value of 15.17 ±1.02 mg/mL. The reducing power of *kelulut* honey assessed using FRAP was outlined in the order of east coast region *kelulut* honey > northern region *kelulut* honey > central region *kelulut* honey. The FRAP values were in the range of 3633.78-7481.08 μM Fe (II)/ kg.

The IC_{50} of the honey samples had a significant inverse correlation (p<0.01) with their bioactive compound compositions, namely total phenolics, total flavonoids, lycopene, β-carotene, ascorbic acid, and AEAC (Table 3). Their FRAP also had a significant and inverse

correlation ($p<0.01$) with their bioactive compound compositions, namely total phenolics, total flavonoids, lycopene, β-carotene and AEAC. The IC_{50} and FRAP had a strong inverse correlation ($r=-0.868$, $p<0.01$). The correlation matrix indicated the importance of the bioactive constituents of honey to its anti-oxidative capacity. The total phenolic content of a honey sample was negatively correlated with its IC_{50} value ($r^2 = -0.789$; $p<0.05$) and positively correlated with the FRAP value ($r^2 = 0.970$; $p<0.05$). In addition, a significant negative correlation was found between the honey sample's ascorbic acid composition and its IC_{50} value ($r^2 = -0.545$; $p<0.05$) and a positive correlation was found between its ascorbic acid composition and its lycopene value ($r^2 = 0.634$; $p<0.01$). These correlations between the bioactive compound content and the antioxidant activity of the extracts suggest that phenolic compounds are primarily responsible for the antioxidant activity of the honey samples as measured in the DPPH and FRAP assays.

Table 3. Correlation matrix of antioxidant content and anti-oxidative activities

	TPC	**TFC**	**IC_{50}**	**FRAP**	**Lycopene**	**β-carotene**	**Ascorbic Acid**	**AEAC**

The fructose and glucose content of the *kelulut* honey samples gathered in this study were lower than those reported in the literature. Honey produced by stingless bees in the semi-arid region of Northeastern Brazil [14] has fructose as its predominant sugar (50.0-59.2 g/100g), followed by glucose (37.7-45.7 g/100g) and sucrose (0.7-3.9 g/100g). Ecuadorian stingless bee honey contained similar amounts of glucose (25.5 g/100g) and fructose (25.2 g/100g) with a smaller amount of sucrose (3.72 g/100g) [15]. Biluca et al. [16] also reported that the stingless bee honey from Santa Catarina, Brazil, contained 8.21-31.3 g glucose/100g and 30.4-46.1 g fructose/100g, while the honey from *Trigona fuscipennis* contained 36.22 g fructose /100g and 20.4 g glucose /100g. The amount of glucose and fructose measured were in accordance with the Malaysian Standard specification on kelulut stingless honey (MS 2683:2017), which dictates that it contains less than 7.5% sucrose and less than 85% fructose. The high concentration of sugar in honey combined with an acidic pH (3-5) do retard the growth of bacteria in honey [17].

The maltose content of the honey samples collected in the current study exceeded the limit set by the Malaysian Standard on kelulut stingless honey (MS 2683:2017), which dictated that the maltose content should be less than 9.5%. However, the current findings were in line with a recent study conducted by Chuttong et al. [18] which reported that Thai stingless bee honey contained 41 g maltose /100g, 17 g fructose/100g, 14 g glucose/100g and 1.2 g

sucrose/100g. An earlier study [19] also reported the *Trigona* honey, specifically of *Frieseomelita aff varia,* contained maltose as the predominant sugar (32.3%), followed by fructose (24.2%), glucose (18.1%), and sucrose (0.2%). The total sugar in our study were higher than those reported for Thai stingless bee honey (55±21 g/100g) [18]. The total sugar content of the *kelulut* honey in the current study was within the range of total sugars reported for Brazilian stingless monofloral honey (62.7-71.2 g/100g) [14]. The sucrose content (0.54-3.48 g/100g) obtained in this study was within the limit set by Codex Alimentarius (2001) [20] which is less than 5g/100g. *Kelulut* honey has a different sugar profile compared to the typical *Apis* spp. honey that contains fructose and glucose as the predominant sugar. This sugar profile in kelulut honey may contribute to its distinct flavor. Previous studies indicated that honey contains the oligosaccharides nigerose (1.11±2.81%), turanose (0.78±2.03%), maltotriose (0.24±1.03%), melezitose (0.21±0.37%) and raffinose (0.10±0.25%) that may also be present in *kelulut* honey.

Phenolic compounds play a role in countering the damage that oxidative stress incurs on the body. Having these active compounds makes the stingless bee honey valuable for medicinal purpose [21]. The vast difference in the phenolic content of the honey samples collected from the three different regions may be attributed to the differing bee species that produce those honey. A study showed the honey samples collected from three stingless bee species, namely *Geniotrigona thoracica*, *Heterotrigona itama,* and *Heterotrigona erythrogastra,* had significant differences in their phenolic content, which were 99.04 ± 5.14, 67.86 ± 7.40, 44.72 ± 6.50 mg/mL, respectively [22]. Apart from the different species of bees, geographical and botanical origins could explain the variation of phenolics content in stingless bee honey. Biluca et al. [16] reported that various stingless bee honey samples contained 10.3-98.0 mg GAE/100g phenolics while Silva et al. [23] reported a range of 1.1-1.3 mg GAE/g of phenolics found in stingless bee honey.

Furthermore, the total flavonoid content of *kelulut honey* were in fair agreement with results reported by Chan et al. [24], in which *Trigona* spp. honey from Malaysia contained 44.60-79.13 mg QE/kg. Tuksitha et al. [22] reported a higher flavonoids range (12.41-17.67 mg/mL) for stingless bee from Borneo. Previous study reported that various kinds of Hungarian honey contained 252-2283 mg proline /kg [23]. The value obtained in this study was within the range. The protein content of floral honey is 1.0-1.5% and the amino acid content is 1.0% of the total protein in honey. Proline is the main amino acid present in honey, constituting 50-85% of the total amino acids [23]. The proline content of honey decreases at a constant rate during storage; thus, it acts as an indicator of ripeness [23]. The minimum value of 180 mg/kg of proline is accepted for pure honey [26]. The value of ascorbic acid obtained in this study was lower than those obtained in Portuguese honey (140.01-145.80 mg/kg [11] and Algerian honey (159.70±0.78 mg/kg). A previous study [27] reported that Algerian honey contained 0.30-1.01 mg carotenoids/ 100 g.

A more recent study reported that floral honey from Tunisia contained 1.16-4.72 mg carotenoids/kg [28]. The carotenoid content of the *kelulut* honey samples collected from the three regions were significantly different (p <0.05), indicating the influence of geography on carotenoid content. Environmental factors and the changing seasons also contribute to the carotenoid content in honey [28]. The ascorbic acid content measured in this study was lower than those measured in Portuguese honey (140.01-145.80 mg/kg) [11] and Algerian honey (159.70±0.78 mg/kg). The value of AEAC in the present study was lower than those reported from other countries such as India (15.1-29.5 mg AEAC/100g) [29] and Bangladesh (18.4-34.1 mg AEAC/100g) [30].

The values of IC_{50} obtained in this study agreed well with the results reported for Tunisian floral honey which had a range of IC_{50} values from 11.08 mg/mL to 93.26 mg/mL [28]. Omani honey had higher IC_{50} values which were 25.1 mg/mL, 49.3 mg/mL, 144.5 mg/mL as the average values for Sumer, Sidr, and multifloral honey, respectively [31]. Our results were

higher than those of Brazilian honey (3.17-8.79 mg/mL) [32]. Despite the differences, we should acknowledge the inter-laboratory differences of these studies. Silva et al. [23] and Biluca et al. [16] reported that stingless bee honey had between 10.6-12.9 mg ascorbic acid equivalent/100g and 1.46-18.5 mg ascorbic acid equivalent/100g, respectively as the concentration needed to scavenge DPPH radicals. Recently, Tuksitha et al. [22] reported that stingless bee honey from Sarawak, Malaysia, contained 25.78-50.66 μM Fe (II)/100g. Compared to that, the samples collected in this study had stronger reducing activities. Our results were in fair agreement with the FRAP values of Polish honey 0.6-5.7 mM Fe (II)/kg honey [33] and stingless bee honey reported by Biluca et al. [16] in the ranged of 61.1-624 μM Fe (II)/100g.

Conclusion

Kelulut honey contains maltose as its predominant sugar and a relatively low amount of sucrose. *Kelulut* honey contains bioactive compounds namely phenolics and flavonoids, the compositions of which were significantly affected by the honey's botanical and geographical origin. Honey from the east coast region contained the highest amount of phenolics and flavonoids. Proline and ascorbic acid were not correlated with geographical factor.

Abstract

This research aims to build a mathematical quantitative structure-activity relationship (QSAR) model, which could relate the relationship between newly-synthesized carbonyl thiourea derivatives with their anti-amoebic activities. Therefore, in this study, inhibition concentration of 50% cells population (IC_{50}) was evaluated for 44 carbonyl thiourea derivatives on pathogenic *Acanthamoeba* sp. (Hospital Kuala Lumpur isolate). QSAR analysis was conducted using the obtained IC_{50} data with additional 4 thiourea compounds of the same group from our previous work by applying three linear regression techniques namely stepwise-MLR, GA-MLR, and GA-PLS. Results showed that these thiourea derivatives are positively active against the tested *Acanthamoeba* sp. with IC_{50} values ranging from 2.56 to 7.81 µg/mL. From the evaluation of the obtained models, the GA-PLS technique is found to be the best model due to its best predictive ability. The final equation of GA-PLS model gave good statistical output with values of r^2 = 0.827, r^2_{cv} = 0.682 *RMSEC*=0.047, *RMSECV*=0.064, and r^2_{test} =0.790 and *RMSEP*=0.051. Y-randomization test has confirmed that the model did not occur from the chance of correlation with r^2 = 0.015-0.372. Small residual with values less than 0.25 from the prediction in the test set proves the robustness of the model. The information generated from this study will provide an insight into designing a new lead compound from carbonyl thiourea containing highly potential anti-amoebic properties.

Keywords: thiourea derivatives, *Acanthamoeba* sp., IC_{50}, anti-amoebic activity, QSAR models

Abstrak

Kajian ini mensasarkan pembinaan model matematik kuantitatif hubungan struktur-aktiviti (QSAR) yang memberi hubungkait antara terhadap terbitan karbonil tiourea hasilan sintesis baru dengan aktiviti anti-amebik. Oleh itu, kepekatan penghambatan 50% populasi sel (IC_{50}) dikaji ke atas 44 sebatian karbonil tiourea terhadap *Acanthamoeba* sp. (Hospital Kuala Lumpur isolat) berstatus patogenik. Analisa hubungan struktur-aktiviti kuantitatif dijalankan menggunakan data IC_{50} yang diperolehi bersama 4 sebatian tambahan kumpulan sama dari hasil kerja kami sebelum ini, dengan mengaplikasi tiga teknik regresi linear, iaitu

stepwise-MLR, GA-MLR dan GA-PLS dijalankan. Hasil kajian menunjukkan bahawa sebatian tiourea ini aktif secara positif terhadap *Acanthamoeba* sp.yang diuji dengan nilai IC_{50} antara 2.56 hingga 7.81 μg/mL. Penilaian terhadap semua model QSAR yang dibina dalam kajian ini menunjukkan teknik GA-PLS adalah model yang terbaik kerana kemampuan ramalannya yang terbaik. Persamaan akhir untuk model GA-PLS menunjukkan output statistik yang baik dengan nilai r^2 = 0.827, r^2_{cv} = 0.682, *RMSEC* = 0.047, *RMSECV* = 0.064, r^2_{test} = 0.790 dan *RMSEP* = 0.051. Ujian perawakan-y mengesahkan bahawa model tersebut tidak terhasil secara kebetulan dengan r^2 = 0.015-0.372. Baki kecil dengan nilai kurang dari 0.25 dari ramalan set ujian membuktikan kekuatan model tersebut. Data terbina dari kajian ini akan memberi maklumat untuk mencipta sebatian penting baru dari tiourea karbonil yang mempunyai aktiviti anti-amebik yang berpotensi tinggi.

Kata kunci: tiourea terbitan, *Acanthamoeba* sp., IC_{50}, aktiviti anti-amebik, model QSAR

Introduction

Acanthamoeba is a pathogenic protozoan that is ubiquitously found in the environment. It can cause *Acanthamoeba* keratitis, which commonly occurs in contact lens users [1]. There are several antimicrobial agents such as chlorhexidine gluconate and polyhexamethylene biguanide that have been used to treat the disease but according to Vontobel et al. [2], both agents do not readily penetrate the cornea of the eyes, which require months of topical administration, making them ineffective for keratitis treatment. Reports showed resistance of *Acanthamoeba* towards these antiseptics, especially during the later stage of infection, which makes it difficult to be treated [3]. Therefore, the development of new potential antiamoebic agents is demanded to overcome these problems. Thiourea, an organosulfur compound has been reported to contain diverse biomedical benefits such as antibacterial, anticancer, antifungal, anti-inflammatory, antithyroid, herbicidal, and antitubercular properties [4, 5, 6]. Naz et al. evaluated the antibacterial activity of thiourea derivatives and found that these compounds significantly inhibited several pathogenic bacteria including *E. faecalis*, *P. aeruginosa*, *S. typhi*, and *K. pneumoniae* [7]. In another study, Keche and Kemble also reported the antimicrobial activity of novel thiourea compounds against several selected bacteria and fungi and they revealed that these compounds have promising antimicrobial activity [8]. Nevertheless, there is still lacking literature regarding the anti-amoebic properties of thiourea derivatives on *Acanthamoeba*. Therefore, a cytotoxicity test was conducted in this study to determine the lC_{50} values for the newly synthesized thiourea derivatives on *Acanthamoeba*.

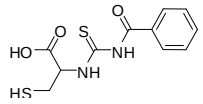
A QSAR study was applied to analyze the molecular structures of the synthesized compounds to correlate with their anti-amoebic activities and allow for the effects of compounds of interest to be predicted [9]. In this study, QSAR methods were used to quantitatively study the relationship between the presented synthesized carbonyl thiourea analogs with their anti-amoebic activity. The approach applied multiple linear regression (MLR) and partial least square (PLS) to build the QSAR equation models. Conventional stepwise methods and genetic algorithm (GA) were employed to choose the best descriptors subset in the model development. Internal and external validations were carried out to evaluate the robustness of the generated models. From the information gained in this study, optimized thiourea-based compounds that work best against pathogenic *Acanthamoeba* could be predicted and developed as new agents to treat *Acanthamoeba* keratitis.

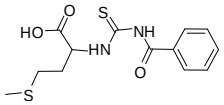
Materials and Methods

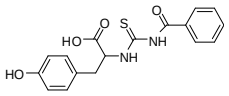
In this study, a set of carbonyls thiourea derivatives consisting of 40 compounds were synthesized and characterized at the Faculty of Science and Marine Environment, Universiti Malaysia Terengganu. These synthesized thiourea derivatives were confirmed by spectral studies of Fourier Transformation Infrared (FT-IR) spectroscopy and ^{1}H and ^{13}C Nuclear Magnetic Resonance (NMR). The preparation of M1–M44 compounds is based on the synthesis method of the previous study with additions of compounds

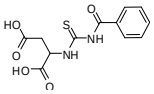
labeled as M7, M8, M25, and M26 attained from the same work [10]. The other synthesized thiourea and their molecular weights are listed in Table 1.

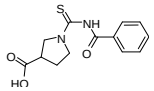
Table 1. Molecular structures of the newly-synthesized carbonyl thiourea derivatives

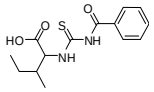


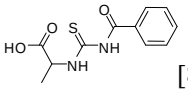


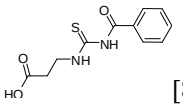


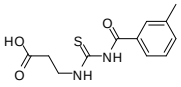


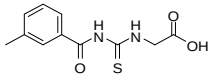


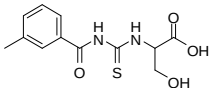


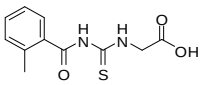


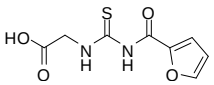












Code	Chemical Name	Molecular Weight	Structure
M1	2-(3-benzoyl thioureido)-3-mercapto propanoic acid	284.35	
M2	2-(3-benzoyl thioureido)-4-(methylthio)butanoic acid	312.41

Determination of IC_{50} values

Thiourea derivatives were prepared and chlorhexidine gluconate (Raza Manufacturing, Malaysia) was used as the positive control whereas 10^4 cells/mL of healthy *Acanthamoeba* sp. without any treatment was used as the negative control [10]. The plates were incubated at 30°C for 72 hours. After incubation, the staining process was performed using the eosin dye method [11]. The absorbance was measured at 490 nm using an ELISA plate reader (Tecan, Australia). The readings were plotted in GraphPad Prism software (version 5.03) (San Diego, USA) to give a non-linear sigmoidal dose-response curve in which the cytotoxicity study was expressed as 50% cytotoxic dose (IC_{50}). T-test (SPSS, version 11.5, USA) was used to compare mean values between untreated and treated cultures, and $p < 0.05$ is considered statistically significant.

Data set selection for QSAR study

The data set that contains thiourea derivatives with anti-amoebic activity is shown in Table 2. The IC_{50} values in the molar (M) unit were converted to pIC_{50} for the convenience of computational work. The data were divided into training and test set. The training set is comprised of 30 thiourea compounds while the test set consisted of the remaining 14 compounds. Compound M7 was later removed from the data set as it was detected to be an outlier throughout the model building by all selected methods of stepwise multiple linear regression (stepwise-MLR), genetic algorithm multiple linear regression (GA-MLR), and genetic algorithm partial least square (GA-PLS).

Table 2. Functional groups of carbonyl thiourea analogs with their anti-amoebic activity

Code	R_1	R_2	IC_{50} (μM)	pIC_{50} (M)

Structure entry and molecular modeling

Structure entry and molecular modeling were first carried out by acquiring a three-dimensional (3D) representation of the thiourea derivative molecules. The compounds' two-dimensional (2D) molecular structures were generated using ChemDraw Ultra (version 10.0). The structures were then converted to 3D structures using Chem3D Ultra 10.0. The 3D molecules of thiourea compounds were analyzed with the MM2 method and MOPAC (Chem3D Ultra 10.0) at default settings to acquire stable molecular structures with the lowest energy.

Descriptors generation

A total of 1661 molecular descriptors of optimized thiourea molecules were computed with DRAGON software (version 5.2). In this analysis, only 0D, 1D, and 2D descriptors were used while the 3D descriptors were excluded since molecular structures of the compounds were not uniformly aligned.

Feature selection

The descriptors that did not contain relevant information for the model development were eliminated from the set. The next step was to find the best subset from the remaining descriptors. Stepwise multiple regression and Genetic Algorithm (GA) were used in this step using MATLAB version 7.6.0 (The Mathworks Inc.) software with PLS Toolbox version 5.2.2 (Eigenvector Research Inc.). Meanwhile, Genetic Algorithm GUI [genalg] function was used for GA selection.

Model development

For the model development, routines were performed in MATLAB with PLS Toolbox whereby MLR and PLS analyses were applied. The approaches for modeling utilize integrated stepwise with MLR (stepwise-MLR), GA with MLR (GA-MLR) and GA with PLS (GA-PLS). Statistical significance of the final model was characterized by the squared correlation coefficient, r^2, root mean square error of calibration, *RMSEC*, and root mean square error of cross validation, *RMSECV*. The obtained outputs were converted [regcon] to equation models. The regression coefficient in the equation indicates the significance of an individual descriptor. A plot of predicted versus experimental activity was evaluated to examine the goodness of fit for the generated models. A plot of residuals versus predicted values was used to detect outliers in the data set.

Model validation

The model validation process was also conducted by MATLAB with the PLS toolbox. Both internal and external validations were conducted in this study. Cross-validation by the leave-one-out (LOO) method was applied to provide a rigorous internal check on the built models. This validation process was accomplished by validating the models from their statistical outputs of cross validated squared correlation coefficient r^2_{cv}, squared correlation coefficient of test set, r^2_{test} and root mean square error of prediction, *RMSEP*. Data scrambling technique by the y-randomization test was performed to ensure that the constructed models were not the result of mere chance correlations. On the other hand, external validation was also performed involving the prediction of activity for compounds from the test set.

Results and Discussion

Inhibition concentration for half of cells population (IC_{50} values)

Thiourea derivatives that exhibited the best anti-amoebic activity were 2-(3-benzoylthioureido)-3-mercaptopropanoic acid and 2-(3-benzoylthioureido)-4-(methylthio)butanoic acid labeled as M1 and M2, respectively. These two thiourea compounds showed the lowest IC_{50} value suggesting that they provide the best intrinsic anti-amoebic activity. These two compounds are amino acid types of derivatives that could be recognized by the presence of hydroxyl (-COOH) with an amine group in the molecule. In general, all derivatives of amino acid groups in this study showed lower IC_{50} values compared to other compounds in the series. This indicates that amino acids could enhance the activity of the thiourea derivatives. Xu et al. [12] supported this finding by highlighting that in general, amino acid derivatives of the compounds could exhibit a variety of biological properties. Meanwhile, Hauck et al. [13] emphasized that amino acid derivatives in the compounds contribute to a hydrophilic moiety, which gives high selectivity toward receptors. Ibrahim et al. [8] that came out with thiourea derivatives labeled as M7, M8, M25, and M26 also suggested that the mechanism of action for the proposed thiourea derivatives toward the protozoan parasite *Acanthamoeba* should focus on the hydrophobicity of thiourea molecules to explain their actions. The suggested drug-receptors for the compounds' main target in the amoeba cells are the transport proteins that are distributed throughout the cell membrane.

Chlorhexidine gluconate was used as a positive control as it is a general biocidal effective against a wide variety of microorganisms [14]. The chlorhexidine-treated amoeba in the experiment exhibited a slightly lower IC_{50} of 6.30 ± 0.49 μM. From the T-test analysis, absorbance readings from the untreated and treated cells showed statistical significance (p <0.05). Thiourea in its basic structure has one sulfur atom. A sulfur atom has six valence electrons, and its electronic configuration is similar to oxygen [15]. Most sulfur-containing organics exhibit a low order of toxicity. However, their toxicity may be enhanced by substitution in the molecules. Patnaik [16] explained that an -SH group attached to a benzene ring imparts greater toxicity to the molecule than that attached to an alkyl group. Therefore, the thiourea derivatives were synthesized with at least one benzene ring as an attachment in this study with an attempt to increase their activity on the tested cells.

Table 3. IC_{50} values of 45 carbonyl thiourea derivatives compound on *Acanthamoeba* sp.

Code	Chemical Name	IC_{50} µg/mL
M1	2-(3-benzoylthioureido)-3-mercaptopropanoic acid	2.56 ± 0.46
M2	2-(3-benzoylthioureido)-4-(methylthio)butanoic acid	2.70 ± 0.27
M3	2-(3-benzoylthioureido)-3-(4-hydroxyphenyl)propanoic acid	3.32 ± 0.18
M4	2-(3-benzoylthioureido)succinic acid	3.96 ± 0.26
M5	1-(benzoylcarbamothioyl)pyrrolodine-3-carboxyl acid	3.08 ± 0.34
M6	2-(3-benzoylthioureido)-3-methylpentanoic acid	3.90 ± 0.20
M7	2-(3-benzoylthioureido)propanoic acid	2.74 ± 0.42
M8	3-(3-benzoylthioureido)propanoic acid	2.92 ± 0.24
M9	3-[3-(3-methylbenzoyl)thioureido]propanoic acid	5.13 ± 0.59
M10	2-[3-(3-methylbenzoyl)thioureido]acetic acid	5.64 ± 0.63
M11	3-hydroxy-2-[3-(3-methylbenzoyl)thioureido]propanoic acid	5.23 ± 0.41
M12	2-[3-(2-methylbenzoyl)thioureido]acetic acid	4.94 ± 0.20
M13	2-(3-furan-2-carbonylthioureido) acetic acid	4.60 ± 0.61
M14	2-[3-(4-methylbenzoyl)thioureido]-3-phenylpropanoic acid	4.95 ± 0.49
M15	5-amino-2-[3-(4-methylbenzoyl)thioureido]-5-oxopentanoic acid	5.51 ± 0.47
M16	2-[3-(4-methylbenzoyl)thioureido]propanoic acid	5.80 ± 0.20
M17	3-hydroxy-2-[3-(4-methylbenzoyl)thioureido]propanoic acid	5.29 ± 0.10
M18	3-methyl-2-[3-(4-methylbenzoyl)thioureido]butanoic acid	5.06 ± 0.40
M19	2-[3-(2-methylbenzoyl)thioureido]propanoic acid	5.31 ± 0.22
M20	3-hydroxy-2-[3-(2-methylbenzoyl)thioureido]butanoic acid	4.62 ± 0.43

QSAR study

QSAR utilizes linear regression of statistical analysis to build mathematical equation models, which could elucidate the relationship for molecular structures of the compounds with their potential biological activities. QSAR will also help to create a preliminary hypothesis regarding the mechanism of action by investigating the compounds on a particular biological system. Through this approach, it is assumed that the compounds that fit in a QSAR model are acting with the same mechanism of action [17].

Development of QSAR model by stepwise-multiple linear regression (stepwise-MLR) analysis

In order to build a QSAR model, feature selection was primarily conducted to discard unnecessary variables from the pool of 202 descriptors. Stepwise multiple regression chose 7 descriptors that fit best with the equation model, which were MATS1m, GATS5m, GATS3e, ESpm01d, ESpm05d, JGI1, and JG12. To avoid the overfitting problem, the proportion of the descriptors to the compound was maintained in a 5:1 ratio of the thumb rule. The descriptors set were maintained to contain five or fewer variables that contain the best information to represent the model. This was done by single exclusion practice of each variable from the selected obtained descriptors. The variables were tested for their significance by removing each one of them and their predictive power was tested each time by using the proposed model. From this technique, two variables, GATS5m and GATS3e, were found to be insignificant for the model and were removed. From the verification by correlation matrix, a high degree of correlation was found between descriptor ESpm01d and ESpm05d with a value of > 0.8. ESpm05d was chosen from the two since it was more significant by giving a statistically better model with higher predictive ability. The regression model was constructed with four descriptors namely MATS1m, ESpm05d, JGI1, and JGI2. According to Hadanu et al. [18], the best model could be selected based on the value of correlation coefficient (r), squared correlation coefficient (r^2), Standard Error of Estimation (SE), degree of freedom (F) or Predictive Residual Sum of Square (PRESS). Frimayanti et al. [19] proposed that the accepted value range for QSAR models is $r^2 > 0.6$ and $r^2_{cv} > 0.5$. The final statistical output for the generated model of stepwise-MLR is shown in Table 4.

Table 4. Statistics for a model developed using the stepwise-MLR method

Statistical Output	Value
r^2	0.732
r^2_{cv}	0.522
RMSEC	0.058
RMSECV	0.080

r^2 = squared correlation coefficient;
r^2_{cv} = cross validated squared correlation coefficient;
RMSEC= root mean square error of calibration;
RMSECV= root mean square error of cross validation

Based on the statistical evaluation, high r^2 and r^2_{cv} values with very low *RMSEC* and *RMSECV* indicate that the constructed model is statistically robust to predict the activity of other compounds outside the training set. This statistical outcome shows that the model is capable to elucidate 73.2% of the variance in anti-amoebic activity.

The final QSAR equation model given by the stepwise-MLR method is shown in Equation 1.

The generated regression model shows the order of significance for used descriptors is as follow: ESpm05d > JGI1 > MATS1m > JGI2. The observed and calculated or predicted activity by using this model was compared and it showed that the predicted pIC_{50} values did not greatly differ from the pIC_{50} values obtained from the ex periments with residual values less than 0.95. The observed values are in the range of 4.57 to 5.05 M while the predicted values range from 5.50 to 5.54 M.

$$pIC_{50} = - 0.0145*MATS1m + 0.1013* ESpm05d - 0.0733*JGI1 - 0.0090*JGI2 + 4.7592 \quad (1)$$

Validation of QSAR regression model from stepwise multiple linear regression (stepwise-MLR)

The statistical output of model validation is shown in Table 5. It proves that the developed model has a high predictive ability. It was given that r^2_{test} was 0.739, which is above 0.5 with an *RMSEP* value of 0.062, which is low enough for roots mean square error of prediction.

The built of the QSAR models must be properly validated prior to use for interpreting and predicting biological responses of non-investigated compounds. Qin et al. [20] emphasized the importance of vigorous validation of QSAR models despite the high fitting accuracy for the training set and apparent mechanistic appeal. The model equation was later used to predict thiourea analogs' anti-amoebic activity in the test set data. The comparison showed that the observed values are in the range of 4.63 to 5.05 M. Meanwhile, the range of the predicted values was 5.49 to 5.56 M. The residuals obtained gave values less than 0.90. This indicates the robustness and high predictive power of the built model. The robustness of a QSAR model should be also validated by a y-randomization test to ensure that the statistical output in the original model, which gave high r^2 and r^2_{cv} values, were not merely from a chance correlation or structural dependency of the training set. If a true QSAR relationship existed with the real dependent variable, the results for the *y*-random runs should be very low [21]. Y-randomization test was run 20 times and gave r^2 values between 0.052 to 0.233, which shows low r^2 and r^2_{test} (Table 6). Thus, it is concluded that the generated model by stepwise-MLR was not obtained from a random chance of correlation.

Table 5. Statistics of prediction for stepwise-MLR model

Statistical Output	Value
r^2_{test}	0.739
RMSEP	0.062

r^2_{test} = correlation coefficient of test;
RMSEP = root mean square error of prediction

Table 6. Y- randomization test of stepwise-MLR model

Iteration	r^2	r^2_{test}	Iteration	r^2	r^2_{test}
1	0.055	0.016	11	0.181	0.052

Development of QSAR model by genetic algorithm multiple linear regression (GA-MLR) analysis

The regression model was constructed with five descriptors namely RBN, MATS2m, EEig07x, JGI1, and N-070. The correlation matrix was investigated to detect highly correlated variables that would be less important for the model, which detected 135 that represents ESpm05d to be highly correlated with 198, representing N-070 by giving a value higher than 0.80 from the correlation matrix. The analysis was executed again to find out which variable was more significant than others by removing each of them from the model. The final analysis concluded that N-070 was more significant compared to ESpm05d and, therefore, it was included in the model. The statistical output of the final model is shown in Table 7. Statistical result of the constructed GA-MLR model shows a high r^2 value that concludes the equation could explain 84.8% of the variance in the compounds' activity. Meanwhile, r^2_{cv} is also quite high with a value of 0.767. *RMSEC* and *RMSECV* obtained are very low with values of 0.044 and 0.055, respectively. The statistical output shows that the GA-MLR method was a good technique to obtain a good model. This result also proves that the hybrid GA-MLR approach produced a better QSAR model compared to the stepwise-MLR method for this study.

The final QSAR equation model of the GA-MLR method is elaborated in Equation 2 in which it shows a significant order of the five selected variables as follows; N-070 > MATS2m > JGI1 > EEig07x > RBN. The variables of MATS2m, JGI1, and N-070 were shown to work reversibly with pIC_{50} while RBN and EEig07x both worked positively with pIC_{50}. The predicted pIC_{50} values were compared to the experimental data. The data revealed that the predicted values ranging from 4.93 to 5.21 M and the experimental values ranging from 4.57 to 5.05 M. Low residual values in the range of less than 0.55 from the activity prediction proves that the constructed model was robust.

$$pIC_{50} = 0.0301*RBN - 0.0576*MATS2m + 0.0445*EEig07x - 0.0529*JGI1 - 0.0896*N\text{-}070 + 4.7602 \quad (2)$$

Table 7. Statistics for the model developed using GA-MLR method

Statistical Output	Value
r^2	0.848
r^2_{cv}	0.767
RMSEC	0.044
RMSECV	0.055

r^2 = squared correlation coefficient;
r^2_{cv} = cross validated squared correlation coefficient;
RMSEC= root mean square error of calibration;
RMSECV= root mean square error of cross validation

Validation of QSAR regression model from genetic algorithm multiple linear regression (GA-MLR)

The statistical result in Table 8 confirms the robustness of the generated GA-MLR model with acceptable values of r^2_{test} and *RMSEP*. Tropsha et al. [22] suggested that a proposed QSAR model is considered predictive if it satisfies the condition of $r^2_{test} > 0.6$. The predicted pIC_{50} values were compared to the experimental data. The predicted values ranged from 4.92 to 5.20 M and the experimental values ranged from 4.63 to 5.06 M. The residuals gave values less than 0.45 suggesting that the model is robust and has high predictive power.

Validation by y-randomization was run 20 times and the test showed that the squared correlation coefficient, r^2 were in the range of 0.004 to 0.300 (Table 9). The difference between randomized models compared to the original GA-MLR statistical representation was significant. Therefore, this proves that chance correlation was negligible in the model development.

Table 8. Statistics of prediction for GA-MLR model

Statistical Output	Value
r^2_{test}	0.777
RMSEP	0.057

r^2_{test} = correlation coefficient of test;
RMSEP= root mean square error of prediction

Table 9. Y- randomization test of GA-MLR model

Iteration	r^2	r^2_{test}	Iteration	r^2	r^2_{test}
1	0.151	0.008	11	0.227	0.457
2	0.047	0.240	12	0.176	0.288
3	0.233	0.099	13	0.226	0.064

Development of QSAR model by genetic algorithm partial least square (GA-PLS) analysis

The third method of QSAR in this study applied GA in combination with the PLS technique. The selected variables used MATS2m, MATS3m, EEig09d, JGI6, and N-070. The correlation matrix of the selected variables showed that no higher correlation than 0.8 for the variables was used hence this explains the consistency to be used in the model. The statistical output for the GA-PLS model is shown in Table 10. The statistical result proves the reliability of the built QSAR model from GA-PLS regression with squared correlation coefficient, r^2 of 0.827 and cross-validated, r^2_{cv} of 0.682. This result is in accordance with a study by Edraki et al. [23] in QSAR analysis of 3,5-bis (arylidene)-4-piperidone derivatives in cytotoxicity models. The statistical output using the GA-PLS model revealed the r^2 of 0.86 and r^2_{cv} of 0.66. The model also gave low root mean square error values for *RMSEC* and *RMSECV*.

Table 10. Statistics for the model developed using the GA-PLS method

Statistical Output	Value
r^2	0.827
r^2_{cv}	0.682
RMSEC	0.047
RMSECV	0.064

r^2 = squared correlation coefficient;
r^2_{cv} = cross validated squared correlation coefficient;
RMSEC= root mean square error of calibration;
RMSECV= root mean square error of cross validation.

This statistical output of the model proves to be able to explain 82.7% of the variance in the experimental activity and r^2_{cv}, which manifests good predictive ability. The best combination of a selected variable by the GA-PLS method is illustrated in Equation 3.

The order of variables are as follows; EEig09d > N-070 > JGI6 > MATS2m > MATS3m in which this QSAR model was used to predict the activity of compounds in the training set. The values of calculated compared to observe activity. The predicted values were in the range of 4.72 to 4.82 M and the experimental values were in the range of 4.63 to 5.06 M. The residuals observed were compared to the predicted values, which were less than 0.25. This explains the robustness of the model. However, the predictive ability of the model was further evaluated in external validation to ensure that the QSAR model also has a good predictive ability for compounds that were not included in the training set.

$$pIC_{50} = -0.0457*MATS2m + 0.0242*MATS3m + 0.0638*EEig09d - 0.0511*JGI6 - 0.0609*N\text{-}070 + 4.7554 \quad (3)$$

Validation of QSAR regression model from genetic algorithm partial least square (GA-PLS)

The result gave good statistical output with r^2_{test} and *RMSEP* of 0.790 and 0.051, respectively (Table 10). The robustness of the GA-PLS QSAR model was also assessed through its predictive power for the comparison of the observed to predicted activity. The predicted values were in the range of 4.72 to 4.82 M while the experimental values were in the range of 4.57 to 5.05 M. Small residual with values less than 0.25 proved the robustness of the equation model, which could be used to predict other compounds that were not included in the model development. The test of y-randomization was run 20 times and confirmed that the model does not occur merely by random chance correlation of statistics since it gave low squared correlation coefficients, r^2 in the range of 0.015-0.372 (Table 11).

Table 10. Statistics of prediction for GA-PLS method

Statistical Output	Value
r^2_{test}	0.790
RMSEP	0.051

r^2_{test} = correlation coefficient of test;
RMSEP = root mean square error of prediction

Table 11. Y- randomization test of GA-PLS model

Iteration	r^2	r^2_{test}	Iteration	r^2	r^2_{test}
1	0.078	0.006	11	0.087	0.085

Comparisons of constructed QSAR models

QSAR mathematical models from three different techniques namely stepwise-MLR, GA-MLR, and GA-PLS were evaluated and compared (Table 12). A genetic algorithm (GA) is a well-suited approach to the problem of variable selection and optimization. GA performs its optimization by comparing root-mean-square error of cross validation, *RMSECV* of proposed

models as the measure of fitness [24]. The hybrid approach (GA-MLR) which combines GA with MLR may be useful in the derivation of highly predictive and interpretable QSAR models [17]. Therefore, this approach, as well as the conventional stepwise-MLR technique, was applied in this study. The method of stepwise-MLR gave four selected variables that are well fitted in the equation model. The model gave good statistical output with high r^2 and r^2_{cv} and low *RMSEC* and *RMSECV*. This indicates that the constructed model has good fitness and is robust. On the other hand, the model obtained from the GA-MLR method contains five descriptors and produced a statistically better model compared to the stepwise-MLR. This showed that GA-MLR is a good technique to obtain a better QSAR model in this study. However, the weaknesses of using the MLR technique are that the data are often crude, imprecise, and strongly collinear. These imply that this traditional regression technique, which assumes the selected descriptors to be exact and 100% relevant and independent of each other, will not always work well. Thus, in situations where many strongly collinear descriptors and biological responses operate together, data analytical methods, other than the classical MLR techniques, must be used [25].

Table 12. Summary of constructed models

	Stepwise-MLR	**GA-MLR**	**GA-PLS**
Statistical output:			
r^2	0.732	0.848	0.827
r^2_{cv}	0.522	0.767	0.682

r^2 = squared correlation coefficient;
r^2_{test} = correlation coefficient of test;
r^2_{cv} = cross validated squared correlation coefficient;
RMSEC= root mean square error of calibration;
RMSECV= root mean square error of cross validation

PLS is well suited to overcome overfitting and multicollinearity problems. It has been used to alleviate the effect of multicollinearity and to prevent overfitting by reducing the dimension size [tran 26]. This approach has also successfully come out with a statistically robust model of five variables that were better compared to the model developed from stepwise MLR and GA-MLR techniques based on the predictive ability. PLS also gave much lower residual values in both training and the test set with < 0.23 and < 0.24, respectively compared to the MLR models that gave higher residual values from their prediction. The descriptors or variables, which demonstrate to be important, are those that have been used more than once from the three approaches. It is suggested that these variables namely JGI1, MATS2m, and N-070 are found to be the influential factors and contributors in the models' development for this study and could possibly have a significant role in modulating the anti-amoebic activity for the thiourea derivative compounds. These variables are in the groups of topological charge indices, 2D-autocorrelations, and atom centered fragments.

GA, MLR, and PLS were also implemented by many authors in their studies for prediction in high-dimensional linear regressions [27,28]. GA is suitable to solve optimization and variable selection problems while MLR yields models that are simpler and easier to interpret compared to PLS because these methods perform regression on latent variables that do not have physical meaning [28]. Due to the co-linearity problem in MLR analysis, one may remove the collinear descriptors before MLR model development. MLR equations can describe the structure-activity relationships but some information will be discarded in the MLR analysis. On the other hand, factor analysis–based methods such as PLS regression can handle the collinear descriptors and, therefore, PLS analysis provides a better analysis with a highly predictive QSAR model [29]. In a previous study, the QSAR model built using PLS and GA-MLR methods showed a remarkable coefficient of determination (r^2) in predicting the anticholinergic side effects of drugs in lower urinary tract infection (PLS: R^2=0.808 and GA-MLR: R^2 =0.804) [26]. A series of 3-hydroxypyridine-4-one and 3-hydroxypyran-4-one derivatives were subjected to QSAR methods using factor analysis-based multiple linear regression (FA-MLR), principal component regression (PCR), and partial least squares combined with genetic algorithm for variable selection (GA-PLS). The result revealed that GA-PLS showed the most significant QSAR model with 96% and 91% predicted variances in the pIC_{50} data (compounds tested against *S. aureus*) [28]. The studies proved that GA-PLS is a reliable QSAR model in predicting the biological activities of chemical compounds based on mathematical and statistical relations.

Descriptors interpretation

In this study, all applied approaches offered a few similar descriptors or variables for the equations, which are JGI1, MATS2m, and N-070. The finding suggests that they might be the most influential descriptors that contribute to the QSAR models and provide a significant role in the anti-amoebic activity for the thiourea derivatives. Meanwhile, the selected and best QSAR model, which was obtained from the GA-PLS technique, gave 5 variables that include EEig09d, N-070, JGI6, MATS2m, and MATS3m. These variables belong to 2D autocorrelation (Moran autocorrelation - lag2/weighted, and -lag3/weighted by atomic masses), edge adjacency indices (Eigenvalue 09 from edge adjacency matrix weighted by dipole moments), topological charge indices (mean topological charge index of order 6), and atom-centered fragment class (Ar-NH-Al). According to Speck-Planche et al. [30], atom-centered fragments are simple molecular descriptors that are defined as the number of specific atom types in a molecule. They are calculated from molecular composition and atom connectivities. Each type of atom in the molecule is described in terms of its neighboring atoms. The atom-centered fragment descriptors have been demonstrated to be very useful descriptors and have been employed in previous QSAR studies. Meanwhile, Viswanadha et al. [31] reported that these atom-centered fragments descriptors provide important information about hydrophobic and dispersive interactions, which are involved in biological processes such as transport and distribution of compounds through cells membrane, as well as the information about the compound's receptor

interactions. From the variables that have been selected in the model of this study, it could be concluded that the atom-centered fragment plays a major role in providing the information on the thiourea molecules' preliminary penetration into *Acanthamoeba* through the cells membrane.

On the other hand, another representative descriptor or variable selected in the generated model of this study is topological structural descriptors, which are a representation of a molecular structure that arises from the chemical identity of each atom. In this study, two Moran autocorrelation descriptors were used in the GA-PLS model. These descriptors describe hydrophobicity scale, average flexibility index, polarizability parameter, the free energy of amino acid solution in water, residue accessible surface area, amino acid residue volume, steric parameters, and relative mutability [32]. In the meantime, physical interpretation of Burden eigenvalues and topological charge indices is difficult because they condense a large amount of structural and property information into a single number [33]. However, these descriptors have been extensively used in medicinal chemistry [34]. Todeschini and Consonni [35] reviewed that due to the relevancy and complexity of amino acid chains and macromolecules, some descriptors were defined to represent amino acid chains and sequences of amino acids. Amino acid properties were modeled for example by connectivity indices, substituent descriptors, charge descriptors, and principal properties. Raychaudury et al. [36] used a topological descriptor to characterize the size and shape of the side chains in the amino acids, which was based on a graph-theoretical approach applied to root weighted molecular graphs with hydrogen included. Substantially, it was relevant with the result obtained from analysis in this study that concentrated on topological descriptors in the model since the thiourea compound series contained 21 amino acids of the side chain of the molecules. Todeschini et al. [37] explained the interpretability of descriptors whereby it is important to take into account that model response is frequently the result of a series of complex biological or physicochemical mechanisms. Therefore, it is very difficult and reductionist to ascribe to the mechanistic meaning of the selected molecular descriptors in a QSAR model. Furthermore, it must also be highlighted that in multivariate models, even though the interpretation of a singular molecular descriptor can be certainly useful, it is only the combination of a selected set of descriptors that is able to model the studied biological end-point. It was also stressed that in QSAR modeling, attention should be focused on the model quality through its predictive ability.

Conclusion

QSAR models were constructed from the obtained IC_{50} values of 44 carbonyl thiourea analogues toward *Acanthamoeba* sp. (HKL isolate) ranging from 2.56 to 7.81 μg/mL. Linear regression techniques, stepwise-MLR, GA-MLR, and GA-PLS were applied to build the best QSAR model to correlate the compounds with their anti-amoebic activity. Three equation models were successfully generated with the hybrid GA-PLS approach that gave the best output with a statistically robust model of five variables. Thus, this GA-PLS QSAR model could be applied in the future for the development of a new lead compound based on carbonyl thiourea with optimized anti-amoebic activity to design a new anti-amoebic agent for A*canthamoeba* keratitis disease.

Abstract

Majority of the polyurethane–urea (PUU) foam is made from petroleum raw materials. Concerns regarding the loss of petroleum resources promote the environmentally sustainable manufacture of foam. The production of PUU foam synthesis from natural materials and waste composites was then developed. The PUU/industrial plywood sawdust waste (IPSW) biofoam was synthesized from a mixture of polyethylene glycol (PEG), methylene diisocyanate (MDI), ethylenediamine (EDA), maleic anhydrate (MAH), and IPSW by using a one-shot method. 5% IPSW was applied to the composition of the synthesized biofoam and the MDI ratio was increased. Fourier Transform Infrared Spectroscopy (FTIR) was used to identify functional groups of biofoam. The pore morphology of the biofoam was observed with Microscope Camera and Scanning Electron Microscopy (SEM), the thermal ability was measured with Thermogravimetric Analysis (TGA), and the sound absorption ability was measured by using a two-microphone impedance tube according to the ASTM E-1050 standard. Based on FTIR spectra identification, the biofoam contains OH, CH, CO, and NH chemical groups. The results reveal that the PUU/IPSW biofoam had intermediate macropore morphology (closed and open cells), thermal resistance above 120^{o}C, and potential materials as sound-absorbing. The improvement in the biofoam properties upon the addition of organic filler shows that the biofoam is promotable as renewable material. This study suggests better formulation design to enhance the biofoam property performance.

Keywords: acoustics, polyurethane-urea foam, sawdust, scanning electron microscopy, thermogravimetric analysis

Abstrak

Kebanyakan busa poliuretan-urea (PUU) diperbuat daripada bahan mentah petroleum. Kebimbangan mengenai kehilangan sumber petroleum menggalakkan pembuatan busa yang mampan secara alam sekitar. Penghasilan sintesis busa PUU daripada bahan alam dan komposit sisa telah dibangunkan. Busa PUU telah disintesis daripada campuran polietilen glikol (PEG), metilen diisosianat (MDI), etilen diamin (EDA), maleat anhidrat (MAH), dan sisa habuk papan industri kayu lapis (IPSW) dengan menggunakan kaedah satu pukulan. Lima peratus IPSW telah digunakan pada komposisi biofoam tersintesis dan nisbah MDI

telah meningkat. Spektroskopi Infra-Merah Transformasi Fourier (FTIR) digunakan untuk mengenal pasti struktur biofoam. Morfologi liang biofoam diperhatikan menggunakan mikroskop kamera dan SEM, TGA untuk pengukuran haba, dan keupayaan biofoam untuk menyerap bunyi diukur menggunakan tabung impedansi dua mikrofon mengikuti standar ASTM E-1050. Berdasarkan pengenalpastian spektrum FTIR, biofoam mengandungi kumpulan kimia OH, CH, CO, dan NH. Keputusan menunjukkan bahawa biofoam PUU/IPSW mempunyai morfologi makropori perantaraan (sel tertutup dan sel terbuka), rintangan haba melebihi 120 ^{o}C, dan berpotensi menjadi bahan penyerapan bunyi. Kemajuan kinerja ketika ditambahkan pengisi organik menunjukkan bahawa ini dapat dipromosikan sebagai bahan terbarukan. Studi ini menyarankan agar membuat formulasi yang lebih baik untuk meningkatkan prestasinya.

Introduction

Population growth and rapid transportation progress have led to environmental problems in the community, including noise pollution. The effects are severe for those who have been exposed, both physically and mentally. This condition can be regulated by using sound-absorbing materials. There are two types of sound-absorbing materials: resonant and porous sound-absorbing materials. The morphology of the latter is made up of channels, gaps, and holes that allow sound waves to pass through [1-3].

Foam is a porous material that can be used to absorb sound. The foam production is synthesized from diols and polyols i.e. polyurethane chemical compounds [2, 4]. Polyurethanes are widely used for other applications such as paints, jacket coatings, elastomers, insulators, elastic fibers, and leather equipment. Polyurethane production and demand projections rose through 2020 [5]. The production of polyurethane foam is incompatible with sustainable development because it uses petroleum as raw material. Therefore, it is necessary to find alternative raw materials that are less harmful to the environment.

Renewable polyol modification is developed in the production of polyurethane by using biomass as raw material through oxypropylation or acid liquefaction process. The production of bio-polyol using oxypropylation method includes the use of palm oil, *Sapium sabiferum* oil, castor oil, soybean oil, grapeseed oil, sunflower oil, tung oil and canola oil. The current bio-polyol production process using liquefaction acid is derived from eucalyptus and pine woods, bamboo, Cellulose nanofibrils, Yaupon holly (*Ilex vomitoria*), sugar-cane bagasse, bagasse, and jute fiber. Both processes can produce environmentally friendly polyurethane foam raw materials [4-8].

In addition to bio-polyols, the use of isocyanate alternatives such as Non-isocyanate polyurethane (NIPU), which is derived from mimose tannins [9], lysine, sorbitol, vegetable oils, and other sources, is another way to keep polyurethane foam production sustainable. Recycling polyurethane foam [4] and integrating natural waste materials into the production process are also green choices. Natural fiber blends of various concentrations and thicknesses in polyurethane foam composites have varied sound absorption capabilities [10]. The addition of *Shorea leprosa* wood fibers to the polyurethane foam affects its acoustic performance [11]. Production of biofoam from polyurethane-urea blends with various concentration of industrial plywood sawdust has a good sound absorption coefficient [12].

It was reported that polyurethane foam composites containing nanosilica and nanosilica solution at an optimum level of 2 wt.% had a negative impact on foam cell morphology, and the TGA test results for rigid polyurethane foam composites containing 1 wt.% nanosilica solution had poor thermal resistance [13]. As compared to foams without the addition of halloysite nanocomposites, rigid polyurethane foam with palm oil as raw material and halloysite nanocomposite had stable thermal resistance, and SEM results showed a smooth cell surface structure and larger cell size [2]. Polyurethane foam synthesized with clove composites (*Syzygium aromaticum*) at various concentrations had rheological behavior, cellular

structure, and further mechanical & thermal performance of the modified material [8].

The other research studied polyurethane foam with addition of diatomite and hydroxyapatite. The thermal degradation of diatomite porous polyurethane foam biocomposites was lower than that of hydroxyapatite porous polyurethane foam biocomposites. Diatomite and hydroxyapatite increase the surface area of the polyurethane foam and harden the pores [14]. Rigid foam made by combining non-isocyanate polyurethane (NIPU) tannins with addictive glutaraldehyde and citric acid had the same morphology, called Open-Cell, but the number of cell wall pores decreased as glutaraldehyde was added, while citric acid increased the number of foam cells. The thermal resistance of the NIPU foam in all compositions was the same except for the composition of 2 grams of hexamine and 6 grams of citric acid which was higher at a temperature of 790 ^{o}C and a residue of 18.7% [9].

This research described the synthesis of polyurethane-urea (PUU) biofoam with industrial plywood sawdust waste composites (IPSW). The PUU/IPSW biofoam was synthesized by adding a chain extender in the form of ethylene diamine (EDA), coupling agent in the form of maleic anhydrate (MAH), and industrial plywood sawdust waste as filler. The chain extender is a low molecule containing an amine group at the end that plays a major role in polymer morphology. The addition of a chain extender and diisocyanate provided a wide range of hard segment characteristics and the physical performance of polyurethane. The morphological structures were characterized by SEM and Microscope Camera. Meanwhile, thermal ability was analyzed by TGA, and acoustics test was conducted through impedance tube.

Materials and Methods

Materials

The materials used to synthesize the PUU/IPSW biofoam were chemical compounds and biomass. The chemical compounds included polyethylene glycol (PEG) 400 (Polyol), 4.4'-diphenylmethane diisocyanate (4.4'-MDI), ethylenediamine (EDA), and maleic anhydrate (MAH) while the biomass was in the form of industrial plywood sawdust waste (IPSW). The detail of various compositions of the PUU/IPSW biofoam are shown in Table 1.

Sample preparation

The biofoam was synthesized by using a one-shot method. This method worked by combining all of the ingredients until they were fully homogeneous, as detailed in Figure 1. First, the polyol and diisocyanate were mixed and stirred. Then, the chain extender (EDA), the coupling agent (MAH), and the IPSW filler were added. The composition of the ingredients was calculated by the mass ratio. The samples were coded as BP0, BP1, BP2, BP3, BP4, and BP5 for the PUU/IPSW biofoam with 0%, 1%, 2%, 3% , 4%, and 5% IPSW respectively with a ratio of PEG:MDI (1:1), and BP1.5 for the PUU/IPSW biofoam of 5% with a ratio of PEG:MDI (1:1.5).

Table 1. Variation of the PUU/IPSW biofoam composition

Samples	PEG (g)	MDI (g)	EDA 0.1% (g) (w/w)	MAH 0.01% (g) (w/w)	Waste % (g) (w/w)
BP0	15	15	0.3	0.03	0
BP1	15	15	0.3	0.03	0,31
BP2	15	15	0,3	0.03	0,62
BP3	15	15	0,3	0.03	0,94
BP4	15	15	0,3	0.03	1,26
BP5	15	15	0,3	0.03	1,6
BP1,5	15	22,5	0.3	0.03	1,6

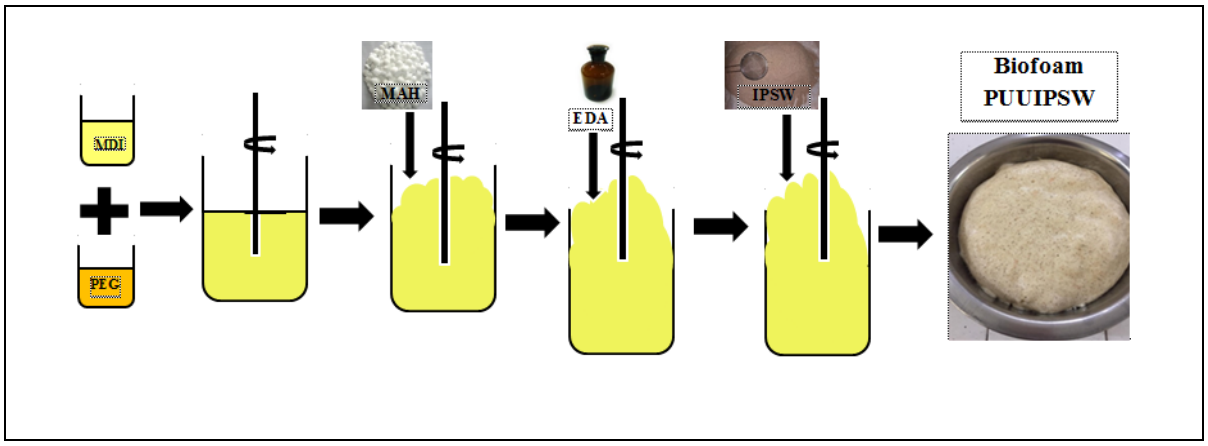

Figure 1. Procedural scheme for the PUU/IPSW biofoam synthesis

Microscope camera

The biofoam pore morphology in was observed by using a Nikon Eclipse 80i microscope camera for 10x magnification. The resulted pore distribution was calculated by using Image J software. The pore distribution data were analyzed by using OriginLab software.

Scanning Electron Microscopy

The morphological properties of biofoam cells were observed by using Scanning Electron Microscopy (SEM) Phenom ProX. the PUU/IPSW biofoam samples were ground into powders and then plated with gold and subjected to 10kV voltage. Prior to the test, the samples' surfaces were gold-plated in order to have conductive properties and to be detectable by the SEM detector Phenom ProX secondary electron detector (SED).

Fourier transform infrared spectroscopy

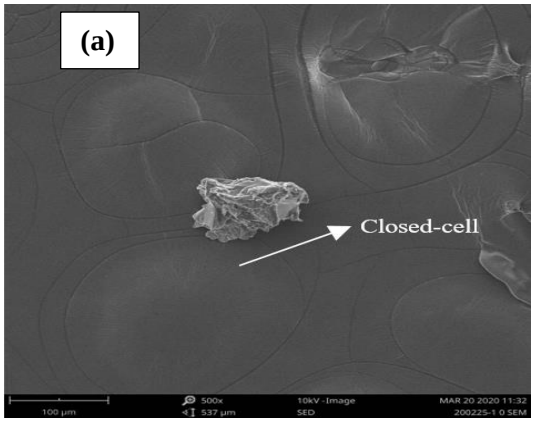
The PUU/IPSW biofoam chemical structure was analyzed with FTIR spectroscopy by using KBr pellet technique with measurements at 3500-400 cm^{-1} wavenumber.

Thermogravimetric analysis

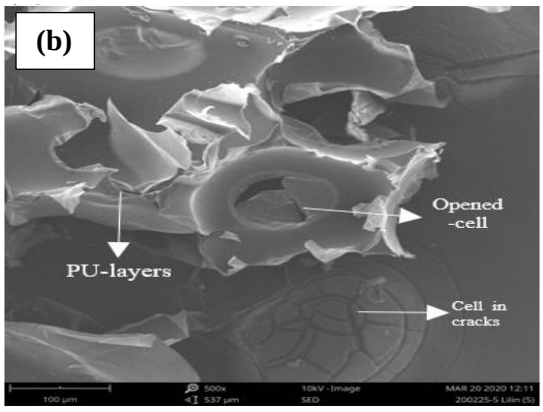
The PUU/IPSW biofoam was subjected to TGA to obtain its thermal resistance with the TGA DSC 200 of Seiko SSC 5200H at a temperature of 25-600 (°C) with a heating rate of 10°C/minute.

Impedance tube testing

The PUU/IPSW biofoam sound-proofing ability was measured with an acoustic test that followed the ASTM E-1050 standard. The biofoam samples were shaped into a 28mm-diameter circle. Two microphone techniques and automated frequency analysis systems were used to quantify the effect of normal sound absorption coefficient and precise normal acoustic impedance comparisons of materials, with frequencies ranging from 0 to 6400 (Hz) [10, 11,15].



Results and Discussion



Cell morphology

Two microscopes, SEM for 500x magnification (Figure 2) and Microscope Camera for 10x magnification (Figure 3), were used to examine the biofoam pore morphology. Three samples, namely BP0, BP5, and BP1.5 were observed on SEM as representative treatments. The results show that majority of the pores formed were macropores since the size was found to be more than 50µm. Three types of biofoam morphology were then determined: 1) open-celled, meaning that the biofoam pores were found to have interconnecting holes between each other; 2) closed-celled, meaning that the biofoam pores were found to not have interconnecting holes between each other; and 3) intermediate-celled, meaning that the biofoam pores were found in a combination of the two. BP0 was found to be closed-celled, with circular to oval shape when it expanded. BP5 was found to be

intermediate-celled with oval shape [3]. Other microstructures were observed in PU layers. BP1.5 had closed-celled microstructure with polygonal shape. It had another microstructure, namely interconnecting hole. According the SEM images, filler addition influenced the biofoam morphology. It was observed that the filler could make a closed-celled sample to be an open-celled one, since it filled the biofoam matrices. Meanwhile, the effect of filler addition to MDI ratio enhancement was found to be not significant. The SEM image results were smooth, demonstrating MAH's ability to act as a coupling agent. The smoothest the sample captured by SEM causes the role of MAH which can relate the filler and the biofoam matrices. Therefore, the surface of samples seemed smooth.

The structure of the cavities and pores created during the polymerization process and the cell size were determined by the gelling and blowing reactions. If the cavity pressure is greater than the wall strength, biofoam with an open-celled structure may be created. At low channel flow rates, the cavity wall thickness retains hardness. However, if the hardening process is completed before the open pore formation, some open pores can form. Closed cells will remain if the cavity wall hardens completely before fracturing [2, 16, 17]. With the addition of filler, the pore distribution continued to reduce in size (Figure 3). It was identified that sample BP0 had the highest pore distribution with pore size in the range of 250-300 µm, while Samples BP1, BP3, BP4, BP5, and BP1.5 had pore sizes in the range of 100-150 µm. Meanwhile, Sample BP2 had pore distribution with pore size in the range of 150-200 µm. The factor which caused different sizes of pore distribution might occur when the minimum biofoam synthesis period and stirring velocity were not fulfilled. It was suggested that foaming under this kind of condition impacted the cell sizes of Sample BP2. This demonstrated that the presence of filler had a direct impact on the morphological properties and distribution. The biofoam mechanical and thermal efficiency depended on these factors [8].

Chemical structure

Urethane and urea are two forms of carbonyl groups formed by hydrogen bonds [18]. The PUU biofoam is derived from polyol and diisocyanate raw materials. Samples of MDI, PEG, BP0, and BP5 were observed to understand the PUU/IPSW biofoam chemical reaction. According to the absorption observed in the FTIR spectra, the -NH functional group was found in the wavenumber range of 3808-3308 cm^{-1} with broad intensity. This covered Samples BP0 (3516 cm^{-1}) and BP5 (3527 cm^{-1}). Samples BP0 (3382 cm^{-1}), MDI (3384 cm^{-1}) and BP5 (3382 cm^{-1}) belonged to -OH functional group found in the wavenumber range 3422-3314 cm^{-1}. The absorption peak of the PUU biofoam formed shifted to a lower wavenumber, suggesting a looser bond [13, 19]. Methylene functional group was detected at the absorption peak wavenumbers of 2972 cm^{-1} and 2971 cm^{-1} which was the -CH asymmetric stretching vibration of CH_3 [9, 19].

The absence of an isocyanate functional group absorption band at wavenumbers 2270-2250 cm^{-1} suggested that the isocyanate reacted properly with polyol (Figure 4). The first explanation is that due to the steric disturbance molecule, the -OH functional group interacted with the -NCO group. Another explanation is that the –NCO functional group interacted with the –OH group in the air, which was caused by humidity [6, 20]. The characteristics of amide III and C = O (-RNHCOO- / urethane linkage) functional groups in the absorption bands of 1230 cm^{-1} and 1077 cm^{-1} suggested that the PUU biofoam was successfully formed and chemically bonded [6, 19, 21]. In addition, another absorption peak was detected, namely the aromatic group C-C/C = C stretching modes in the wavenumber range 1600-1607 cm^{-1} [22]. The properties of EDA as a chain extender contributed to the PUU biofoam's hard segment character, which can be detected when the biofoam is heated or cooled. When PUU biofoam is heated to a specific temperature, it has a peak intensity –H bonded urethane C = O groups while urea groups decrease. This also applies if it is cooled to a temperature of 120-30 (°C) so that the peak intensity of -H bonded urethane C=O groups increases while the peak intensity of free urethane C=O decreases [18]. More information is presented inTable 2.

Table 2. Peaks of FTIR spectra of BP0, PEG, and MDI

Wavenumber (cm^{-1})				Wavenumber Range (cm^{-1})	Functional Groups
MDI	**PEG**	**BP0**	**BP5**		
-		3516	3527	3808-3308	The stretching vibration of -NH
3384	-	3382	3382	3422-3314	-OH stretching modes from hydroxy groups
-	2972	2972	2971	3000-2970	-CH asymmetric stretching vibration CH_3 (methylene groups)
2257	-	-	-	2270-2250	-NCO- (isocyanate asymmetric stretching)
1720	-	1719	1724	1724-1705	Disorder H-bonded (C=O)OC in urethane
-	1644	1638	1635	1648-1627	Order H-bonded urea C=O
1607	1602	1600	1600	1615-1580	Aromatic C-C/C=C Stretching Modes
1233	-	1230	1230	1257-1222	υC-N+ δN-H (Amide III)
1075	-	1077	1075	1083-1070	H-Bonded (C=O)OC in urethane

TGA analysis

Thermogravimetric Analysis (TGA) is used to calculate the effect of filler addition (industrial plywood sawdust waste) and the ratio of MDI to its thermal performance, while DTG is a derivative of its mass loss. Samples BP0, BP5, and BP1.5 were observed because they were representatives to the treatment. Figure 5 and Table 3 show the results of the TG and DTG tests. Temperature characteristics were divided into T_{Onset} and T_{max}. T_{Onset} was the degradation of temperature when the mass loss was 5%, while T_{max} was the maximum degradation temperature of all samples [6]. All samples had T_{max} which was divided into three stages. Before the samples were degraded at the T_{Onset} temperature in the initial stage, there was a small degradation below 100ºC which was the degradation of moisture, solvent light organic molecules, and impurities from the biofoam [23]. The T_{Onsets} of the three samples were all above 120 ºC, with BP1.5 having the highest value of 130 ºC. The first and second stages of degradation occurred at temperatures of 190-209 (ºC) and 294-295 (ºC) respectively, and involved the decomposition of polymer urethane bonds [7, 13, 21]. The last degradation that occurred was the soft segment decomposition of the MDI biofoam at a temperature above 500ºC. This stage involved combustion and aromatic oxidation [7, 24], as well as the degradation of lignin (industrial plywood sawdust) and other molecules that were difficult to separate from the previous stage [21, 25]. Furthermore, the DTG curve (Figure 5) shows that the greatest mass loss occurred at 294 ºC which was the hard segment decomposition stage while the temperature above 525 ºC was the soft segment decomposition stage.

Figures 5(a)-(c) show the TGA results. It was found that BP0, or the biofoam without the addition of waste or MDI ratio, had better thermal resistance. This is because its thermal degradation profile showed that mass loss generally occurred at higher temperature compared to BP1 and BP1.5 (Figure 5 (a)). When biofoam filler was added, it is suggested that two things might have occurred: 1) the organic filler might contain a small amount of water residue as a result of the formation of urea bonds which increases the activation energy for thermal degradation [8], or 2) the addition of filler improved strength by giving the part a hard segment character, which increased thermal resistance [23]. Based on the results found, it should be the result that led to the second reason but this research showed that BP0 had highest thermal conductivity. It means that the filler-free biofoam had good thermal resistance. Another factor that caused a decrease in thermal performance was the uneven distribution of the filler in the polymer matrix which affected density. Besides, the TGA results were also influenced by pore

morphology. The modified biofoam's high pores and open cavities hastened the degradation process, thus reducing the thermal efficiency of the substance being analyzed [8].

DSC analysis was used to measure the change in mass of the heat-treated samples. TGA cannot normally detect physical changes in polymer structures such as glass transition, crystallization, or melting, but these can be determined through DSC [23]. The DSC analysis (Figure 5) reveals that none of the biofoam samples had endothermic melting peaks. This could be caused by a physical changeover of the polymer, or the density from melting at a fast cooling rate to a glassy amorphous state or impure samples. Samples B5 and BP1.5 had a single exothermic peak at 522 °C and 538 °C respectively, while Sample BP0 had two exothermic peaks at 539 °C and 551 °C.

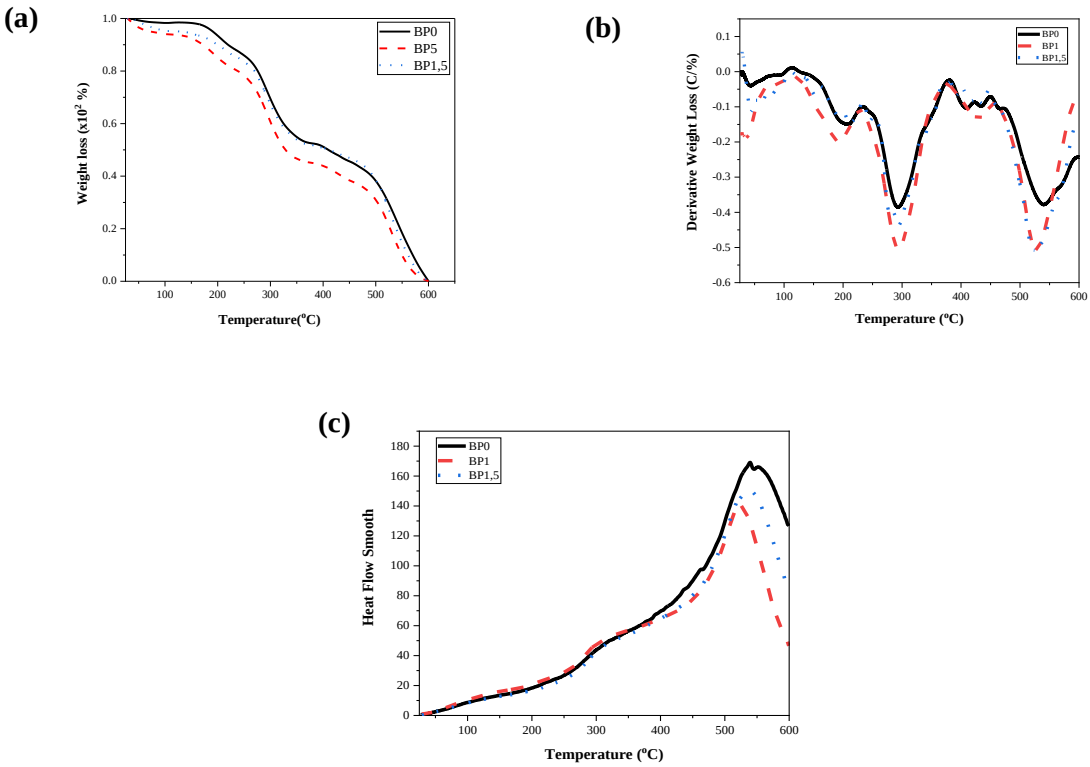

Figure 5. TGA (a), DTGA (b), and DSC (c) of the PUU/IPSW biofoam

Table 3. The sections of thermal degradation on the PUU/IPSW biofoam

Sample Codes	T_{onset} (°C)	(Stages) T_{max} (°C)			Residual Mass 600 °C (%)
		I	II	III	
BP0	126	206	294	539	37.29
BP5	130	190	295	528	23.00
BP1.5	130	209	294	527	33.48

Sound absorption coefficient

The sound absorption coefficient (α) for all samples is shown in Figure 6. The three samples (BP0, BP4, and BP1.5) were measured in the wavenumber range of 0-6400 (Hz) with two microphone impedance tubes and with similar sample thickness of 1.5 cm. Sample BP4 was selected as the representative to the treatment for 1:1 ratio, and the addition of IPSW with highest SAC compared to the other samples. The detailed information regarding SAC for all samples can be found in previous publication [12]. The results showed that BP4 had the highest sound absorption, with a value of 0.69 at 3864 Hz, followed by BP0 with a value of 0.65 at 4552 Hz, and BP1.5 with a value 0.45 at 4760 Hz. All samples showed the best acoustic performance at high frequencies above 3800 Hz. Based on these results, it was found that BP4 had the best acoustic performance, showing that that of BP0 and BP1.5 was not optimal. The addition of filler to the synthesis of polyurethane foam can enhance sound absorption [10, 11]. But this did not apply to the PUU/IPSW biofoam sample with IPSW of above 4% [12] and did not enhance MDI ratio. Several other factors influenced the biofoam sample ability to absorb sound which are explained in the following.

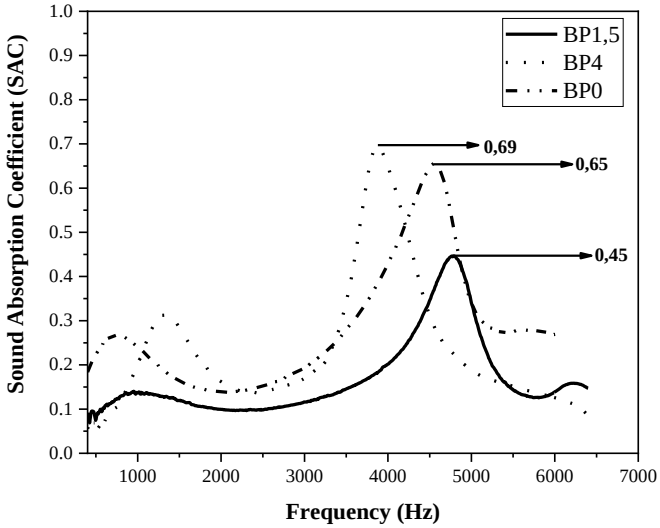

Figure 6. The PUU/IPSW biofoam sound absorption coefficient

Effect of texture, pore morphology, and density

Sound-absorbing foam will have a high SAC value if it has the following material characteristics [20, 25, 26]:

1. Flexible foam texture
2. Open-celled microstructure
3. Small-sized pores in large numbers
4. Higher density (not measured in this research)

The synthesized PUU/IPSW biofoam had the characteristics of semirigid texture, intermediate microstructure, smaller pore size, and higher SAC value than the control biofoam. This can be caused by other influencing factors such as the characteristics of the pores. Even if the size is small and numerous, it may not meet aspects such as structure and pore characteristics of sound-absorbing materials, including those mentioned below [17].

1. The material contains several pores and holes, all of which are small and uniform in size
2. The pores and holes must be connected.
3. The pores and holes inside the material must connect with the outer surface.

Effect of filler addition

The biofoam filler used, called IPSW, was measured by 30 mesh size. The filler had an impact on pore size in such a way that biofoam with added filler had smaller pores than those without filler addition. The smaller pore size was closely related to improved sound absorption mechanism. It is suggested that smaller pores allowed sound waves to dissipate sound energy and dampened it as they move through the sound-absorbing material. Therefore, smaller pores in large numbers allowed more sound wave to collide with the cell wall, lengthening the reflection & bending portion and causing more energy to be absorbed, resulting in higher SAC [10, 15, 20, 27]. The smaller pore size in the synthesized biofoam is shown in Figure 3. The existence of other factors that predominantly affect sound absorption such as the unfulfilled criteria for pores as sound absorbers had resulted in the reduced acoustic performance of the PUU/IPSW biofoam. However, if adjusted and designed with a better formula, the PUU/IPSW biofoam had a great potential as a noise-absorbing material with wide range frequency.

Effect of MDI ratio enhancement

Isocyanate (MDI) is composed of hard segment. Enhancing the MDI ratio can reduce SAC, as shown in Sample BP1.5. Biofoam with added MDI ratio had leaning rigid texture. The texture rigidity was caused by the closed-celled microstructure. Another factor which could make the biofoam texture rigid was chain extender [19, 20].

Conclusion

The PUU/IPSW biofoam was successfully synthesized after its functional groups (–NH, -OH, -CH, -CO and C-C) were identified in the FTIR spectra. Addition of filler and increase in MDI affect pore morphology, thermal resistance, and acoustic performance. Samples BP0 and BP1.5 of the synthesized biofoam had close-celled microstructure morphological type while Sample BP5 had intermediate-celled type. All samples had thermal resistance above 120 ^{o}C. Sample BP4 had the highest SAC with the value of 0.69. The acoustic output was poor, resulting in lower-frequency SAC when tested. However, if adjusted and designed with a better formula, PUU/IPSW biofoam can absorb sound at wide-range frequency. Lastly, filler addition could enhance the biofoam property performance. Therefore, IPSW is promotable as an organic filler for renewable material.

Acknowledgement

The authors thank Rosid Eka Mustofa for assisting with the OriginLab analysis, Iklima Maharani for directing the sample preparation stages, Safira C for laboratory access to the Microscope Camera tool, and all SEM, TGA, FTIR, and Acoustic laboratory test equipment operators who tested all samples in this research.

Abstract

Palm oil has become one of the potential renewable resources in biolubricant application. However, the direct application of palm oil as a biolubricant is restricted due to its low oxidative stability and poor low temperature properties. These drawbacks can be overcome by molecule structural redesign through chemical modification process. Palm oil (PO) was modified via epoxidation, ring opening and esterification process. The epoxidized palm oil (EPO) was prepared by using an *in-situ* performic acid catalyst. Then, EPO was ring-opened using oleic acid in the presence of *p*-toluenesulfonic acid (PTSA) as a catalyst and further esterification with oleic acid using sulfuric acid as catalyst. The molecular structure confirmation of modified palm oils was proven through the oxirane oxygen content (OOC) value, iodin value, hydroxyl value, Fourier transformation infra-red (FTIR), proton and carbon nuclear magnetic resonance (^{1}H-NMR and ^{13}C-NMR) spectroscopy analysis. Results showed that the conversion of PO into EPO has improved its oxidative stability (190 °C). While, the esterification process has resulted in branching and bending in the molecule structure of the final product (palm oil dioleate, PODO), which improved its pour point (-10 °C), flash point (315 °C) and viscosity index (146). These make PODO suitable to be used in biolubricant application.

Keywords: biolubricant, epoxidation, esterification, ring opening, palm oil

Abstrak

Minyak sawit merupakan salah satu sumber yang boleh diperbaharui yang berpotensi dalam penghasilan biopelincir. Walaubagaimanapun, penggunaan secara terus minyak sawit sebagai biopelincir adalah terhad disebabkan oleh kestabilan oksidatif yang rendah dan sifat suhu rendah yang lemah. Kelemahan ini boleh diatasi dengan ubahsuai struktur molekul melalui proses pengubahsuaian kimia. Minyak sawit (PO) diubahsuai melalui proses pengepoksidaan, pembukaan gelang dan pengesteran. Minyak sawit terepoksida (EPO) dihasilkan menggunakan mangkin asid performik yang dijana secara in-situ. Seterusnya, EPO ditindakbalaskan melalui pembukaan gelang menggunakan asid oleik dengan kehadiran p-toluena asid sulfonik (PTSA) sebagai mangkin dan diikuti dengan pengesteran dengan asid oleik dengan menggunakan mangkin asid sulfurik. Pengecaman struktur molekul minyak sawit terubahsuai dibuktikan melalui nilai kandungan oksigen oksiran, nilai iodin, nilai

hidroksil, spektroskopi infra-merah transformasi Fourier (FTIR), proton dan karbon nuklear magnetik resonans (^{1}H-NMR dan ^{13}C-NMR). Keputusan menunjukkan penukaran PO kepada EPO telah memperbaiki nilai kestabilan oksidatifnya (190 °C). Manakala proses pengesteran telah menghasilkan struktur molekul yang bercabang dan bengkok bagi hasil akhir (dioleate minyak sawit, PODO) dan telah memperbaiki nilai takat tuang (-10 °C), takat kilat (315 °C) dan indeks kelikatan (146). Ini menjadikan PODO sesuai untuk digunakan dalam aplikasi biopelincir.

Kata kunci: biopelincir, pengepoksidaan, pengesteran, pembukaan gelang, minyak sawit

Introduction

Currently, there are wide ranges of base oils used in lubricant application, which include mineral oils, synthetic oils, re-refined oils and plant oils. Among these, mineral oils are the most commonly used [1]. However, mineral oils pose a constant threat to ecology and vast ground water reserves due to their inherent toxicity and non-biodegradable nature [1, 2]. The reduction of petroleum oil resources and increasing greenhouse gas emissions also provide a clear picture of the importance of the move towards sustainable development [3]. The use of renewable sources in the industry is vital to ensure sustainable development.

Plant oils are found to be the best alternative source to replace mineral oils in the production of biolubricant because they are renewable raw materials, biodegradable, non-toxic and environmentally friendly. Plant oil itself exhibits good lubrication properties with high viscosity index [4]. Biolubricants hold great potential for environmental conservation as an alternative lubricant. The global market size for biolubricants was USD 2.20 billion in 2019 and is projected to reach USD 2.46 billion by 2025, at a compound annual growth rate (CAGR) of 4.1% between 2020 and 2025 [5]. Stringent regulations and the growing acceptance among end-users are projected to drive the biolubricants market [5].

However, plant oils have several drawbacks that will restrict their direct application in the lubricant industries such as low oxidative stability [6, 7] and poor low temperature properties [3, 8]. The low oxidative stability is due to the presence of bis-allylic protons in plant oil's structure which are highly susceptible to free radical attack and therefore undergo oxidative degradation to form polar oxy compounds [9-13]. The rate of the oxidation process can be attributed to the number of unsaturated fatty acids present in its composition [10,14]. Meanwhile, poor low temperature properties include cloudiness, precipitation, poor flowability and solidification at relatively high temperatures [8, 15]. The poor low temperature properties also will limit its use at a low operating temperature [6].

The oxidative stability and poor low temperature drawbacks that occur in the plant oils can be overcome by molecule structural redesign through chemical modifications. The presence of the double bonds and their reactivity have allowed the functional addition reactions into the unsaturated fatty acids. The epoxidation process is one of the most important functionalization reactions of the double bond to other stable functional groups to improve the plant oil's oxidative stability [6, 16, 17]. The epoxidation of plant oil using peracids is one of the most important steps and a useful modification process toward the double bonds because the epoxides are reactive intermediates that can be converted to other functional groups through ring-opening reactions [18]. Plant oils with high content of unsaturated fatty acid are used to produce high epoxy functionality materials [19]. Epoxidized plant oils products from the epoxidation process can be used as high-temperature lubricants [20], plasticizers [21] and high temperature coating materials [22].

Meanwhile, the modification that can be used to improve poor low temperature properties of plant oil is ring opening and esterification reactions. The oxirane ring opening by acidic or alkaline catalyzed reaction with suitable reagent provides interesting polyfunctional compounds [15, 23], whereas reducing structural uniformity of the oil by attaching alkyl side chains would improve the low-temperature

performance [15, 24]. The branching group which resulted from ring opening reaction will interfere with the formation of macro-crystalline structures during low-temperature applications and provide enhanced fluidity to plant oils. These modified plant oils with chain branching were reported to have the superior performance of the physicochemical properties and are promising as biolubricants [25]. Products obtained from ring opening can be used as low-temperature lubricants [20].

Palm oil which is abundantly available all over Malaysia become one of the potential plant oils that can be used as biolubricant base stock [26, 27]. In this paper, the modification of palm oil molecule structure to produce a base stock oil for lubricant application as shown in Figure 1 is reported. Palm oil contains a high percentage of unsaturated fatty acid (49.4%) [28], which serves as good starting material for the epoxidation process. Palm oil was converted into epoxidized palm oil followed by the ring opening and esterification reactions with oleic acid to enhance the lubrication properties. The structure of products was confirmed by FTIR and NMR spectroscopy. Physicochemical properties of products were examined by using several tests such as oxidative stability, pour point, flash point and viscosity index.

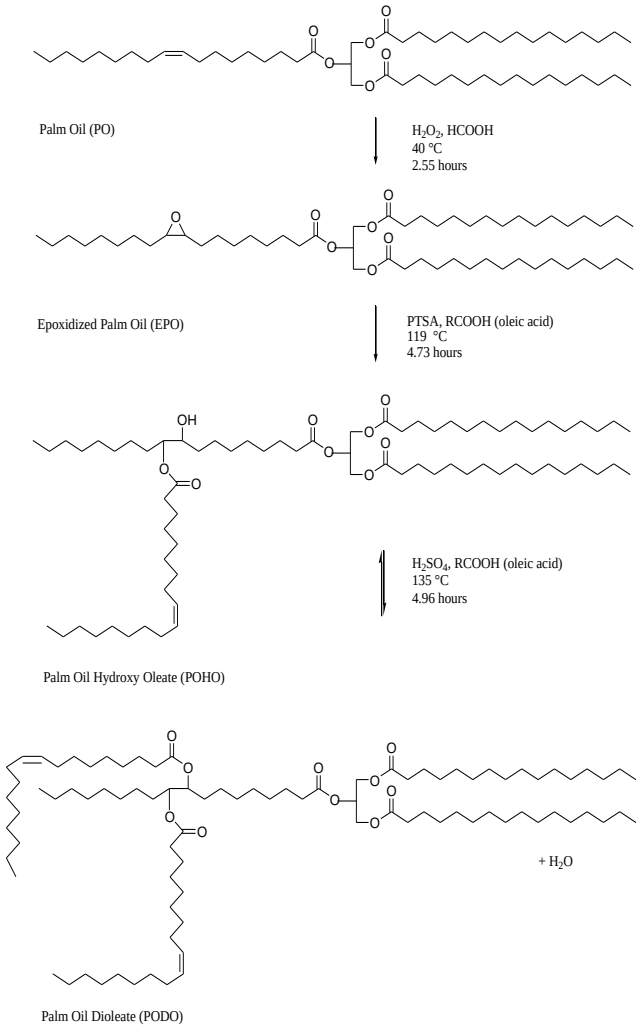

Figure 1. The schematic reaction for the modification of palm oil

Materials and Methods

Materials

Palm oil was obtained from Jomalina Refinery, Teluk Panglima Garang, Selangor, Malaysia. Formic acid (88%) was obtained from Fisher Scientific and hydrogen peroxide (30%) from Merck. Oleic acid (90%) was purchased from Sigma Aldrich. Ethyl acetate, toluene, sodium hydrogen carbonate and sodium chloride were purchased from Systerm.

Chemical modification processes

The epoxidation process was carried out based on the optimum conditions reported by Nurazira et al. [27]; mole ratio of PO: HCOOH: H_2O_2 (1:5.91:3.6), reaction temperature of 40 °C and reaction time of 2.55 hours. Next, the ring opening process was carried out based on the optimum conditions reported by Nurazira et al. [29]; mole ratio of EPO: oleic acid (1:3), reaction temperature of 119 °C, reaction time of 4.73 hours and 1.02% of *p*-toluenesulfonic acid (PTSA). The next esterification was carried out by using a mole ratio of POHO and oleic acid at 1:3, reaction temperature of 135 °C, reaction time of 4.96 hours and 1.86% of sulphuric acid.

Characterization of modified palm oils

The unsaturation of oil was determined by iodine value (IV) test using the Wijs method [30]. Oxirane oxygen content (OOC) value was determined by direct method using hydrobromic acid solution in glacial acetic acid (AOCS Cd 9-57) [31]. Hydroxyl value (HV) was performed according to analysis method (AOCS Tx 1a-66) [31]. The structure of modified oils was confirmed by using Fourier Transformation Infra-red (FTIR), proton and carbon Nuclear Magnetic Resonance (^{1}H-NMR and ^{13}C-NMR). FTIR spectra were recorded on a Perkin Elmer Infrared Spectrophotometer in the range of 400-4000 cm^{-1}. ^{1}H and ^{13}C NMR were recorded on JEOL-ECP 400 spectrometer (400 MHz ^{1}H/100.61 MHz ^{13}C) using $CDCl_3$ as a solvent.

Physicochemical properties tests of modified palm oils

The American Society for Testing Materials standards such as ASTM D-6186, ASTM D-5853, ASTM D-92 and ASTM D-2270 were used to measure oxidative stability, pour point, flash point and viscosity index [32]. The oxidative stability test was conducted using Differential Scanning Calorimetry (DSC). 1.5 mg of sample was placed into an aluminum pan with a pinhole cover to allow interaction between ester product and oxygen gas which acts as reaction gas. Then, aluminum pan was put into DSC and heated for 20 minutes up to temperatures of 250 °C by using nitrogen gas. Onset temperature was recorded to determine the oxidative stability.

In the pour point test, the sample was filled into a U-shaped glass tube until it reached a height of 4 cm. The thermometer was placed at one end of the U-shaped tube and both ends of the U-shaped tube was covered with parafilm. The U-shaped tube containing the sample was placed in the refrigerator (minimum temperature -80 °C) for 24 hours to ensure that the sample froze completely. After being left overnight, the U tube was removed and flipped upside down. The lowest temperature at which movement of the sample was observed was recorded as the pour point.

For flash point testing, 2 mL of sample was placed in a crucible and heated on a heating plate. A thermometer with a maximum reading temperature of 360 °C was placed on the sample to measure the sample's temperature. The temperature was rapidly increased at first and then at a slow constant rate as the flash point was approached. The lowest temperature at which the vapors above the surface of the liquid ignited was taken as the flash point.

For the viscosity index test, the Rheometer Anton Paar (Physica MCR 301 model) was used to measure the viscosity and viscosity index of the tested sample. The diameter used for both samples was 0.051 mm. Samples was tested at 40 °C and 100 °C [32]. The sample viscosity index was calculated based on the formula below:

$$\text{Viscosity index} = (L-U)/(L-H)\times 100$$

where: U= oil's kinematic viscosity at 40 °C, L and H = values based on the oil's kinematic viscosity at 100 °C.

Results and Discussion

Palm oil is golden yellow and exists in the semi-solid form at room temperature. The liquid fraction contains unsaturated triacylglycerol (TAG), whereas the solid fraction contains more saturated TAG. The epoxidation process is more likely to occur at unsaturated TAG.

In epoxidation reaction, hydrogen peroxide acts as an oxygen donor, while formic acid acts as an oxygen carrier and gets regenerated once the epoxidation reaction takes place [33]. Formic acid also takes part in the overall reaction as a catalyst in the formation of the oxirane ring and as a reactant in the hydrolysis of the oxirane ring. To attain the maximum oxirane oxygen content, the level of the formic acid should be such that these two effects are balanced [34,35]. Figure 2 shows the mechanism of the epoxidation reaction.

The results for the epoxidation of palm oil are shown in Table 1. The average percentage yield of epoxidation was 86% (w/w). The epoxi dation process can be monitored through the IV and OOC values. The IV should be as small as possible after epoxidation, while OOC should be as large as possible. There was a difference between the IV before and after epoxidation. The initial IV of palm oil before epoxidation was 57.8 m/g, while the IV obtained for EPO after epoxidation was low approaching zero (0.09 mg/g). EPO showed a high OOC value which was 3.46% with 99.43% of relative conversion oxirane (RCO). The theoretical value of OOC was 3.49%. It means almost all unsaturated fatty acids in PO were successfully epoxidized and converted to oxirane rings to produce EPO.

Many nucleophilic reagents are known to add to an oxirane ring, resulting in ring opening. The ester branching groups produced from oxirane ring opening based esterification reactions are effective for attaining the desired molecular spacing. Most of the oxirane ring groups were opened and converted into ester bonds in the molecule with the hydroxyl group [26, 36]. The modified plant oils with chain branching were reported to have superior performance properties and are promising as biodegradable lubricants [26,36,37]. Figure 3 shows the mechanism of ring opening reaction.

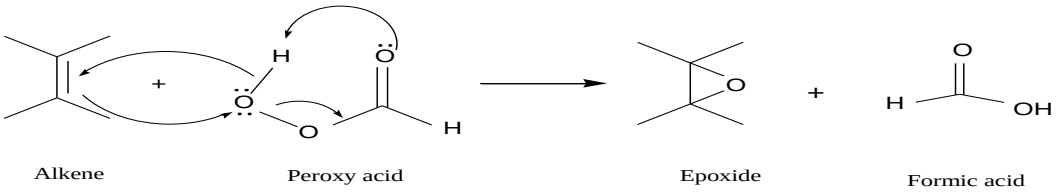

Figure 2. The mechanism of the epoxidation reaction

Table 1. Analysis results for modified palm oils

Compound	PO	EPO	POHO	PODO
Yield (%)	-	86	84	80
Iodine value (mg/g)	57.8	0.09	59.4	109.8
OOC value (%)	-	3.46	0.041	-
RCO (%)	-	99.43	-	-
Hydroxyl value (mgKOH/g)	19	23	118.7	25.4

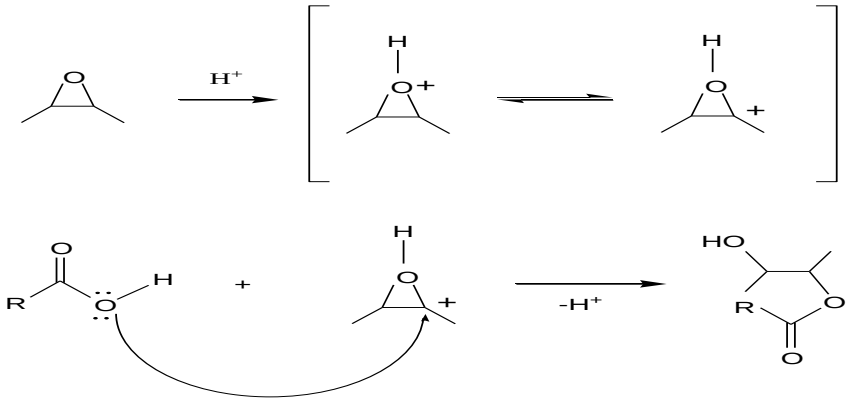

Figure 3. The mechanism of the ring opening reaction

This study reports the oxirane ring opening reaction of epoxidized palm oil (EPO) by the nucleophilic addition of oleic acid (OA) in the presence of homogenous acid catalysts which was *p*-toluenesulfonic acid (PTSA). PTSA was preferred to be used in the reactions due to the maximum yield of epoxy ring opening and no evidence of any side reaction occurred during the reaction [38]. The nucleophilic attack by the fatty acid molecule which was oleic acid on the oxirane ring of epoxidized palm oil (EPO) in the presence of PTSA as catalyst resulted in the ring opened product: palm oil hydroxy oleate (POHO).

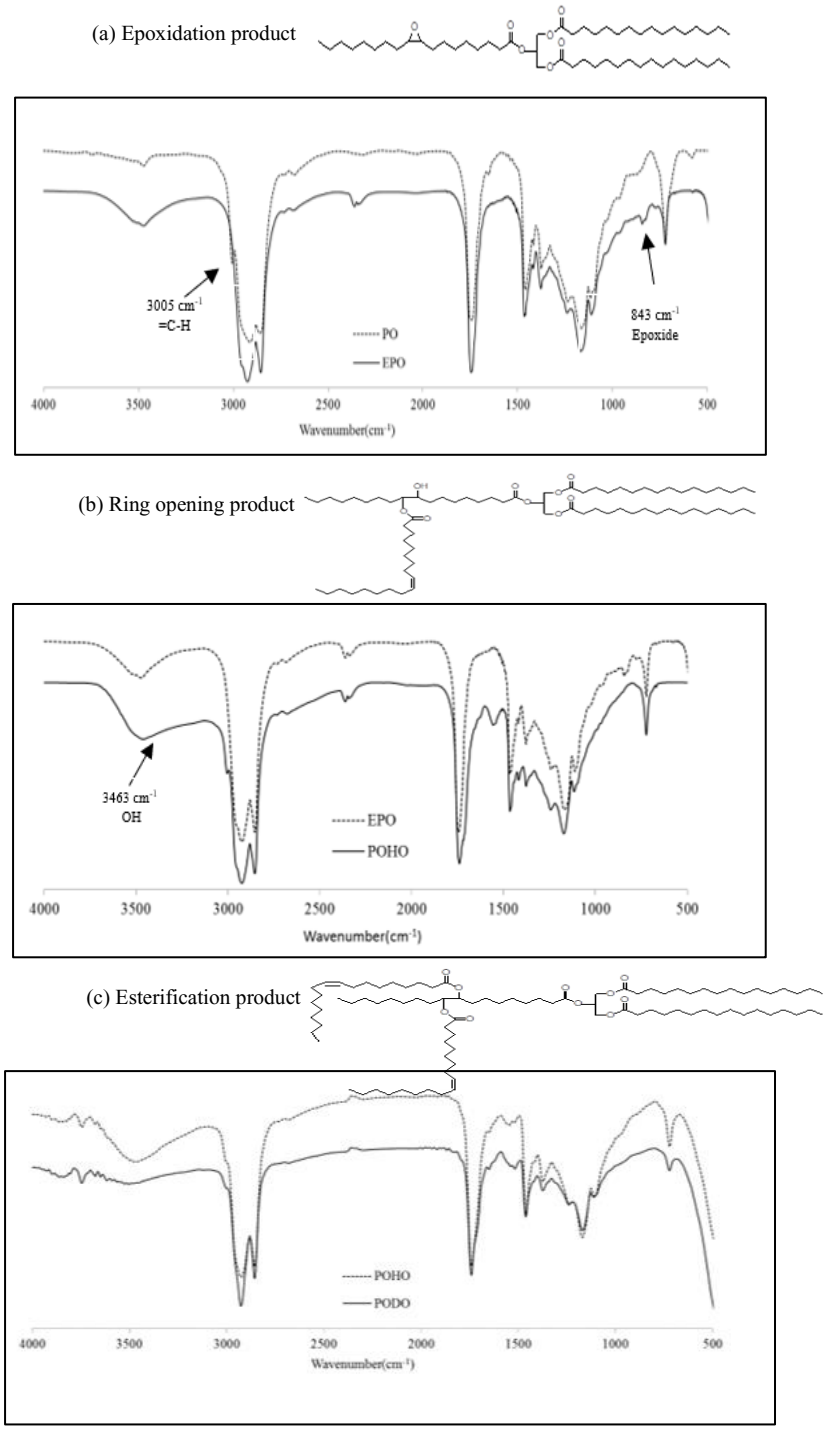
The results for the ring opening process are shown in Table 1. The average percentage yield of ring opening was 84% (w/w). The ring opening process can be monitored through IV, HV and OOC values. The OOC value should be as small as possible. This is because the reduction of OOC value is proportional to the number of epoxides opened. OOC value obtained after ring opening process was low approaching zero (0.041%). It showed that the entire epoxide ring was successfully opened during the ring opening reaction with the oleic acid to produce POHO. The entire epoxide ring had been successfully converted to hydroxyl oleate ester functional groups. This can be evidenced by the increase of IV and HV of the product. The addition of the olefin which exists from the oleate acyl group had increased the IV of POHO to 59.4 mg/g. There was also an increase in HV from 23 mg KOH/g to 118.7 mg KOH/g after the ring opening process. Further esterification of POHO with oleic acid produced the final product: palm oil dioleate (PODO). The average percentage yield of the final esterification process was 80% (w/w). There was a decrease in HV of PODO to 25.4 mgKOH/g and an increase of IV (109.8 mg/g) after esterification. It means that the hydroxyl group of POHO was reacted with oleic acid to produce the oleate acyl group.

FTIR spectra

The presence of functional groups in all modified oils was identified by using FTIR spectroscopy. Figure 4 shows the FTIR spectra of PO, EPO, POHO and PODO. The disappearance of the double bond functional group peak at 3005 cm^{-1} which was initially present in the PO spectrum indicated the conversion of the double bond to the epoxy group. It can be proven by the presence of a C-O-C oxirane peak at 843 cm^{-1} in the EPO spectrum. Pavia et al. [39] reported the presence of epoxy group can be monitored at wavenumber range of 815-950 cm^{-1} which agrees well for this study.

The disappearance of the epoxide peak showed that the entire oxirane ring had been successfully converted to hydroxyl oleate ester functional groups during the ring opening reaction with oleic acid. This is evidenced by the increase of peaks intensity of the hydroxyl (OH) functional group at 3463 cm^{-1} and C=O stretching at 1740 cm^{-1} in the POHO spectrum. A significant change in the ring opening process also can be evidenced by

the existence of the C=C olefin peak of the oleate acyl group at 3003 cm^{-1} in the POHO spectrum. The final esterification product (PODO) was evidenced by the reduction of the peak intensity of the hydroxyl group in the PODO spectrum.



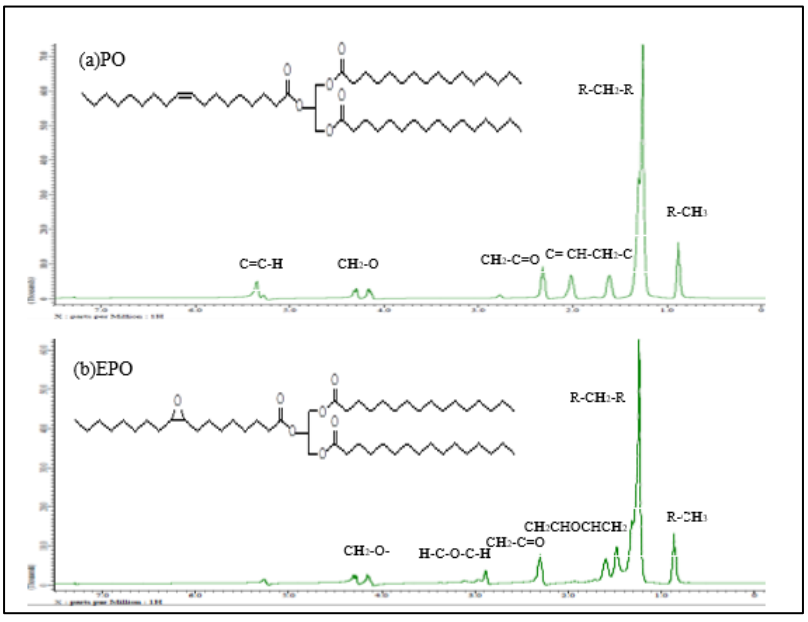


Figure 4. FTIR spectra of (a) epoxidation; (b) ring opening; (c) esterification products

NMR spectra

Figure 5 shows ^{1}H NMR spectra of PO, EPO, POHO and PODO and Table 2 shows the chemical shift for all products. The epoxidation process (EPO) can be proven by the disappearance of olefin proton at 5.34 ppm (C=C-H) and allylic proton at 2.0-2.05 ppm (C=C-C-H), which initially were present in the PO spectrum. They were replaced by the existence of a peak signal at 2.89 ppm, which corresponds to the proton of oxirane ring (CHOCH) and a peak signal at 1.49 ppm that represents epoxy proton (CH_2-CHOCH-CH_2) in the EPO spectrum. The result of ring opening reaction can be confirmed by the disappearance of peak signal of oxirane ring proton (CHOCH) in the POHO spectrum. Peak signal for olefin proton and allylic proton can be detected at 5.30-5.36 ppm (C=C-H) and 1.97-2.09 ppm (C=C-C-H) in the POHO spectrum. The final product showed that there was a disappearance of the C-O-H peak signal (C-O-H) in the PODO spectrum.

Figure 6 shows ^{13}C NMR spectra of PO, EPO, POHO and PODO and Table 3 shows the chemical shift for all products. The peaks at 127.85- 130.17 ppm in the PO spectrum represented the double bond (C=C). Conversion of the double bond to oxirane ring can be proven by the disappearance of double bond peak and existence of carbon atom of epoxy (C-O) at 54.19-57.22 ppm in EPO spectrum. The results of ring opening reaction can be evidenced by the disappearance of epoxy carbon, the existence of carbon olefin (C=C) at 129.60-129.97 ppm and also the existence of peak signal at 73.50 ppm, which represents the carbon next to the hydroxyl group (HC-OH) in POHO spectrum. The final product showed that there was a disappearance of the HC-OH signal peak in the PODO spectrum.

Table 2. The chemical shifts for ^{1}H NMR PO, EPO, POHO and PODO spectra

Compound	**Chemical Shift, ppm**	**Chemical Shift, ppm (Reference[36])**	**Remarks**
PO	5.34	4.5-6.5	C=C-H
	2.00 - 2.05	1.6-2.6	C=C-C-H
EPO	2.89	2.5-3.5	CHOCH
POHO	5.30-5.36	4.5-6.5	C=C-H
	1.97-2.09	1.6-2.6	C=C-C-H
	4.99	0.5-5.0	C-O-H
PODO	5.34-5.37	4.5-6.5	C=C-H
	2.00-2.07	1.6-2.6	C=C-C-H

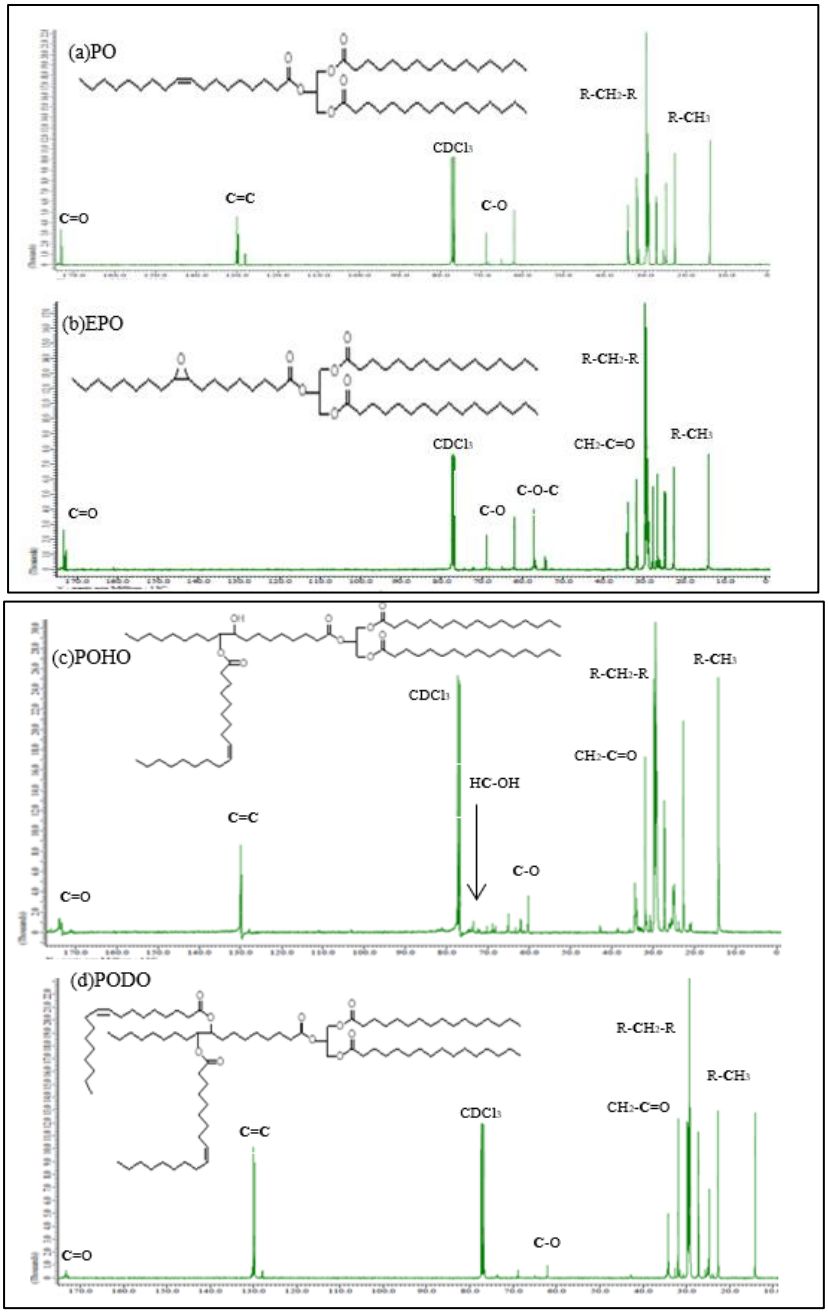

Figure 6. ^{13}C NMR spectra of (a) PO; (b) EPO; (c) POHO and (d) PODO

Table 3. The chemical shifts for ^{13}C NMR PO, EPO, POHO and PODO spectra

Compound	Chemical Shift, ppm	Chemical Shift, ppm (Reference[36])	Remarks
PO	127.85- 130.17	100-150	C=C
EPO	54.19-57.22	56.9-58.5	C-O-C
POHO	129.60-129.97	100-150	C=C
	60.18-63.30	40-80	C-O
PODO	127.88-130.16	100-150	C=C

Physicochemical properties

There were several tests conducted to determine the physicochemical properties of the modified oils. The physicochemical properties results obtained are shown in Table 4. The ability of a substance to resist oxidative degradation is an important property of biolubricant. Oxidative stability is determined by the onset temperature (OT) using Differential Scanning Calorimetry (DSC). OT is the temperature at which the occurrence of a sharp increase in the rate of oxidation of the sample. Higher onset temperature indicates that the lubricant has high oxidation stability [6]. Based on the DSC analysis, there was an improvement in oxidative stability for EPO (190 °C) compared to PO (181 °C). It was due to the conversion of the double bond group to the epoxy group which will reduce the active site of oxidation and make it less susceptible to radical attack. However, POHO and PODO showed low oxidative stability due to increasing double bond content and carbon chain, which will increase the potential active site for the oxidation process.

Table 4. Physicochemical properties of PO, EPO, POHO, PODO and commercial lubricants (100A and 100B)

Compound	PO	EPO	POHO	PODO	100A[a]	100B[b]
Oxidative stability (°C)	181	190	170	157	n/a	n/a
Pour point (°C)	7	18	-8	-10	-19	-27
Kinematic viscosity (40 °C)	56.97	97.72	616.46	83.45	96	96.7
Kinematic viscosity (100 °C)	9.24	14.56	60.73	15.30	10.9	11
Viscosity index (VI)	130	133	125	146	97	100
Flash point (°C)	240	255	295	315	276	254
ISO viscosity grade	46	100	680	100	100	100

a:100A: Denicol Compressor Oil ISO VG 100 [41],
b: SubsTech Hydraulic Oil ISO 100 [42]

Pour point is one of the important quality parameters to determine cold flow or low temperature properties of the lubricant. The cold flow properties of plant oils are extremely poor and these limit their use at low operating temperatures especially as automotive and industrial fluids. Plant oils tend to form

macrocrystalline structures at low temperatures through uniform self-stacking of the linear triacylglycerol molecules. The macrocrystals restrict the easy flow of the system due to the loss of kinetic energy of individual molecules during self-stacking [6, 15, 40]. PODO has the lowest pour point (-10 °C) compared to other products due to the branched carbon chain and bent structure. It makes it more restricted to self-stacking and more hollows in the structure, thus easier for it to flow, which contributed to the lowest pour point. In general, the presence of a branching group at the end of the molecule will disrupt this stacking process and create a steric barrier around the individual molecules and inhibit crystallization [18]. This will result in the formation of microcrystalline structures rather than macro structures. At lower temperatures, the microcrystalline structures can easily tumble and glide over one another resulting in better fluidity of the total matrix [6], resulting in a lower pour point. Moreover, the disappearance of the hydroxyl group in PODO esters means that no hydrogen bonds exist in the molecule, which causes the molecules to be less sticky to each other and to move freely around.

Viscosity also becomes one of the important quality parameters for lubricating oils. The efficiency of the biolubricant in reducing friction and wear is greatly influenced by its viscosity. The viscosity of PO is lower than EPO due to the existence of a double bond, which provides the lubricating properties of liquids by degrees of unsaturation. POHO has a higher viscosity due to the presence of intermolecular hydrogen bonding from the hydroxyl group resulted from the ring opening reaction. The hydroxyl group gives a higher polarity that influences the viscosity of the oil, in which more polar molecule of oil, the higher the viscosity [40]. In general, the hydroxyl group will form a bond between molecules and cause lubricating oil to become more viscous. After the final esterification process, the viscosity of PODO decreased due to the disappearance of the hydroxyl group. The viscosity of PODO was in the medium range, which was 83.45 centistokes (cSt) at 40 °C and decreasing to 15.30 cSt at 100 °C. It shows the viscosity of biolubricant decreases as temperature increases. The least viscous biolubricant which still forces the two moving surfaces apart is desired. If the biolubricant is too viscous, it will require a large amount of energy to move and if is too thin, the surfaces will rub and friction will increase [6]. The viscosity index highlights how the viscosity of biolubricant changes with variations in temperature [6]. PODO showed the highest viscosity index (146) compared to other products. It shows the viscosity of PODO is less affected by temperature changes and does not drastically change when the temperature varies. This is a good indicator and it is suitable for use at a large temperature range.

The flash point is often used as a descriptive characteristic of fuel oil and it is also used to describe oils that are not used as fuels such as a lubricant. Flash point refers to both flammable oils and combustible oils. The oils with a flash point of less than 43 °C are flammable, while those having a flash point above this temperature are combustible. Biolubricant which has a low flash point value is considered to have been contaminated by volatile and usually requires special precautions when handling these biolubricant [6]. PODO showed the highest flash point (315 °C) compared to other products. It is due to the increasing carbon number which causes an increasing molecular weight that gives a higher flash point. In addition, PODO also has a big branched molecular structure which requires more energy to burn. This will increase the flash point of PODO. A high flash point is important to ensure that the lubricant is not burned in the engine during its operation.

Table 4 also shows a comparison of lubrication properties between the biolubricant base stock produced (PODO) with commercial lubricants in the market. The selected commercial lubricants are ISO VG 100 grade lubricants, namely Denicol Compressor Oil (100A) [41] and SubsTech Hydraulic Oil (100B) [42]. Based on the comparison made, PODO has a higher viscosity index compared to 100A and 100B lubricants. The pour point value of PODO is also lower than 100A and 100B lubricant. In addition, PODO also recorded much higher flash point value than 100A and 100B lubricants.

Conclusion

The chemically modified palm oils showed improvement in physicochemical properties. The epoxidized palm oil (EPO) has the highest oxidative stability due to the reduction of double bond content, while the final esterification product, palm oil dioleate (PODO) has the lowest pour point due to the greater ability of the branched chain esters to disrupt crystalline formation. A bigger, bending, branching and hollow structure makes the molecule less compact, thus improve the lubricity of the lubricant. PODO also showed the highest viscosity index and flash point due to the big branched molecular structure. This makes PODO as plausible to be used as a biolubricant with better lubrication properties.

Abstract

In this study, the removal performance of bisphenol A (BPA) from synthetic wastewater using the forward osmosis method was compared between polyamide thin film composite membrane (PA -TFC) and polysulfone (PSf) membrane substrate. The thin-film composite membrane was prepared by using flat polysulfone (PSf) sheets as membrane substrate through in-situ interfacial polymerization technique. To generate the thin film surface on the PSf substrate, M-phenylenediamine (MPD) and 1,3,5-benzene trichloride (TMC) were utilized as monomers in aqueous and organic solutions, respectively. The BPA retention efficiency of the PSf and TFC membranes was examined and compared accordingly. The membranes were characterized by using atomic force microscopy (AFM), field emission scanning electron microscope (FESEM), Fourier transform infrared spectroscopy (FTIR), and contact angle analysis. The fabricated thin film on the PSf substrate membrane has enhanced its hydrophilicity which aids in wastewater treatment by increasing the membrane's water flow rate. A synthetic BPA wastewater solution of 100 mgL-1 was prepared to evaluate the performance of the membrane. Based on the finding of this study, the PSf substrate and PA -TFC membrane yielded 25% and 91% of BPA removal from the feed solution, respectively.

Keywords: bisphenol-a, polyamide, thin-film composite membrane, forward osmosis

Abstrak

Dalam kajian ini, penyingkiran bisfenol A (BPA) dari air sisa sintetik disiasat menggunakan membran filem komposit nipis poliamida (PA -TFC) dan dibandingkan dengan substrat membran polisulfon (PSf) menggunakan proses osmosis hadapan. Membran TFC diperbuat melalui teknik pempolimeran dengan menggunakan permukaan PSf sebagai substrat membran. M-fenildiamina (MPD) dan 1,3,5-benzena triklorida (TMC) digunakan sebagai monomer dalam larutan berair dan organik untuk menghasilkan permukaan filem nipis pada substrat PSf. Penyingkiran BPA melalui membran PSf dan TFC disiasat dan dibandingkan. Setiap membran dicirikan dengan mikroskopi tekanan atom (AFM), mikroskopi imbasan elektron pancaran medan (FESEM), spektroskopi inframerah transformasi Fourier (FTIR) dan analisa sudut sentuhan. Lapisan filem nipis yang dihasilkan pada membran substrat PSf meningkatkan daya hidrofiliknya, yang membantu dalam rawatan air sisa dengan meningkatkan kadar pengeluaran air. 100 ppm larutan sisa air BPA sintetik disediakan untuk menguji prestasi membran. Dari data yang diperoleh dari kajian ini, substrat PSf dan membran PA -TFC menghasilkan 25% dan 91% penurasan BPA dari sisa tersebut.

Kata kunci: bisfenol a, poliamida, membran filem komposit nipis, osmosis hadapan

Introduction

The rapid growth and development of modern industries have led to serious environmental issues nowadays. The threats posed by organic micropollutants especially pharmaceutically active and endocrine-disrupting compounds have been of great concern over the previous years. Numerous studies have been performed on investigating their removal mechanism from the wastewater [1]. These compounds are highly related to the effluents of industrial sectors such as pharmaceutical, plastic, dye and textiles, oil refineries, and petrochemical industries [2]. Industrial wastewater treatment plant (WWTP) effluent is an important source of these compounds, as these micropollutants are hardly removed by the conventional treatment processes [3, 4]. Thus, advanced membrane treatment of WWTP effluents to remove these pollutants could be an effective approach to reduce their presence in the ecosystem and thus contribute to mitigating the environmental risk.

Bisphenol-A (BPA) is an endocrine disruptor that is commonly utilized in the manufacturing of polycarbonate, epoxy resins, dental composites, and medical equipment [5]. This organic pollutant has huge potential to cause serious health hazards to humans, wildlife, and the ecosystem even at low concentrations [6, 7]. Structurally, BPA consists of phenolic and hydroxyl groups in combination with an aromatic ring. BPA has a molecular weight of 228 g/mol and shows relatively low solubility in water with the range of 120-300mg/L at 25 ^{o}C [8]. However, its solubility increases if dissolved in polar organic solvents or aqueous solutions with alkaline concentrations. The total daily intake (TDI) of BPA has been regulated at 50µg/kg/day, while the oral reference dosage for BPA has been set at 100 µg/L as the maximum allowable concentration in drinking water according to the United States Environmental Protection Agency [9].

BPA can cause adverse health effects because it is an endocrine disruptor that binds to receptors in living organisms [38]. BPA acts as a hormone receptor blocker for various hormones and interferes with their activity which leads to damage to the human body. For instance, it acts as an antiestrogen by competing with endogenous E and inhibiting its estrogenic response [10]. Previous laboratory studies reported that this compound may also bind directly to the sex hormone receptors (androgen receptors) and inhibit the activity of endogenous androgen [11]. These hormone-inhibiting effects may lead to fertility problems such as decreased sperm quality, polycystic ovary syndrome, and sex hormone concentrations. Increases in chronic diseases such as type 2 diabetes, obesity, cardiovascular disease, prostate, and breast cancer have been linked to early exposure to BPA [12]. In addition, there is a high probability that maternal exposure to BPA can cause postnatal abnormalities in DNA methylation status, disrupting the expression of some particular genes and the epigenetic programming of gene expression during child development [13]. Due to their widespread dispersion in the environment and continuous usage in industry, it is critical to develop new treatment techniques for their degradation, detoxification, and removal in wastewater effluents.

Concentrative processes such as absorption, ozonation, and Fenton have effectively removed the major microbial contaminants and chemicals from wastewater treatment facilities. However, the application of these techniques for the removal of endocrine disruptors is restricted [14, 15, 16]. In addition, due to stringent water quality requirements, it is becoming increasingly important to remove BPA from water sources, even if it presents in extremely low concentrations. Pressure-driven membrane separation methods such as reverse osmosis (RO), nanofiltration (NF), ultrafiltration (UF), and microfiltration (MF) in pore sizes ascending order, have been demonstrated to be effective in removing BPA from wastewater and producing high-quality water from WWTP secondary effluent [17]. According to Schrotter et al., membrane technology has been utilized to treat approximately 60 million m^3 of water per day, with RO being the most widely used membrane process for wastewater treatment. Meanwhile, microfiltration and ultrafiltration have a combined average capacity of 20 million m^3 per day, accounting for 60% of total drinking water production [17].

Unlike chemical oxidation and biodegradation, membrane filtration does not utilize chemicals or

generate by-products/new metabolites, making it more suitable for treating drinking water due to its environmentally friendly's characteristic [17]. The membrane process uses a variety of mechanisms to remove micropollutants from wastewater. For example, BPA removal in NF and RO is performed by sieving and electrostatic interactions, while the removal mechanism in MF and UF is generally based on the adsorption process [18, 19]. When compared to traditional techniques, the employment of membrane separation processes has numerous advantages: low energy cost, easy operational control, no use of chemicals, and compact structure with possible material recovery [20].

Zhao et al. examined the removal of BPA using a commercial UF hollow fibre membrane at a dosage of 1000 µg/L. Due to the large pore size of the UF membrane (0.04 microns), the BPA removal efficiency was found to be < 5%. The removal approach applied the adsorption mechanism of the membrane rather than the size exclusion technique [21]. The UF-Koch membrane was tested for the removal performance of BPA at the concentration of 1µM. This membrane showed significant retention efficiency of BPA (> 40%), which was attributed to the adsorption process on the membrane surface [22]. Bing-Zhi et al. [2010] investigated the removal of BPA from wastewater using a commercial MF membrane. They found that this membrane showed poor BPA retention performance, with the removal rate decreasing from 95% to 20% at the end of the filtration process as the membrane got saturated with BPA [23].

Yuskel et al. observed that the RO and NF membranes performed well when tested for removing BPA from synthetic wastewater at a concentration of 50 mg/L with an operating pressure of 10 bar. The NF membranes made of compressed and loose polyamide were used in the experiment. A polyamide and cellulose acetate RO membrane was also tested. The dense RO and NF membranes demonstrated excellent BPA removal (> 98%), while the loose NF membrane demonstrated much lower rejection (80%), and the cellulose acetate RO membrane demonstrated low rejection of BPA of 10-40%, which was attributed to BPA adsorption on the membrane surface [24]. These technologies, however, fall short because they are particularly susceptible to membrane fouling, have large pore sizes (MF and UF), and rely on high pressure to work [17].

Forward osmosis (FO) is an alternative membrane filtration process that has been utilized in recent decades for desalination, wastewater treatment, and production of high-quality water. The FO method uses the osmotic differential pressure between the draw and feed solutions to reject the trace organic pollutants. [25]. This process has a great advantage over the conventional membrane filtration process as it does not require the application of hydraulic pressure to operate, and fouling propensity is minimal due to the generation of osmotic pressure from the concentrated draw solution [26]. Even when fouling occurs, it can easily be reversed and controlled via chemical, physical, or physiochemical cleanings unlike the RO and NF methods [27, 28].

Presently, there have been advancements in the type of membranes fabricated using interfacial polymerization (IP) that can be used with the forward osmosis process, such as the thin film composite and thin film nano-composite membranes. these membranes are controlled by the osmotic pressure of water and are usually utilized in the wastewater separation and desalination processes in pharmaceuticals and chemical industries [29]. TFC membranes are believed to be a viable method for eliminating tiny organic contaminants such as BPA from industrial and pharmaceutical effluents since they are modified to have smaller pore sizes as compared to RO, NF, and UF membranes. Nowadays, TFC membranes made from modifying a thin-film layer of aromatic polyamide on a porous membrane substrate are employed in wastewater treatment operations [30, 31]. The greater retention of feed solution components, along with an increase in permeate flow has led to their widespread adoption. TFC membranes can remove heavy metals, organic micropollutants such as pharmaceuticals, endocrine disruptors, and pesticides from wastewater [17]. In general, polyamide membranes have been reported in the literature that they performed better than cellulose acetate-based membranes in rejecting organic micropollutants. This is because they have lower pressure requirements and operate under more flexible settings [32].

Thus, the goal of this study is to determine if employing a thin-film composite membrane to remove BPA from pharmaceutical effluent is more feasible and efficient than using conventional polysulfone substrates. The interfacial polymerization method was used to fabricate the TFC membrane on the polysulfone membrane substrate layer. Both membranes' efficiency in removing BPA from the synthetic wastewater was compared in this study.

Materials and Methods

Materials and reagents

Bisphenol A (BPA), polysulfone (PSf), polyvinylpyrrolidone (PVP), N-methyl-2-pyrrolidinone (NMP), M-phenylenediamine (MPD), 1,3,5-benzenecarbon trichloride (TMC) were procured from Sigma Aldrich Chemicals Company. These materials were all of the analytical grades and were used exactly as they were received. All of the experiments were conducted using distilled water.

Forward osmosis membrane fabrication: Membrane substrate preparation (Psf substrate)

The wet phase inversion method was used to prepare the PSf membrane substrate. Firstly, a dope solution with the composition of PSf/NMP/PVP (wt.%) = (15/82/3) was prepared. The NMP was then dissolved in PSf pellets, and PVP was added as an additive to increase the porosity of the membrane substrate. The casting solution was continuously stirred until the polysulfone pellets were completely dissolved in the solution. The dock solution was then poured on the glass surface with a 200µm casting rod. The casted membrane on the glass surface was instantly submerged in a water bath for the wet phase inversion. The generated PSf support membrane was kept in distilled water before use.

Thin-film composite membrane fabrication

The thin-film polyamide layer was fabricated by using the interfacial polymerization method as shown in Figure 1. Two solutions were prepared: an aqueous solution comprising of 2 wt.% MPD in distilled water and an organic solution comprising of 0.05 wt.% TMC dissolved in heptane. The PSf membrane substrate was immersed in the MPD solution for 3 minutes. After that, a thin-film polyamide layer was formed by carefully pouring the TMC solution on top of the membrane for 3 minutes. The generated Polyamide Thin-Film Composite (PA-TFC) membranes were stored in distilled water and kept at room temperature before use.

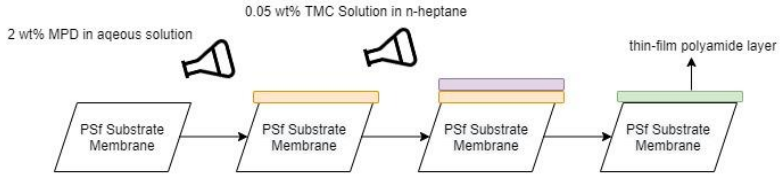

Figure 1. Preparation of polyamide TFC layer via interfacial polymerization method

Characterization of the PA-TFC FO membrane: Morphological Analysis

The morphological structures including top surface and cross-section of the PSf substrate and PA -TFC membrane were examined using field emission scanning electron microscopy (FESEM, Zeiss, supra 55VP, 12-2,000,000x). The samples were then further examined using a Zeiss Supra V55 microscope.

Contact angle analysis

The contact angle of the membranes was measured at room temperature with a GSPJ-360 goniometer and distilled water was used as the measuring liquid. When water was dropped onto the membrane's surface, the CA was instantaneously calculated and recorded. To reduce experimental errors, 10 measurements were conducted at random points on the membrane surface, and the average CA was calculated.

Fourier-transform infrared spectroscopy

An infrared spectroscope (Perkin Elmer, Frontier 01) with a range of 550-4000 cm^{-1} was used to investigate the chemical changes on the membrane surface before and after the TFC treatment. FTIR spectroscopy was used to detect the active polyamide layer as well as other functional groups.

Atomic force microscopy analysis

The surface roughness of the membrane was measured using an AFM (Hitachi AFM500II). The membrane samples were cut into sections of 5 cm × 5 cm. The samples were then mounted on the device for AFM investigation using a metal block.

Preparation of the Synthetic Wastewater and Determination of the PA-TFC Performance

Due to BPA's insolubility in water, a working feed solution with a concentration of 100 mgL^{-1} was prepared by dissolving the prescribed amount of BPA in a small amount of methanol before it was introduced to the experimental feed solution. The solution was then stirred at 120 ºC with a magnetic stirrer until the BPA particles were completed dissolved. The draw solution consisted of 4M NaCl. The active layer of the membrane was positioned toward the feed solution.

The forward osmosis experiment was conducted according to the setup as shown in Figure 2. The initial quantities of the feed and draw solutions were 500 and 800 mL, respectively. The draw and feed solutions were interacting directly with each other through the membrane module. The temperature of both solutions was maintained at room temperature. Membrane orientation was kept on AL-FS mode to mitigate the fouling effect [14]. The feed and draw solutions were recirculated in co-current mode to the membrane module at 200 mL/min using a BT600M dual-channel pump. The feed solution was placed on a precision balance (Huazhi Scientific Instrument HZK-3102) to record the weight variations associated with the water flux calculation. The precision weight balance was linked to a computer for data logging via the Serial-Port-to-Keyboard software provided by Huazhi Scientific Instrument. The samples were taken at predetermined intervals, and the concentrations of the feed and draw solutions were measured using a UV-Vis spectrophotometer. Each of the experiments was conducted twice in order to ascertain the accuracy and precision of the results.

Water permeation flux, J_w *in* L/m^2h was calculated using the change in weight of the feed solution over time and the membrane area, A_m(m^2) as shown in equation (1):

$$J_w = \frac{\Delta w}{A_m \Delta t} \quad (1)$$

Δw = The recorded weight change of the feed solution, and Δt(h) = Experimental test time

Equation (2) is used to calculate BPA rejection in the FO process

$$R\ (\%) = \frac{(C_i - C_f)}{C_f} \times 100\% \quad (2)$$

where, R = The rejection percentage of BPA, C_i = Concentration of BPA in the feed solution at the start of the experiment (mg/L), and C_f = Final concentration of BPA in the draw solution after the experiment (mg/L).

Results and Discussion

Morphological analysis (FESEM)

The morphological structures of the surface and cross-section of the PA-TFC membrane were examined using FESEM (Zeiss, supra 55VP). In addition, the FESEM images were used to confirm the presence of the selective layer (PA layer) on top of the PSF membrane substrate. As depicted in Figure 3a, the thin polyamide layer can be seen on top of the PSf membrane substrate, which contains dense and porous layers. The denser layer of the membrane was found on top of the porous support layer, and it was believed to be a polyamide thin-film layer formed via interfacial polymerization. This morphological evidence indicates that the membrane's rejection capability is improving while its permeability is decreasing [33]. According to Khorshidi et al., one disadvantage of the denser layer of the membrane is the low water flow, and the only option to address this issue is for the dense layer to be extremely thin. The PA selective layer as depicted in Figure 3a was estimated to be roughly 4.4µm thick, which is sufficient because the typical thickness of PA thin film is around 200nm. The thickness of the PA layer is proportional to the concentration of TMC, which best explains the formation of the PA layer because low TMC concentrations were used in the preparation of the membrane (0.05%) [30].

There is a difference in the membrane surface appearance between the PSf and PA-TFC membranes, as shown by the FESEM surface images in Figures 3(b) and 3(c). The PSf substrate has a smooth and porous surface, but the PA-TFC membrane has a ridge-and-valley structure that results in a rough surface texture, as shown in Figure 3(b). The PSf membrane substrate has a porous structure with long finger-like pores formed under a thin sponge-like layer, making it excellent for FO membranes to minimize the structural parameters. The polyamide layer produced in this study has a ridge-valley structure, which is typical of TFC polyamide membranes prepared with the monomers MPD and TMC [34]. Miao et al. found that the ridge-and-valley structure is a significant indicator of the formation of the polyamide layer on the PSf membrane [35].

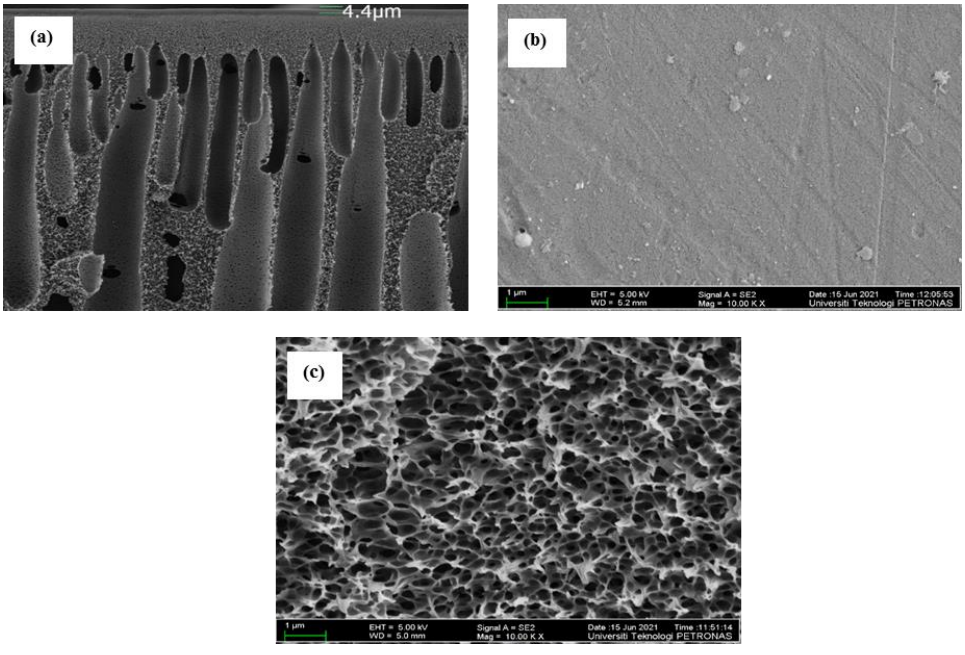

Figure 3. FESEM top surface morphologies of (a) cross section images of the PA-TFC membrane, surface images of (b) Polysulfone substrate and (c) Polyamide-TFC membrane

Fourier-transform infrared spectroscopy studies

The top surface of the modified PA-TFC membrane and Polysulfone substrate layer was analyzed using FTIR to examine the chemical compositions. Figure 4 shows the IR spectra of the Polysulfone and PA-TFC membrane. The transmittance peak at wavelengths of 1150 cm-1 (O-S-O stretching), 1243 cm-1 (C-O-C stretching) and 1106 cm-1 (S=O stretching) are the characteristics of sulfone group. Also, the absorption at 1013 and 833 cm-1 are assigned to the C-H stretching of the polysulfone aromatic rings. The peaks at 1605, 1538, 1486, 1247, 997 and 750 cm-1 are attributed to C=O of the amide linkage, O-H bending of the carboxylic acid, C-H bending, C-N stretching, C=O stretching and C-Cl stretching, respectively. These observations indicate the formation of polyamide layer on the polysulfone substrate. The absorbance at 3320 cm-1 suggests the N-H stretching of the amine functional group, indicating that the polyamide structure was formed through the interfacial polymerization of MPD and TMC [36].

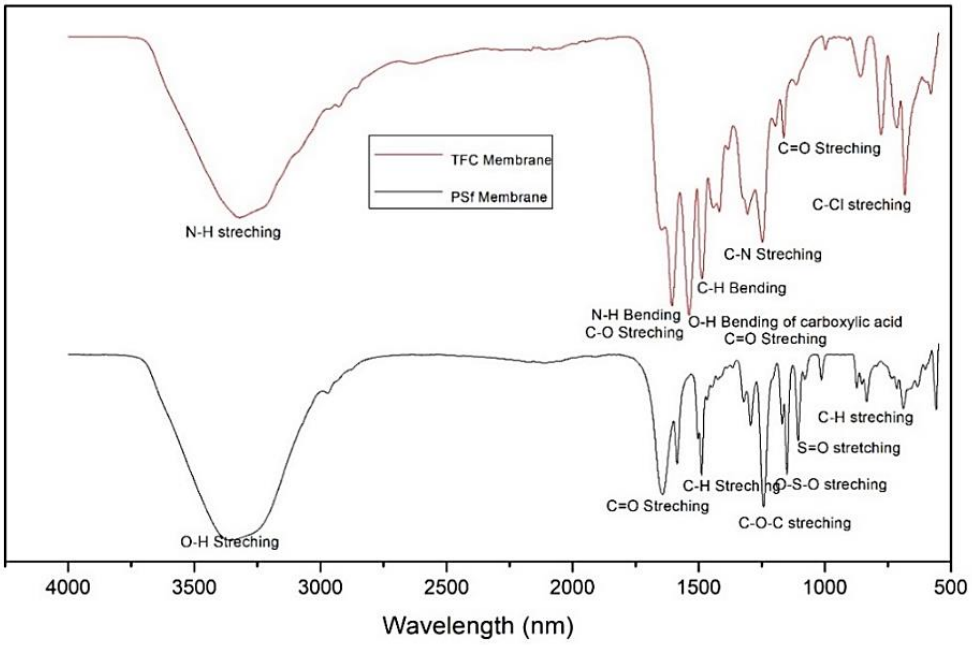

Figure 4. FTIR Spectra of PA-TFC and PSf membranes

Atomic force microscopy

The AFM was utilized to examine the surface morphology of polyamide layer (Figure 5). The three-dimensional images show the PSf substrate and the coated TFC-PA membrane via interfacial polymerization with different top surface roughness. The PSf membrane has a smooth surface with a root mean square (RMS) value of 4.5nm while the TFC-PA membrane has a higher root mean square value of 20.76 nm with increased surface roughness. This is because the polyamide layer was effectively polymerized over the porous PSf substrate layer [37]. The polymerization of the PA layer results in increased ridge-and-valley microstructure, raising the surface roughness value to 20.76nm. The increased surface roughness of the TFC membrane was also attributable to nodules generated on its surface as a result of MPD and TMC interaction. The advantage of having a higher surface roughness on the TFC membrane is that it will have a larger surface area for water to interact, resulting in a higher water flux performance for the membrane [38]. Morgan's theory states that the membrane roughness is related to the heterogeneity of different reactions between the amide and diacid chloride reactions following the initial formation of the Polyamide film [39].

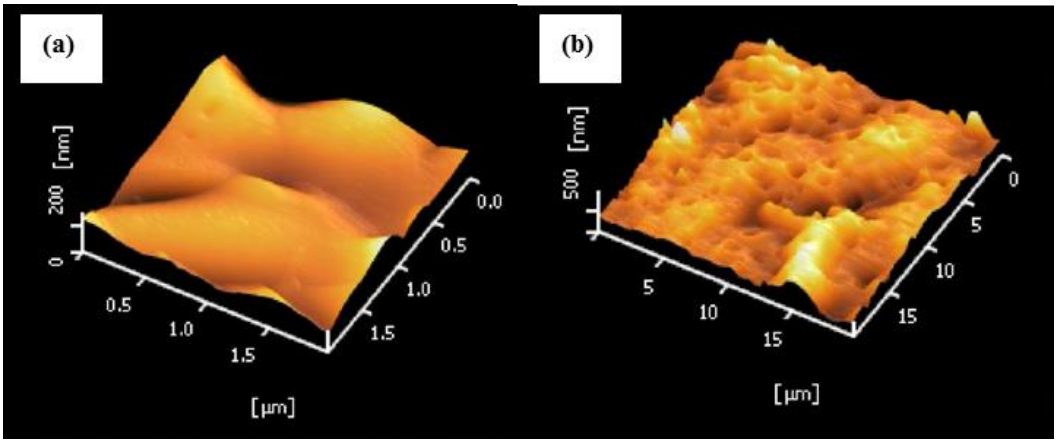

Figure 5. AFM surface morphology of (a) Polysulfone membrane substrate and (b) the thin-film composite membrane

Contact angle test

The contact angle of a membrane is one of its most important physical characteristics since it reveals its hydrophilicity and fouling susceptibility. An ideal membrane should be hydrophilic with high water flow rate and low fouling properties. The contact angle of the PSf substrate and the TFC membrane was assessed using a goniometer to determine their hydrophilicity. Figure 6 shows that the average contact angle for both membranes was less than 90^{o}, which indicates its hydrophilicity. The hydrophilicity of the TFC membrane (36.04^{o}) is higher than that of the PSf membrane (65.57^{o}), indicating that more amide groups are generated on the TFC membrane surface. TFC membranes have lower contact angle values because the polyamide layer structure contains strong polar amide functional groups that are hydrophilic in nature [40]. The presence of the pendant carboxylic acid groups inside the main chain has contributed to the increased hydrophilicity of the TFC membrane [33]. The TFC membrane thickened as the interfacial polymerization reaction time increased, contributing to its dense structure. This also explains why the contact angle of TFC membrane is decreasing [34].

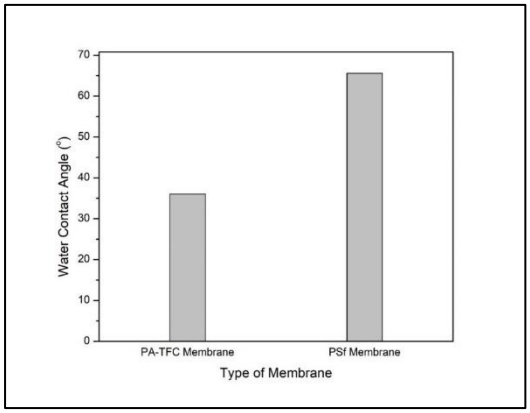

Figure 6. Comparison of contact angle values between PA-TFC and PSf membranes

Water permeability flux

The water flux change between TFC and PSf membrane was examined (Figure 7). Permeate flow is known to be highly related to membrane pore size, hence the increase in water flux in PSf substrate was expected. TFC membranes have a low water flux because of their dense structure, which obstructs water flow and hence reduces the water flux value across the membrane [29]. In addition, it is worth noting that a denser active layer offers better rejection and lower fouling propensity [41].

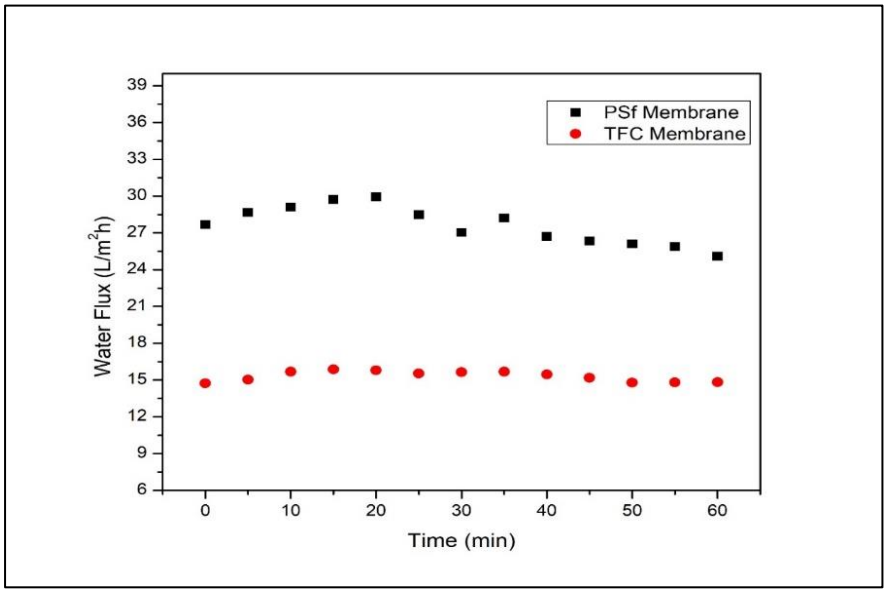

Figure 7. Water flux of FO with the model solution and pure water as feed (experimental conditions: AL-FS, 4M NaCl as DS

BPA removal

The retention of BPA was investigated utilizing both the PA-TFC and PSf membranes, and the results were compared accordingly. Figure 8 demonstrates that the overall rejection of BPA was within the range of 91% with the membrane orientation mode at AL-FS, whereas the PSf membrane yielded a rejection of 25%. The thin-film active layer produced on the membrane substrate was predicted to increase the retention capacity of TFC forward osmosis membrane. The thin-film layer which has a higher ridge-and-valley microstructure, entraps the BPA at the active layer. BPA rejection of more than 90% suggested that its pore size is substantially smaller than BPA particle size, which explains the high removal from the feed solution. The dense top coating of the TFC membrane was believed to have contributed to the significant BPA rejection due to its excellent substance retention properties [29, 34]. The result shows that the thin-film composite membrane fabricated through the IPIS method can be used to remove BPA from industrial and pharmaceutical wastewaters.

In terms of the forward osmosis rejection efficiency of BPA, the result from this study is slightly higher than the values reported by Zhu et al. (approx. 80%) [42], Hancock et al. (approx. 70%) [43] and Linares et al. (approx. 49%) [44]. These above-mentioned studies were basically carried out using the cellulose triacetate forward osmosis membranes. The interfacial polymerization of the polyamide layer on the polysulfone substrate could improve the BPA rejection by FO according to the findings of this study and comparisons with earlier research. This modification will enhance hydrophilicity, increase substance rejection from feed solution, and maintain the highest possible flow rates [29].

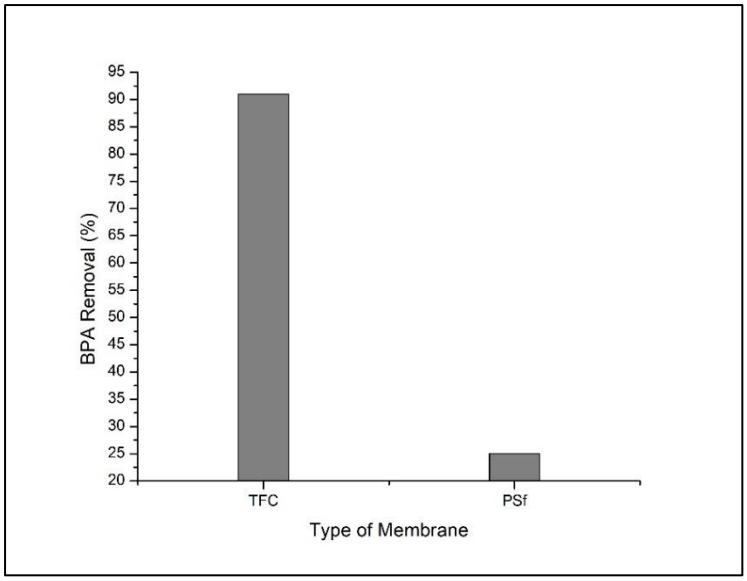

Figure 8. Rejection of BPA by PA-TFC and PSf membrane

Conclusion

This study assessed the effectiveness of a successfully fabricated PA-TFC membrane on a polysulfone membrane substrate using the interfacial polymerization method. Both membranes were examined and compared for their retention performance of bisphenol-A from a synthetic wastewater solution of 100mg/L using the forward osmosis process. The polyamide-based membrane performed well with a retention efficiency of 91%, whereas the polysulfone membrane retained just approximately 25%. The performance results of both membranes indicate that the fabricated membrane appears to be more promising and provides greater BPA retention than the polysulfone membrane substrate using the forward osmosis technique. It can be used to treat pharmaceutical and industrial wastewaters, which primarily contain small organic pollutants like phenols that are difficult to remove using other conventional or membrane treatment processes.

Abstract

Chemical pollutants emitted by the textile industry are a major source of water contamination, resulting in dangerous diseases and most of the effluent treatment techniques are relatively ineffective. As a result, metal oxide-based photocatalysts emerged as a viable alternative to the already existing dye treatment methods. The current work focused on the synthesis and characterization of Ni-doped ZnO/GO heterostructures and evaluation of its photoactivity under sunlight irradiation. The nanocomposite was prepared via a simple mixing approach, by varying the weight ratio of graphene oxide (GO) ranging from 0.1 to 0.4 g prior to the incorporation into Ni-doped ZnO surfaces. The X-ray diffraction analysis revealed that Ni and GO were successfully incorporated into the wurtzite-structure of ZnO nanocomposites. FESEM images showed a uniformed particle with the average size of about 100-500 nm for all samples. The photocatalytic activity was assessed by monitoring the degradation of methylene blue (MB) dye under direct sunlight irradiation. Ni-doped ZnO/$GO_{0.1}$ nanocomposite exhibited the greatest degradation performance by degrading 94% MB. The highest degradation rate constant of 0.0250 min^{-1} was obtained within 120 minutes of reaction time. The current study is easy, effective, and compatible; hence it can be employed in the future to treat textile dye wastewater.

Keywords: graphene oxide, methylene blue, nickel, photodegradation, sunlight

Abstrak

Bahan pencemar kimia yang dikeluarkan oleh industri tekstil merupakan sumber utama pencemaran air, mengakibatkan penyakit berbahaya dan kebanyakan kaedah rawatan sisa bahan buangan yang dicipta masih tidak berkesan sepenuhnya. Justeru,

fotomangkin berasaskan logam oksida dihasilkan sebagai alternatif yang berdaya maju bagi kaedah rawatan pewarna sedia ada. Penumpuan kepada sintesis dan pencirian yang mudah bagi heterostruktur ZnO/GO yang didopkan dengan Ni dan penilaian fotoaktivitinya di bawah cahaya matahari. Nanokomposit disediakan melalui kaedah campuran yang ringkas dengan mengubah nisbah berat grafin oksida (GO) diantara 0.1 hingga 0.4 g sebelum dimasukkan ke dalam permukaan ZnO berdop Ni. Analisis pembelauan sinar-X mendedahkan bahawa Ni dan GO telah berjaya dimasukkan ke dalam struktur ZnO. Imej FESEM menunjukkan partikel seragam dengan saiz purata diantara 100-500 nm untuk semua sampel. Aktiviti fotokatalitik dinilai dengan memantau degradasi pewarna metilina biru (MB) di bawah penyinaran cahaya matahari secara lansung. Nanokomposit $ZnO/GO_{0.1}$ berdop Ni mempamerkan prestasi degradasi yang paling tinggi dengan nilai peratus degradasi 94% MB. Pemalar kadar degradasi tertinggi ialah 0.0250 min^{-1} diperolehi dalam masa 120 minit masa tindak balas. Kajian ini didapati mudah, berkesan dan sesuai, justeru ia boleh digunakan pada masa hadapan untuk merawat sisa buangan pewarna dari industri tekstil.

Kata kunci: grafin oksida, metilina biru, nikel, fotodegradasi, cahaya matahari

Introduction

In the past decades, contamination of freshwater resources with a large amount of dyes has been widely reported, mainly due to the rapid industrialization. They are employed in textile, paper, foods, cosmetics, pharmaceuticals, and printing industries [1]. The dyes are believed to have found their way entering the groundwater through dyeing process, leaching from various dye industries, and inappropriate discharge of untreated dye effluents [2, 3]. Human exposures to dyes occurred through consumption of food, water, air inhalation and direct contact with body and skin. This exposures hence have affected the human health and aquatic lives due to their toxicity [4, 5]. It is therefore essential to use promising treatment strategies, aiming to restore the quality of contaminated water by ensuring the sustainability of the environments with economically viable approach.

Presently, photocatalytic advanced oxidation processes (AOPs) have been studied extensively for water restoration, mainly due to its favorable degradation activity toward recalcitrant organic pollutants as compared to conventional water treatment approaches [6, 7]. The method highlights on the use of semiconductor oxides as the catalyst assisted with UV or solar irradiation during the process. It is a cost-effective method in such a way that it operates at/near ambient temperature and pressure for the *in-situ* production of reactive radical species such as •OH and $•O_2^-$ on the surface of the photocatalyst [8]. The process aims for the mineralization of the contaminants to harmless inorganic by-products, water, and carbon dioxide through a series of redox reaction [9]. Of various semiconductor metal oxides, zinc oxide (ZnO) is most likely to be of the highest interest and regarded as an ideal catalyst due to its exceptional capability such as wide and direct bandgap semiconductor materials, higher photocatalytic efficiency, ability to absorb over a larger fraction of the UV or solar spectrum, non-toxic, low cost and environmentally sustainable [10–13].

Nonetheless, ZnO has their own limitation such as lower reusability and adsorption ability, wide band gap energy (3.37 eV) which can only be fully utilized under UV ($\lambda < 387$ nm) [14]. It is well-established that solar light consists of merely ~4% UV, so it is not very effective for large band gap materials. Also, rapid charge recombination is believed to be a major loss for the photoexcited charge carriers and a critical factor that limits the photo-efficiency for wide band gap photocatalyst [15–17]. To overcome these drawbacks, the construction of heterojunctions by coupling ZnO with suitable band potentials materials has been revealed to be an efficient strategy to simultaneously improve its photoactivity and photostability. Researchers found that modifying ZnO surface by doping with metal such as nickel (Ni) could extend the light absorption range towards visible region [18]. In this respect, Tawale et al. [19] investigated different microstructural and photoluminescence performance of bare ZnO, Ni doped ZnO and Cr doped ZnO. The result revealed that the Ni-doped ZnO nanostructures had the stronger PL intensity compared to Cr doped and undoped ZnO nanostructures. Apparently, high quality and good physicochemical properties will enhance the photocatalytic properties.

Wang et al. [18] reported on the recyclable photocatalyst based on flower-like nickel zinc ferrite nanoparticles/ZnO (NZF/ZnO) using a hydrothermal method. It was found that the samples prepared using 2.0 wt.%, 4.0 wt.% and 6.0 wt.% NZF nanoparticles exhibit better degradation performance towards rhodamine B (RhB) with increasing amounts of NZF, and 6.0 wt.% NZF has the best photocatalytic activity under visible irradiation. This result may come from the fact that the sample grown with 6.0 wt.% NZF has a smaller diameter and a larger surface area. Moreover, the much higher photocatalytic performance comes from the charge separation effect due to the band alignment between NZF and ZnO.

Combination of semiconductor oxide on carbonaceous materials such as graphene oxide is also attractive to improve the charge separation efficiency for enhanced photoactivity. This is due to the fascinating properties of GO such as high adsorption capacity, high electron mobility, large surface area and high thermal conductivity [4, 20–23]. This can be seen from the research conducted by Wu and Wang [24], where they conducted a study on the preparation of graphene oxide/hexagonal flower-like ZnO (GO/ZnO) micro/nanoparticles through hydrothermal method. It was found that the degradation percentage of rhodamine (RhB) dye reached 90.8% in 60 min, which was much higher than pure ZnO. The micro/nanostructure of GO/ZnO significantly improved the photocatalytic ability compared to pure ZnO. Kherabadi and his co-workers [4] reported on the synthesis, physicochemical properties and performance of three-dimensional (3D) Ag/ZnO/graphene as photocatalyst using a combined hydrothermal-photo deposition method. The dye degradation under both UV and visible light irradiation exhibited an enhanced photoactivity in comparison to ZnO/graphene and graphene alone. The deposition of Ag nanoparticles onto the surface of ZnO/graphene enhanced the photocatalytic efficiency due to the electron capturing properties.

In this research, an attempt has been made to synthesize Ni-doped ZnO/GO nanocomposites using a simple mixing approach. The morphological, structural properties, and photocatalytic activities of the nanocomposites were also investigated utilizing methylene blue (MB) dye as the probe molecule. Attempts has made to investigate the influence of variation GO weight ratio to Ni-doped ZnO on its performance as photocatalyst. The resultant nanocomposite photocatalyst certainly tends to harvest direct sunlight absorption effectively for photoexcited electron-holes formation, enhance the interfacial charge migration and hold better photostability during the photocatalytic reaction. The growth of Ni-doped ZnO/GO provides a simple, environmentally friendly and cost saving approach.

Materials and Methods

Materials

Commercial zinc oxide powder (ZnO, purity > 99%), Graphene oxide powder (GO, purity > 99%), nickel powder (Ni, purity > 99%), and methylene blue dye were purchased from Merck (Selangor, Malaysia). All chemicals and reagents were used as received and no purification step was performed. Deionized water was utilized throughout the synthesis and other experimental process.

Synthesis of Ni-doped ZnO/GO nanocomposites

In this work, a simple mixing approach was employed to prepare the heterostructures photocatalyst. Firstly, 0.5 g of Ni and 9.5 g of ZnO powder were mixed in a 100 mL of deionized water under continuous magnetic stirring for 30 min. After that, GO was added into the mixture and the amount was varied from 0.1 to 0.4 g. The amount of Ni and ZnO powder was kept constant throughout the process. The mixed solution went through an ultrasonic agitation using a sonicator (Powersonic 405) at a power of 350 W with a 40 KHz working frequency for 60 min. Following that, the mixtures solution was continuously stirred with a heating temperature of 60°C for 1 h on magnetic stirrer. Subsequently, the obtained Ni-doped ZnO/GO catalysts in the form of a fine powder were filtered, washed several times with deionized water and dried at 300°C for 1 h, yielding a greyish powder. The samples were labelled as ZnO/Ni, ZnO/Ni/$GO_{0.1}$, ZnO/Ni/$GO_{0.2}$, ZnO/Ni/$GO_{0.3}$, and ZnO/Ni/$GO_{0.4}$ accordingly. The morphology of the Ni-doped ZnO/GO nanocomposites was examined using a field emission scanning electron

microscopy (JEOL JSM-7600F). X-ray diffraction patterns were obtained by PANalytical X'pert Pro powder diffraction equipment at room temperature (Cu Kα radiations of λ =1.5418 Å) between 2θ range of 10–90° with a scanning speed of 2°/min. Following that, the Ni-doped ZnO/GO samples then underwent photocatalytic degradation measurement.

Photocatalytic degradation study

The photocatalytic degradation of the Ni-doped ZnO/GO nanocomposites were evaluated using methylene blue (MB) dye on each interval under direct sunlight irradiation as shown in Figure 1. In a typical procedure, 10 mg of photocatalyst was dispersed in 100 mL of 10 mg/L of MB aqueous solution for every run. Prior to irradiation, the suspension was magnetically stirred for 30 min under dark condition to reach the adsorption/desorption equilibrium. Following that, the suspensions were subsequently exposed to sunlight irradiation under continuous stirring for 120 min. At predetermined time intervals, an aliquot of 5 mL of sample was extracted out and the residual concentration was monitored using UV-vis spectrophotometer at λ_{max} = 664 nm. The percentage of degradation of MB was calculated using equation (1). All the photocatalytic degradation experiments were carried out under similar condition on a sunny day from 12.00 to 2 pm, in the month of Mac where the temperature was T= (34±2) ºC at Bandar Tun Abdul Razak Jengka, Pahang.

$$\text{Percentage of degradation (\%)} = (C_o - C_t)/C_o * 100 \quad (1)$$

where C_0 is the concentration of MB before irradiation, while C_t is the concentration of MB at time 't'.

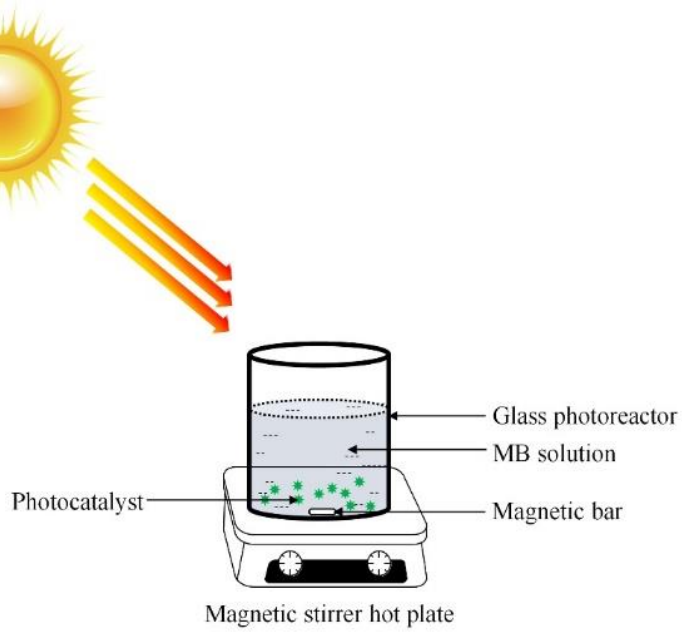

Figure 1. Illustration of the degradation process of Ni-doped ZnO/GO nanocomposites against MB under sunlight irradiation

Results and Discussion

X-ray diffraction pattern analysis

The crystalline phases of the pure and nanocomposites samples were analyzed by XRD, and the corresponding diffraction patterns are shown in Figure 2. Typically, all the diffraction peaks of pure ZnO (Figure 2a) are indexed according to the standard reference of hexagonal ZnO wurtzite structure (JCPDS No. 36-1451). The diffraction peaks at 2θ of 31.8°, 34.4°, 36.4°, 47.6°, 62.9°, 66.6°, 67.9° and 69.2° were respectively

assigned to the (100), (002), (101), (102), (103), (112) and (201), and were consistent with hexagonal zincite structure of pure ZnO [25, 26].

Meanwhile, Figure 2b shows the pattern for the peak of Ni obtained at 44.59° and 51.97° that corresponded to the (111) and (200) crystal faces of Ni standard pattern (JCPDS No. 04-0850) [27]. GO powder exhibits a diffraction peak at 26° corresponding to the (002) plane as can be seen in Fig. 2c. Interestingly, the presence of ZnO wurtzite structure with a very small peak of Ni were identified in the Ni-doped ZnO sample (Figure 2d). The existing of small Ni peak might be due to very small doping content of Ni element. All samples of Ni-doped ZnO/GO displayed the characteristic peaks belonging to ZnO (Figure 2e–h). However, the characteristic peak of Ni and GO was not observed in the XRD patterns possibly because of the low Ni and GO content (0.1 to 0.4 g), which is below the detection range of the XRD instrument. Also, no shift was observed in the position of ZnO diffraction peaks as compared to pure ZnO, proving that the native crystalline structure of ZnO had been maintained after the preparation of the hybrid heterostructure materials. The XRD analysis also revealed that the Ni and GO were incorporated into the wurtzite structure of ZnO crystal as there was no impurity or secondary phases existed in the pattern for all Ni-doped ZnO/GO samples.

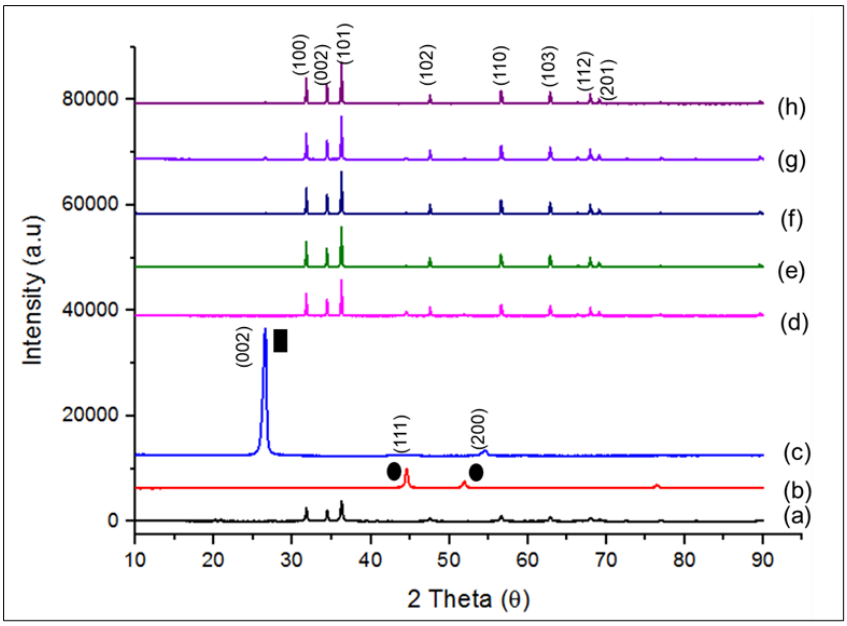

Figure 2. X-ray diffraction patterns of (a) pure ZnO, (b) pure Ni, (c) GO, (d) Ni-doped ZnO, and (e-h) Ni-doped $ZnO/GO_{0.1-0.4}$. (GO and Ni labelled as black square and circle in the graph respectively)

Surface morphological and structural analysis

The surface morphological and structural of pure ZnO, Ni-doped ZnO and Ni-doped $ZnO/GO_{0.1-0.4}$ nanocomposites were characterized by FESEM analysis (Figure 3). It could clearly be seen that similar structure particles with average size of about 100–500 nm was observed for pure ZnO, Ni-doped ZnO and Ni-doped $ZnO/GO_{0.1-0.4}$ nanocomposites. The incorporation of nickel and GO were not visible in the FESEM images. Nonetheless, the overall shapes for all samples composed of rod-like and cubic-like structures.

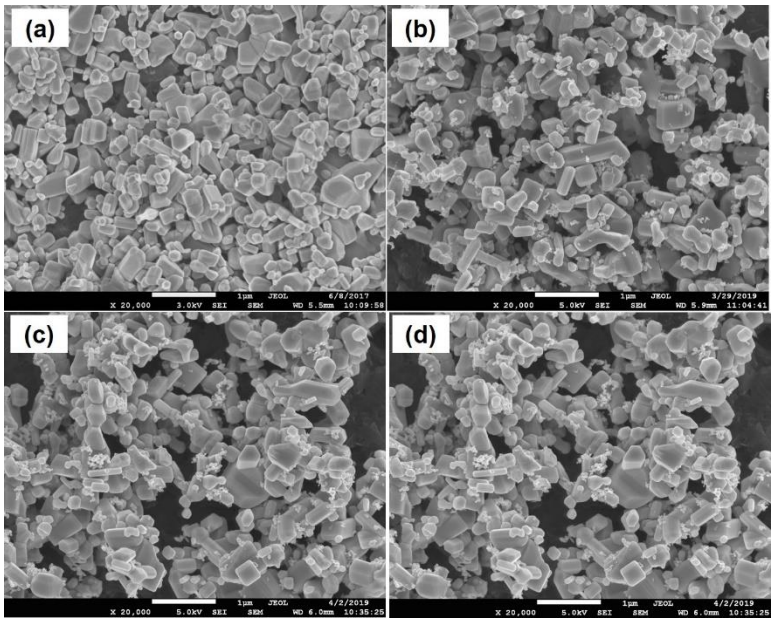

Figure 3. Selected FESEM images for (a) pure ZnO, (b) Ni-doped ZnO, (c) Ni-doped ZnO/$GO_{0.1}$, and (d) Ni-doped ZnO/$GO_{0.4}$

Evaluation of photocatalytic activity

Photocatalytic measurement of Ni-doped ZnO/GO nanocomposites photocatalyst in the removal of MB based on UV-vis spectra is depicted in Figure 4. The overall results revealed that the maximum absorption of MB at 664 nm decreased gradually as a function of time in the presence of different photocatalysts.

All the degradation behaviours were analysed and extrapolated in the following graph as presented in Figure 5. As depicted in the insert of Figure 5, no change was observed in the first 30 min before being exposed to sunlight for photodegradation of MB using ZnO/Ni/$GO_{0.1}$ catalyst because the MB was adsorbed on the surface of catalyst which led to an unchanged concentration and this unable the degradation of MB under dark condition. The photolysis of MB also seems negligible, indicating the stability of MB under sunlight. This is supported from our previous findings where the photolysis of MB under UV light was also insignificant even though UV contains high photon energy (shorter wavelength) as compared to sunlight (longer wavelength) [28]. The photocatalytic activity of pure ZnO reached almost 80% percentage of degradation against MB in aqueous phase. In contrast, the addition of Ni onto the ZnO surface did not improve the degradation efficiency since the percentage obtained was reduced to 15%. The addition of small amount of Ni to the ZnO might contribute to the decreasing of the percentage of degradation. Some researchers had found that the existence of Ni acted as a co-catalyst that reduced the over-potential of electrons at conduction band of ZnO which gave negative effect by lowering the degradation efficiency of ZnO itself. Previously, it was reported that there is high tendency for the occurrence of NiO (as a secondary phase) alongside Ni/ZnO on the catalyst surface which might impose undesirable defects and hence acted as a barrier to light absorption [29]. The transitions of metal ions substituted into the ZnO lattice also act as a recombination centre for electron-hole pairs and subsequently, producing lower percentage of degradation [30]. However, the incorporation of GO (0.1 g) into the samples shows a significant change in photocatalytic activity as compared to pure ZnO and Ni-doped ZnO samples with percentage obtained was around 95%. This was ascribed to the increase in the active sites and enhanced electron mobility which was responsible for the MB degradation.

The photocatalytic enhancement is also attributed by the strong and synergistic interaction between Ni/ZnO and GO in which the GO itself acts as an electron trapping site. The active sites here is referring to the GO surfaces which contain oxygenated functional groups (such as C=O, OH, etc.) that help in enhancing the electron mobility. Graphene itself is known to have superior charge carrier mobility properties (2×10^5 cm^2 V^{-1} s^{-1}) which allow for better electron transfer [31]. Theoretically, when ZnO is receiving the photon energy, the electrons (e^-) excited from the valence band (VB) to the conduction band (CB), leaving positive holes (h^+) behind. These excited electrons are then migrated to the Ni atom and GO sheet and subsequently avoiding the recombination behaviour through effective separation of electron-hole pairs. In this view, more charge carriers are produced from series of redox reactions with subsequent reactive oxidative species (such as •OH and $•O_2^-$) for efficient MB degradation [31]. The recombination could not be avoided if the electrons fall back to the valence band and no photocatalytic reaction could be observed. Thus, an appropriate amount of GO played a crucial role to facilitate the electron transfer and to support ZnO for effective electron mobility and separation of photogenerated charges. The percentage of degradation however decreased significantly at a higher GO content (0.2–0.4 g) due to the agglomeration of the nanocomposites which reduced the surface area and light absorption capacity of the photocatalysts. The percentage obtained for those nanocomposites with varied concentrations of GO displayed were almost comparable to each other.

Even though GO serves as an electron acceptor and mediator for an efficient carrier mobility [32], the presented results also suggested that, different GO content that was incorporated to the Ni-doped ZnO samples significantly affected the degradation efficiency. It might be due to the hindrance of actives sites by excess molecules that simultaneously prevented the light to reach and maximumly absorb the number of dye molecules on the photocatalyst surface. The light scattering and low penetration of light towards the catalyst surface decreased the effective irradiation for the reaction to progress [33]. This phenomenon further reduced the generation of photoexcited electron-hole pairs which leads to the decreased in the photocatalytic performances. This statement is in a good agreement with You et al. in which the decrease in the photocatalytic performance might be due to an excessive presence of GO content which resulted in agglomeration of particles. Hence, the photodegradation rate became more saturated. Furthermore, the higher content of GO in the catalyst lattice could cause a "shielding effect" that might shade the light and limited the light absorption capacity of the photocatalyst [34].

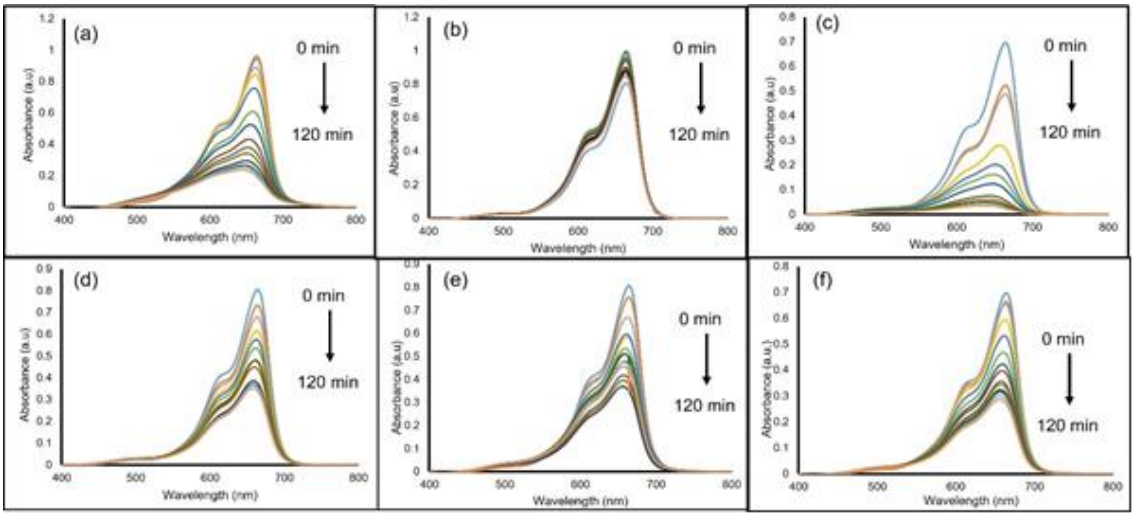

Figure 4. UV–vis absorbance spectra as a function of time for the degradation of MB using (a) pure ZnO, (b) Ni-doped ZnO, and (c – f) Ni-doped ZnO/$GO_{0.1–0.4}$ nanocomposites

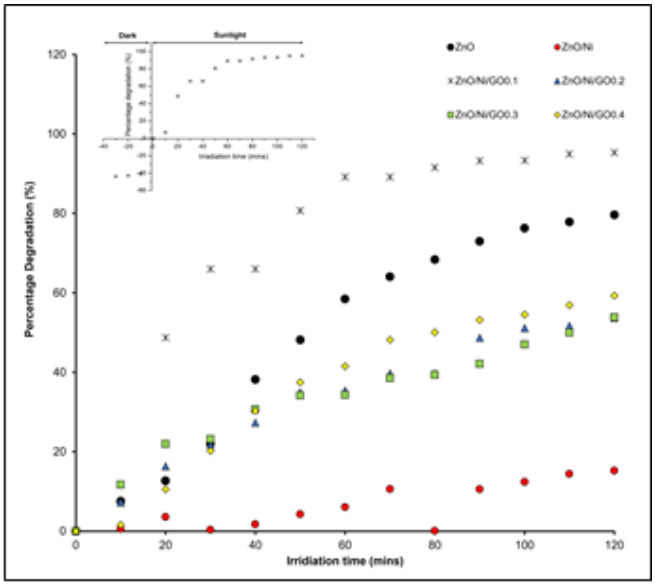

Figure 5. Percentage of degradation of MB under sunlight irradiation in the presence of different photocatalysts and the insert shows the photodegradation of MB under dark and sunlight irradiation using ZnO/Ni/$GO_{0.1}$ catalyst

Further analysis on the kinetic of MB disappearance had been carried out by plotting a first order decay plot of the characteristic of MB absorption peak. The experimental data were fitted based on the Langmuir–Hinshelwood (L–H) kinetic model as expressed by equations (2) and (3), hence the rate constant, *k* of the photocatalyst can be evaluated and quantified.

$$r = dC/dt = kC \quad (2)$$

where *r* and *k* represent the pseudo first-order reaction rate and rate constant, respectively. The equation can be rewritten as

$$\ln (C/C_o) = -kt \quad (3)$$

The pseudo first-order rate constant was determined from the slope of the plot of -ln (Co/Ct) versus irradiation time, t as illustrated in Figure 6. Linear plots were observed (with R^2 values higher than 0.9) which attested that photodegradation of MB obeyed pseudo-first order kinetics. The calculated pseudo-first order rate constant and corresponding R^2 values are presented in Table 1.

The results showed that the Ni-doped ZnO/$GO_{0.1}$ exhibited the highest *k* value of 0.025 min^{-1} compared to other samples which were found to be 0.0138, 0.0013, 0.070, 0.066 and 0.0081 min^{-1} for pure ZnO, Ni-doped ZnO, Ni-doped ZnO/$GO_{0.2}$, Ni-doped ZnO/$GO_{0.3}$, and Ni-doped ZnO/$GO_{0.4}$, respectively. As depicted in Table 1, the incorporation of GO into the Ni-doped ZnO composite influenced the photocatalytic performance as ZnO/Ni/$GO_{0.1}$ nanocomposite exhibited the highest percentage degradation of MB under direct sunlight. It can be suggested that Ni-doped ZnO/$GO_{0.1}$ should be regarded as the best photocatalyst as compared to pure ZnO and other samples. Nevertheless, the incorporation of excess amount of GO to ZnO did not give a significant trend of photodegradation performance due to the hindrance of actives sites by excess molecules that simultaneously prevents the light to reach and maximumly absorbed on the photocatalyst surface. The light scattering and low penetration of light towards the catalyst surface decreasing the effective irradiation for the reaction to progress [9].

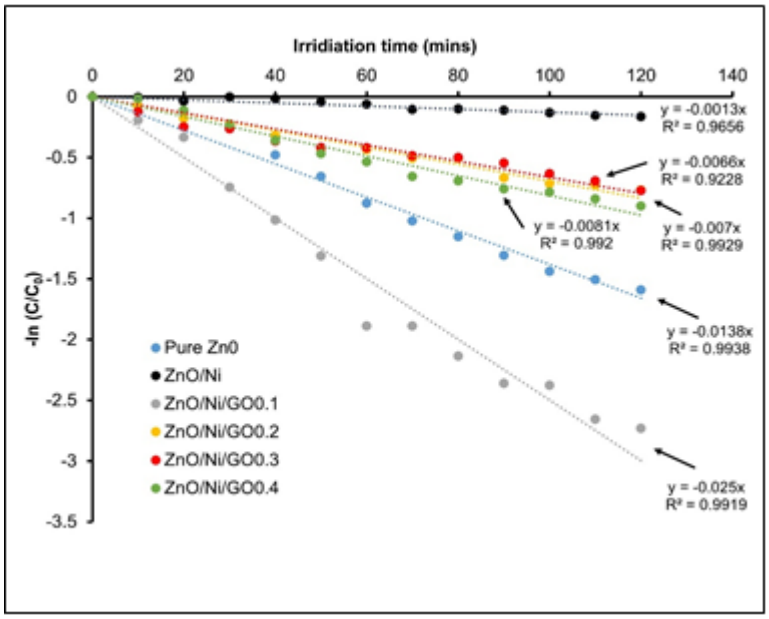

Figure 6. Plots of -ln (C/Co) versus irradiation time for the kinetic of disappearance of MB in the presence of different photocatalysts

Table 1. Photodegradation activities of MB using pure ZnO, Ni-doped ZnO, and Ni-doped ZnO/GO nanocomposites at different GO contents under sunlight irradiation

Sample	Percentage Degradation (%)	Photodegradation Rate Constant, k (min^{-1})	R^2 Value
Pure ZnO	79.64	0.0138	0.9808
ZnO/Ni	15.24	0.0013	0.9102
ZnO/Ni/$GO_{0.1}$	95.33	0.0250	0.9705
ZnO/Ni/$GO_{0.2}$	53.68	0.0070	0.9710
ZnO/Ni/$GO_{0.3}$	53.83	0.0066	0.9228
ZnO/Ni/$GO_{0.4}$	59.32	0.0081	0.9717

Conclusion

In this study, the XRD analysis revealed that the Ni and GO were successfully incorporated into the wurtzite structure of ZnO crystal as there were no impurity or secondary phases existed in the XRD pattern for sample Ni-doped ZnO/$GO_{0.1–0.4}$ nanocomposites. Other than that, it also showed the absence of Ni peak in the nanocomposite samples and this might be due to very small doping content of Ni element. The FESEM images with average size of about 100–500 nm was observed for pure ZnO, Ni-doped ZnO, Ni-doped ZnO/$GO_{0.1}$ and Ni-doped ZnO/$GO_{0.4}$ nanocomposites. Moreover, the morphological characteristics for all prepared samples composed of rod-like and cubic-like structures. The Ni-doped ZnO/$GO_{0.1}$ nanocomposite exhibited the best photocatalytic degradation of MB under direct sunlight within 120 min of reaction with percentage of degradation reaching 93.49% and photodegradation rate constant, k value of 0.0250 min^{-1} as compared to other samples. Overall, this research suggests a viable method

for improving the photocatalytic activity of ZnO-based photocatalysts, and it has promising implications for environmental issues.

Abstract

The seaweed industry plays a significant socio-economic role in tropical coastal communities. This study presents the biosorption behaviour of Pb(II) aqueous solution onto seaweed *E. denticulatum*. The impact of pH contact time, the initial concentration of the metals, and the adsorption activities were studied. The findings demonstrated that the Pb(II) uptake rate rose with increased concentration and contact time. The Pb(II) uptake reached saturation at 1000 mg/L after 120 min at room temperature. Pb(II) biosorption onto *Eucheuma denticulatum* fitted well to the Langmuir isotherm, with a maximum adsorption capacity (q_{max}) of 416.67 mg/g. The results suggest that this type of seaweed, *E. denticulatum*, is an effective biosorbent for removing Pb (II) and may control toxic metal pollution in tropical aquatic ecosystems.

Keywords: biosorption, *Eucheuma denticulatum*, heavy metals, Langmuir and Freundlich models

Abstrak

Industri rumpai laut memainkan peranan sosio-ekonomi yang sangat penting bagi masyarakat pesisir pantai tropika. Kajian ini menunjukkan tingkah laku biojerapan larutan akues Pb(II) ke atas *Eucheuma denticulatum*. Pengaruh hubungan masa pH, kepekatan awal logam, dan kajian penjerapan-penyerapan telah dilakukan. Hasil kajian menunjukkan bahawa kadar pengambilan Pb(II) meningkat dengan peningkatan kepekatan dan masa hubungan. Pengambilan Pb(II) mencapai titik tepu pada 1000 mg/L setelah 120 minit pada suhu bilik. Biojerapan Pb(II) ke atas *E. denticulatum* dipasang dengan baik pada isoterm Langmuir dengan kapasiti penjerapan maksimum (q_{max}) 416.67 mg/g. Hasilnya menunjukkan bahawa rumpai laut *E. denticulatum* adalah biopenjerap yang berkesan untuk menghilangkan Pb(II) dan mungkin boleh digunakan untuk mengawal pencemaran logam toksik di ekosistem perairan tropika.

Kata kunci: biojerapan, *Eucheuma denticulatum*, logam berat, model Langmuir dan Freundlich

Introduction

Heavy metal pollution is a serious concern due to its profound impact, even at small concentrations. It is caused by enhanced industrialisation and human activities that release various contaminants into the environment [1, 2, 3]. Heavy metals are considered among the most toxic groups reaching the food chain via waste disposal in water bodies and on land [4]. Therefore, eliminating heavy metal ions in wastewater is crucial for public health protection. The conventional methods for treating toxic metals are expensive and difficult to manage. Some methods lead to ineffective metals removal, restricted tolerance to pH change, slight metal selectivity, and the generation of toxic by-product waste that must be appropriately disposed of [5]. Attention has focused on heavy metals biosorption using various biological materials as this enables a higher metal binding capacity than chemical-based methods [6, 7].

Biosorption is a subtraction technique directed at contaminants or pollutants through inactive biomass, which allows the contaminants to be passively concentrated and bound to their cellular structure. Several absorbent materials have previously been used, including algae [8], fungi [9], bacteria [10], seaweeds [11], and some higher plants [12]. Several studies have assessed the efficiency of using different biosorbent materials for treating heavy metals in wastewater. For example, Tabaraki et al. [13] assessed the efficiency of brown seaweed on Pb(II) ions biosorption. At optimal conditions, they found the maximum seaweed uptake for the Pb(II) ions uptake to be 195±3.3 mg/g. The study of peanut shell efficacy on Pb^{2+} ions was carried out by Taşar et al. [14], and 39 mg/g was the maximum uptake obtained. The biosorption capacities of olive mill solid (OMS) and olive stone (OS) on Pb^{2+} ions uptake were examined by Blázquez et al. [15] in batch experiments under varied temperatures. The results revealed that the maximum Pb uptake was 6.57 mg/g on OS and 23.69 mg/g on OMS at 25 ºC. Gerola et al. [16] investigated the biosorption capacity of the residue of passionfruit skin onto Pb^{2+} ions and found that the maximum biosorption capacity was 204 mg/g at pH 4 for 170 min. Senthilkumar et al. [17] evaluated the biosorption functions of ten (10) different seaweed species on Pb^{2+} ions uptake under varied pH environments. The brown seaweed *Turbinaria Conoides* displayed optimal Pb^{2+} ions uptake of 439.4 mg/g at pH 4.5 and a temperature of 30 ºC. The work of Abdel-Aty et al. [18] presented the applicability of Blue-Green Alga *Anabaena Sphaerica* as a biosorbent of Cd^{2+} and Pb^{2+} ions from aqueous solutions. The ideal biosorption capacity was 111.1 mg/g and 121.95 mg/g, respectively, at peak conditions. The adsorption capacities of Macroalgae *Eucheuma Spinosum*, *Padina Minor*, and *Sargassum Crasifollum* were assessed by Putri [19] for their Pb^{2+} biosorption. The maximum biosorption capacity (55.56 mg/g) was demonstrated by *Sargassum Crasifollum*, followed by *Padina Minor* (40.00 mg/g), while the lowest (32.26 mg/g) was demonstrated by *Eucheuma Spinosum*. Studies on Pb^{2+} ions adsorption from aqueous solutions using raw and chemically modified green freshwater algae (*Scenedesmus Obliquus*) were conducted by Abdel Ghafar et al. [20]. The modified biomass was found to have higher biosorption capacity (207.2 mg/g) compared to raw biomass (112.0 mg/g). Therefore, algae have proven to be a more efficient and promising biosorbent to use for heavy metal removal from wastewater. The biosorption method is comparatively inexpensive and it offers elevated efficiency in terms of metal removal, as well as minimum chemical and/or biological sludge production, among others [21].

Algae biosorbent materials are gaining significant attention due to their abundance in the oceanic environment, relative easiness to process, and high accumulated ability of metal content. Algal-like seaweed is sufficient to facilitate a complex solid-liquid separation process, thus making seaweed a suitable form of biomass for heavy metal biosorption in the marine environment [22]. Seaweeds are marine algae found in coastal areas. The red algae *Eucheuma cottonii* and

Eucheuma denticulatum are grown in eastern Africa's tropical coastal regions [23, 24]. The seaweed industry in Tanzania employs more than 30,000 people [25]. Approximately 5,000 tons of dry seaweed are exported annually from Tanzania [25]. The high production of seaweed in Tanzania has motivated the authors to propose this substance as a potential biosorption material.

Heavy metal pollution has recently gained scientific attention due to its ubiquity in marine and coastal ecosystems [26]. Heavy metals' pathways into the human body are through food, water, and air. They are absorbed through the skin or by exposure from various agricultural, manufacturing, pharmaceutical, and urbanisation activities. Lead (Pb) is among the heavy metals proving to be the most serious toxic contaminant in Tanzania [27, 28, 29].

Previous studies have demonstrated the high metal-binding abilities of brown and green seaweeds [30, 31, 32]. However, there is a lack of data on the heavy metal biosorption by red seaweed species (*E. denticulatum*) in Tanzania. Therefore, this study discusses the biosorption behaviour of Pb(II) solution onto *E. denticulatum*. The findings from this study on *E. denticulatum* as a potential biosorption material of toxic metals have extensive consequences for the economy and health of farmers engaged in seaweed aquaculture in the coastal areas of Tanzania.

Materials and Methods

Study area

This study was conducted in three locations (Unguja Ukuu, Tumbe, and Kiungoni) along the coastal areas of Zanzibar. Tumbe and Kiungoni are located in the northern part of Pemba Island (Figure 1), while Unguja Ukuu is situated in the southern part of Unguja island (Figure 2). Seaweed farming is mainly found in these areas. Fresh seaweed *E. denticulatum* samples were cleaned carefully on-site with ocean water to eliminate impurities.

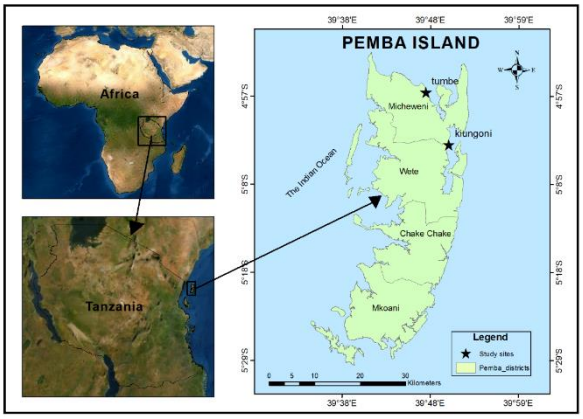

Figure 1. The sampling areas in the Pemba Island coastal region

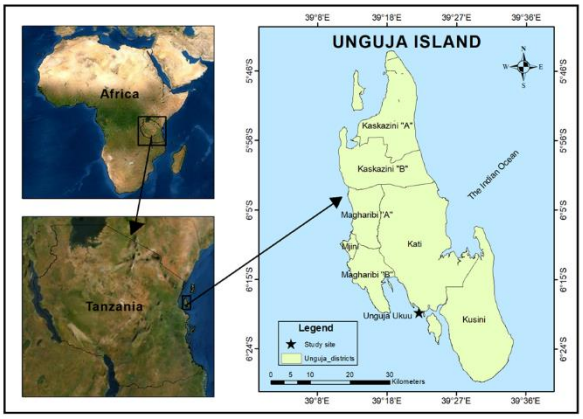

Figure 2. The sampling area in the Unguja Island coastal region

Sample preparation

The seaweed samples were washed with tap water, before being washed again with deionised water to eradicate salts and particulate matter from the surface of samples. The samples were then air-dried for 48 hours and then oven-drying at 80 ℃ for 24 hrs. The dried samples were ground into a homogeneous powder using a laboratory blender and stored in a desiccator before the biosorption experiments were conducted.

Pb(II) ions solution preparation

Pb(II) ions stock solution was prepared by dissolving 1.60g of Pb $(NO)_3$ in 1000 ml of deionised water. The different concentrations of Pb(II) solutions (50, 100, 250, 500, 1000, 1500, and 2000 mg/L were prepared by diluting the stock solution. The initial pH of the standard solutions was adjusted to the desired value by adding 0.1 M HCl or 0.1 M NaOH. The analytical grade of chemicals from Merck was used in this study. The concentrations of the standard solutions of 0.20, 1.00, 2.00, 7.00, 10.00, and 20.00 mg/L were precisely prepared.

Preliminary concentration of Pb(II) in *E. Denticulatum*

The initial Pb(II) ions levels were determined using a modified version of the methods devised by Luis et al. [33] and Rubio et al. [34]. Next, 25 g of *E. denticulatum* was oven-dried at 70 ℃ for 12 hours. Then, the sample was burned in a furnace at 550 ℃ for 20 hours to remove the organic matter. The ash of the sample was digested in 2 mL of HNO_3 (v/v) for 18 hours. The digested solution was filtered with a filter paper (Whatman no 2) and transferred into a 50 mL test tube. The solution was meshed up to 30 mL with deionised water. The atomic absorption spectrometer (AAS) Thermo Scientific model iCE 3300 was used to determine the Pb(II) ion concentrations.

Batch biosorption experiments

The batch biosorption experiments were established using a magnetic stirrer (120 - 180 min) at 120 rpm in a 250 mL beaker. Next, 50 mL of the standard solution was introduced into the beaker and biosorbent was added appropriately. The different parameters were organised as follows: solution pH (2-8), contact time (0-150 minutes), initial Pb(II) ion concentration (50-2000 mg/L). The Pb (II) ion biosorption characteristics were evaluated using a biomass weight of 0.5 g. The solution was separated using a Whatman filter paper No 2 or centrifuging and decanting.

Optimum pH for Pb(II) biosorption

The Pb(II) biosorption optimum pH was established by adding 50 mL solutions of 50 mg/L Pb (II) ions into a 100 mL centrifuge tube with 0.5 g of dry seaweed. The samples, which were of varying pH (2.0 to 8.0), were adjusted using 0.1 M NaOH or 0.1 M HNO_3 [35]. The mixtures were stirred for 180 minutes with a magnetic stirrer at room temperature. The supernatant was collected after centrifuging the mixture using the Gallen Kamp Centrifuge 200 at the lowest rate for 10 minutes. The AAS was used to determine the Pb(II) ion concentration in the supernatant. The analysis of each sample was performed in a duplication setting.

Optimum contact time for Pb(II) adsorption

The optimum contact time for Pb(II) adsorption was determined at optimum pH by adding 0.5 g biomass to 50 mL of the 50 mg/L metal solution. The mixture was stirred for 180 min using a magnetic stirrer at moderate speed at room temperature. At 5, 10, 30, 60, 120, and 180 min, the samples were removed, centrifuged, decanted. The supernatant was collected and stored for AAS analysis. The samples were prepared in duplicate.

The effect of Pb(II) ion concentration on biosorption

The effect of Pb(II) ion concentration on biosorption was investigated by mixing 0.5 g of seaweed and 50 mL of solutions of known concentrations at room temperature. The Pb(II) ion concentration levels were 50, 100, 250, 500, 1000, 1500, and 2000 mg/L. The solution mixture was corrected to the required pH with HNO_3 or NaOH solution before it was stirred with a magnetic stirrer at moderate speed and room temperature for 120 minutes. The samples were decanted using a Gallen Kamp Centrifuge 200 centrifuge for 20 minutes. The supernatants were then kept in centrifuge tubes and determined using the Atomic Absorption Spectrometer (AAS). This process was performed in duplicate.

Biosorption models

The Langmuir and Freundlich isotherm models were used to calculate Pb(II) biosorption from the aqueous solutions. The following is a linearised Langmuir equation [36]:

$$\frac{1}{q} = \frac{1}{q_{max}} + \frac{1}{b.q_{max}C_f} \quad (1)$$

where q_{max} is the Langmuir adsorption capacity (mg/g) and b is the adsorption energy (l/mg). The intercept and slope from the 1/q Vs $1/C_f$ graph were used to calculate q_{max} and b.

The following equation represents the Freundlich isotherm linear form [37]:

$$\log q = logK + \frac{1}{n}\, logC_f \quad (2)$$

where *K* is the Freundlich constant correlated to adsorption capacity, and *n* is the adsorption intensity. Furthermore, the separation factor R_L describes the essential characteristics of the Langmuir isotherm [38]:

$$R_L = \frac{1}{1+bq_{max}} \quad (3)$$

Kinetic adsorption study

Adsorption kinetics is a significant aspect of biosorption studies since it presents valuable information concerning adsorption mechanisms and allows the investigation of the controlling biosorption mechanism. The assessment of Pb^{2+} ions adsorption kinetics onto *E denticulatum* was conducted using pseudo-first-order and pseudo-second-order kinetics. The pseudo-first-order equation was devised by Febrianto et al. [39]

$$\log(q_e - q_t) = \log q_e - \frac{k_1\, t}{2.303} \quad (4)$$

where q_e and q_t (mg/g) are the equilibrium and time t, respectively, of the adsorption capacities. k_1 (min^{-1}) is the pseudo-first-order adsorption rate constant. The linear correlation of $\log(q_e - q_t)$versus t implies that the reaction fits with the pseudo-first-order reaction. The slope and the model's intercept, respectively, give k_1 and q_e.

According to Ho and Ofomaja [40], the pseudo-second-order reaction is expressed as:

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad (5)$$

where k_2 (g $mg^{-1}min^{-1}$) is the rate constant for the pseudo-second-order adsorption model. The linear relationship from the $\frac{t}{q_t}$ versus t plot gives the values of q_e and k_2 from the slope and intercept, respectively.

Results and Discussion

The initial levels of Pb(II) in seaweed

The initial concentration of Pb (II) detected in *E. denticulatum* was 0.084 µg/g. The results indicate that only trace amounts of Pb(II) were present in the *E. denticulatum* samples. The lead levels in Zanzibar's coastal areas range from 228 to 1150 ppm [41]. It was surmised that the trace value might be attributed to the anthropogenic sources and/or the natural background value.

Optimum pH for the biosorption of Pb(II)

The solution pH plays a vital role in controlling the metal ions biosorption of metal ions from aqueous solutions [42]. The findings presented in Figure 3 indicate that the removal of Pb(II) was low in an acidic medium (pH < 4). As pH increased, the metal uptake also increased until pH 4. Afterwards (beyond pH > 4), it showed a rapid decline. At low pH, the biosorption capacity was low due to the competition for binding sites on the biomass surface between the H^+ ions and the metal ions [43, 44]. Therefore, repulsive forces between the metal ions and the protonated biomass cell wall prevent the metal ions from approaching the cell wall [38]. However, as pH increased, the concentration of H^+ ions declined. The biomass became more negatively charged, resulting in the electrostatic attraction of the positive charge metal ions. Therefore, biosorption rose to its maximum point [45, 46, 47] before the precipitation of metal hydroxides occurred at higher pH due to the high OH^- ion concentration. This resulted in a decline in uptake capacity [48] and the electrostatic repulsion between the negatively charged anionic species in the solution [49]. This study revealed that the adsorption rate of Pb(II) ions was optimum at pH 4 and with a concentration of 4.7 mg/g. Therefore, the findings suggest that pH 4 is the most effective pH to use for Pb (II) biosorption, based on the range investigated (Figure 3).

Various biosorption studies employing algal biomass have demonstrated similar results (that pH 4 is the optimum pH). These include the works by Yipmantin et al. [50] using *Chondracanthus* (red alga); Lee and Park, [51] using brown seaweeds; and Nessim et al. [52] using *Ulva fasciata*, green seaweed and *Sargassum sp*., brown seaweed.

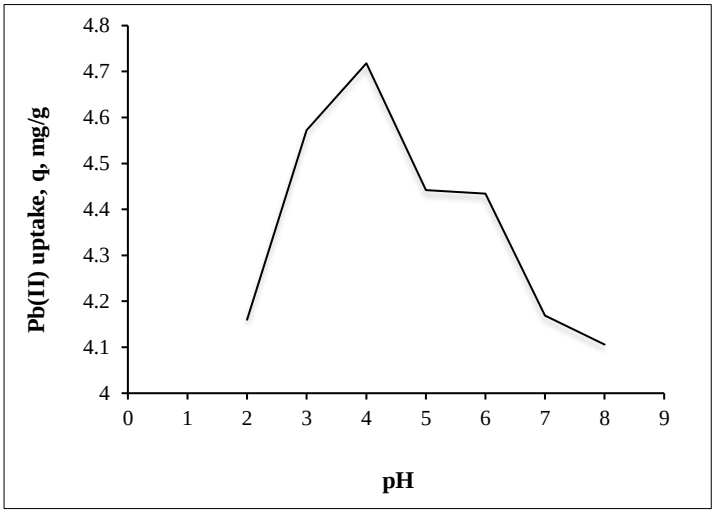

Figure 3. Variation of Pb(II) uptake of *E. denticulatum* with pH

Optimum contact time for Pb(II) biosorption

The metal ions biosorption in aqueous solutions is highly influenced by contact time, as shown in Figure 4. The results from this research study demonstrated that Pb(II) uptake onto *E. denticulatum* increased with longer contact times. Initially, during the first 20 minutes, there was a rapid Pb (II) uptake and a gradual increase until equilibrium at 120 minutes. Meanwhile, no further changes in biosorption were noticed beyond 120 minutes. Thus, 120 minutes can be considered the ideal contact time in other biosorption experiments.

The sharp increase in biosorption during the early stage was likely due to the high solute concentration gradient [53] and the availability of vacant active sites on the biomass surface. Thus, the adsorption of metal ions took place on these sites [54, 55]. In the subsequent stages, the metal removal declined because the active sites were gradually occupied [56] and there was difficulty occupying the residual binding spots due to the forces between the solid and bulk phases [57, 58].

Several biosorption studies have demonstrated that metal ions adsorption employing algal biomass attained maximum adsorption in the interval between 60 and 120 min. These include the works of Ibrahim, [59] using *Corallina mediterranea, Galaxaura oblongata, Jania rubens*, and *Pterocladia capillacea* (red macroalgae); Ozudogru, [60] using *Padina pavonica* (brown algae); and Abdel-Aty et al. [18] using *Anabaena sphaerica* (freshwater alga).

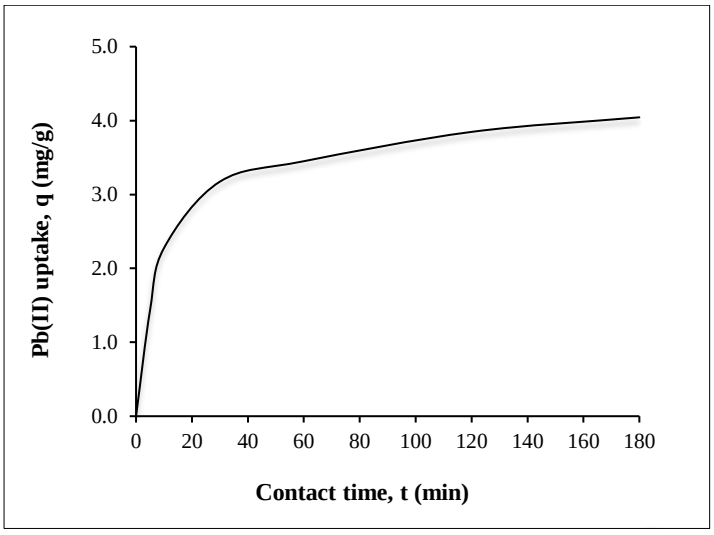

Figure 4. Effect of contact time on Pb(II) adsorption

Effect of initial metal ion concentration on Pb(II) biosorption

The initial metal ion concentration highly affects the biosorption capacity due to a substantial driving force that eliminates the resistance of all the metal ions between the aqueous and solid phases [61]. The present study demonstrated a rapid increase in Pb(II) biosorption with increased metal ion concentration until 1000mg/L, as shown in Figure 5. The metal uptake increased slowly, implying that the biomass had approached the saturation point [62].

The increased Pb(II) uptake during the early stage might be due to the enhanced driving force of metal ions into the biomass surface and the presence of abundant binding spots on the biosorbent surface areas [63, 64]. Consequently, when the Pb(II) ion concentration increases further, the active sites are overburdened by the ions, thereby preventing further metal ions adsorption [64, 65]. Thus, the metal uptake was enhanced with an increase in the initial levels of Pb(II) ions, reaching saturation when Pb(II) concentration attained a threshold value.

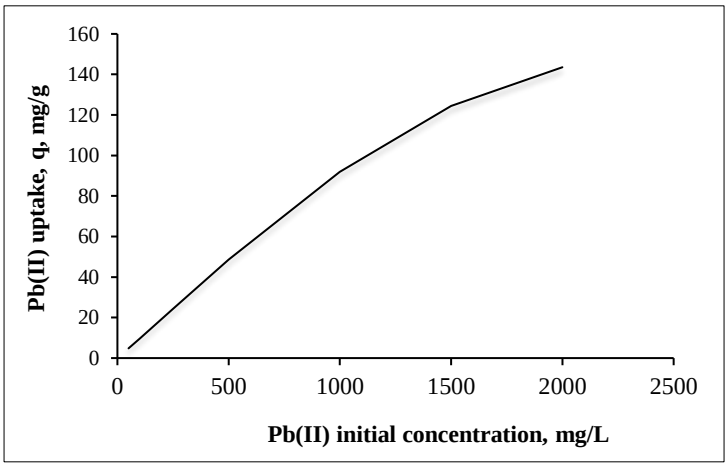

Figure 5. Effect of initial Pb (II) concentration on Pb(II) biosorption onto *E. denticula*

Biosorption models

The Freundlich and Langmuir models are isotherm models used to present the relation between equilibrium metal biosorption (q) and final concentration (C_f) at equilibrium [66]. Both adsorption models were used to measure the relationship between the Pb (II) uptake capability (*q*) and equilibrium concentration (C_f). The constants and correlation coefficients of the adsorption models employed were determined from the respective adsorption isotherms (Table 1). It was found that the Langmuir model (R^2 = 0.9935) fitted well, compared with the Freundlich model (R^2 = 0.9534). The high Langmuir correlation coefficient suggests the conformity of the P(II) adsorption to the model, implying the existence of monolayer adsorption conditions in the Pb (II) – *E. denticulatum* system [67].

The maximum Langmuir monolayer Pb(II) uptake capacity (q_m) and the Langmuir constant (b) isotherm were 175.13 mg/g and 0.01476 l/mg, respectively, implying the high uptake of Pb(II) by the biomass, which might have been due to its low capability of forming complex [68]. The presence of carboxylate polysaccharides in seaweed promotes the binding of cations with large ionic areas [69]. Moreover, the range of the Pb(II) ions separation factor, R_L = 0.2789, fell between 0 and 1 ($0 < R_L < 1$), implying that Pb(II) adsorption is favourable at all the concentrations studied [70].

The slopes and intercepts from the linear graphs (Figures 6 and 7) were used to compute the Langmuir and Freundlich isotherm constants, and the results are summarised in Table 1.

The magnitude of the Freundlich constant *K* suggests the high adsorption capacity of Pb(II) ions on *E. denticulatum***.** The value of n = 1.67 (n > 1) indicates that under the given experimental conditions, the heterogeneity of the biomass surface and the metal ions were adequately and intensively adsorbed by the dried seaweed *E. denticulatum.*

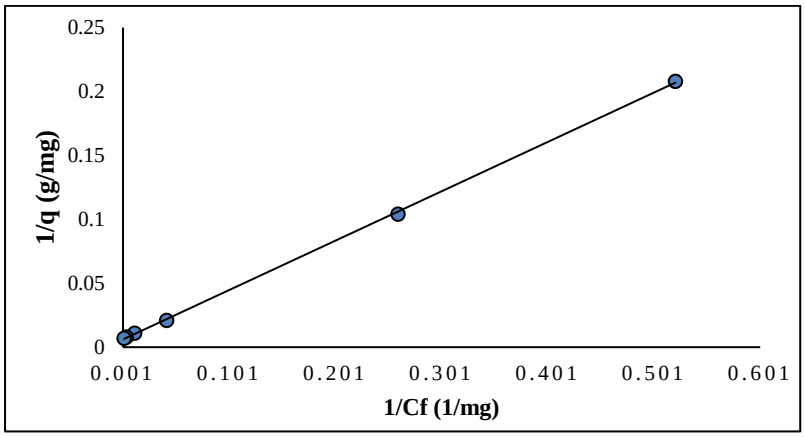

Figure 6. Langmuir isotherm for Pb (II) biosorption by *E. denticulatum*

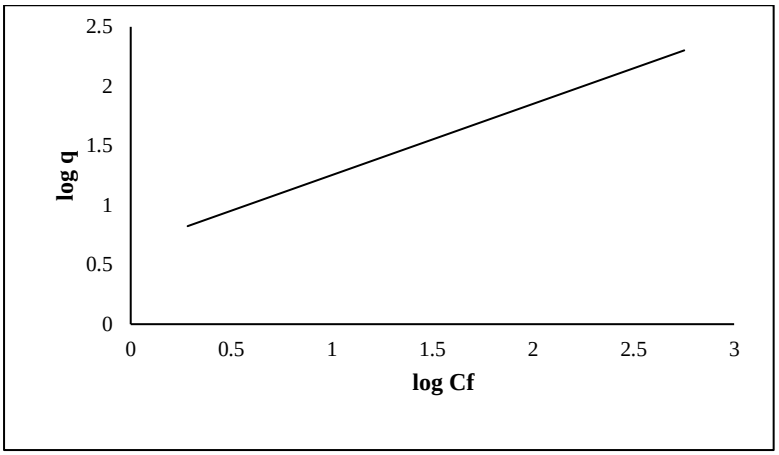

Figure 7. Linearised Freundlich isotherm for Pb(II) biosorption by *E. denticulatum*

Table 1. The Langmuir and Freundlich parameters and correlation coefficients for the biosorption of Pb (II) onto *E. denticulatum*

Metal	**Langmuir Isotherm Parameters**			**Freundlich Isotherm Parameters**			
	q_{max}, mg/g	*b*, l/mg	R^2	*K*, mg/g	1/*n*	*n*	R^2
Pb	175.13	0.01476	0.9991	4.517	0.632	1.67	0.9272

Kinetic studies

The Pb^{2+} ions adsorption rate onto *E.denticulatum* was estimated for contact times ranging from (0 – 180) min. The experimental data were interpreted using pseudo-first-order and pseudo-second-order kinetic models. The kinetic parameters and regression coefficients were obtained from their corresponding linear graphs (Figures 8 (a) and (b)) and these are summarised in Table 2. The $\log(q_e - q_t)$ Vs. t plot gives an approximate line, and the rate constant (k_1) and q_e can be estimated from the slope and the intercept, respectively. The k_1, q_e, and R^2 are shown in Table 2. Even though the plot is linear and the R^2 is 0.911, the value of q_e does not agree with the experimental q_e value (4.044). Therefore, Pb(II) adsorption does not follow pseudo-first-order kinetics.

The pseudo-second-order kinetic model was employed to find a more trustworthy Pb (II) adsorption kinetics description. The results from the $\frac{t}{q_t}$ Vs. t plot indicates that the pseudo-second-order kinetic model fits the metal adsorption experiment. The regression coefficient (R^2) was 0.998, and the q_e equals 4.3802 mg/g, which is close to the experimental q_e (4.044mg/g).

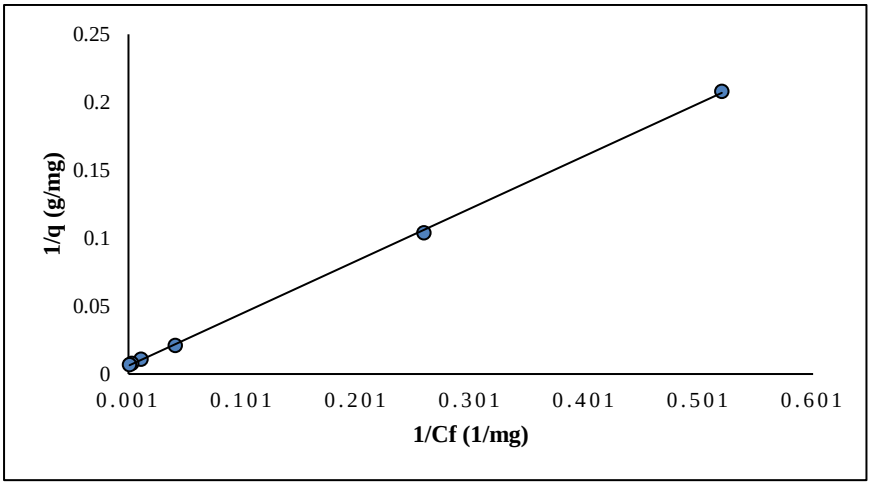

Figure 8(b). Pseudo-second-order for Pb(II) adsorption kinetics onto *E. denticulatum*

Table 2. The pseudo-first-order and pseudo-second-order kinetics parameters and correlation coefficients for the Pb (II) adsorption kinetics onto *E. denticulatum*

Pseudo-first-order kinetics			**Pseudo-second-order kinetics**		
K_1 (min^{-1})	qe (mg g^{-1})	R^2	K_2 (g $mg^{-1}min^{-1}$)	q_e (mg g^{-1})	R^2
20.0237	2.801	0.911	0.0148	4.3802	0.998

Conclusion

The present study demonstrated that the seaweed *E. denticulatum* was an effective biosorbent of Pb^{2+} from aqueous solutions. The availability of biomass and its cost-effectiveness are additional benefits that make it a potential biosorbent for treating heavy metals in the marine environment. The impact of processing constraints - including pH, metal ion concentrations, and

absorption period - significantly affected the equilibrium process. The Pb^{2+} uptake increased with the increase in metal ion concentration. It was also ascertained that the metal uptake increased with the rise in pH until pH 4; thereafter, the metal uptake began to decline. The Langmuir model might better represent the adsorption isotherms compared to the Freundlich model. According to these findings, the seaweed *E. denticulatum* can be considered a potential biosorbent for removing heavy metal from marine and coastal areas due to its high biosorption capability.

Abstract

Photoelectrochemical (PEC) water splitting is a promising method that involves a direct route to produce green hydrogen (H_2). An efficient semiconductor photoelectrode that has a suitable band gap between the valence and conduction band is stable in an aqueous solution and cost-effective. Efficient charge transfer and outstanding light absorption are required to achieve enhanced PEC water splitting performance. However, the wide band gap of current photoelectrode such as zinc oxide (ZnO) limits their ability to transport electron, causing photogenerated electron–hole pair recombination and poor PEC performance. This study aims to design an efficient photoelectrode by incorporating a three-dimensional (3D) graphene with ZnO, where 3D graphene serves as a co-catalyst/support to enhance the photocatalytic activity of ZnO. The 3D graphene was first synthesized on nickel foam (Ni-foam) via chemical vapor deposition method with the flow of argon, H_2, and methane gas flow in a quartz tube, followed by the growth of ZnO via a hydrothermal method at 150 °C and 200 °C. FESEM, EDX and Raman confirmed the successful growth of ZnO on 3D graphene/Ni-foam. The flower-like ZnO was observed by FESEM after the hydrothermal method, and the highest photocurrent density was measured at 150 °C (108.2 mA cm^{-2}). Therefore, flower-like ZnO flower-like on 3D graphene/Ni-foam can be used as an efficient semiconductor photoelectrode in PEC water splitting.

Keywords: 3D graphene, zinc oxide, photoelectrode, photoelectrochemical water splitting

Abstrak

Pembelahan molekul air secara fotoelektrokimia (PEC) merupakan kaedah yang menggunakan laluan yang mudah untuk menghasilkan hidrogen (H_2). Fotoelektrod semikonduktor yang cekap mempunyai jurang jalur yang sesuai antara jalur valensi dan konduksi, stabil dalam larutan berair dan kos yang rendah. Pemindahan cas yang cekap dan penyerapan cahaya yang baik diperlukan untuk mencapai prestasi pembelahan molekul air PEC yang tinggi. Walau bagaimanapun, jurang jalur fotoelektrod yang lebar seperti zink oksida (ZnO) menghadkan kebolehannya untuk pengangkutan elektron, menyebabkan penggabungan semula lubang–elektron terjana dan prestasi PEC yang rendah. Kajian ini bertujuan untuk merekacipta fotoelektrod yang cekap dengan menggabungkan tiga-dimensi (3D) grafin dengan ZnO, di mana 3D grafin bertindak sebagai pemangkin bersama/sokongan untuk meningkatkan aktiviti fotokatalitik ZnO. 3D grafin disintesis pada busa nikel (busa-Ni) melalui kaedah pemendapan wap kimia dengan aliran gas argon, H_2 dan metana dalam tiub kuarza, diikuti dengan pertumbuhan ZnO melalui kaedah hidrotherma pada

150 °C and 200 °C. FESEM, EDX dan Raman mengesahkan pertumbuhan ZnO pada 3D grafin/busa-Ni. Pertumbuhan ZnO seperti bunga dapat dilihat dengan alat FESEM selepas melalui kaedah hidrotherma dan ketumpatan foto arus yang tinggi diukur pada suhu 150 °C (108.2 mA cm^{-2}). Oleh itu, ZnO berbentuk seperti bunga pada 3D grafin/busa-Ni boleh digunakan untuk fotoelektrod semikondutor yang cekap dalam pembelahan air secara PEC.

Kata kunci: 3D grafin, zink oksida, fotoelektrod, pembelahan molekul air secara fotoelektrokimia.

Introduction

Photoelectrochemical (PEC) water splitting is a potential technology that involves a direct route using sunlight and water to produce green hydrogen (H_2) for a variety of applications [1, 2]. Water is a primary source of H_2, and the consumption and cycle of H_2 are in a continuous loop. In addition, as compared to a photovoltaic-electrolysis system, the PEC system is simple and space saving with fewer components [3]. However, current solar-to-hydrogen (STH) efficiencies of the PEC system, 16.2% produced by a multijunction semiconductor, are insufficient compared with existing technologies. Thus, continuous, high-efficiency, and sustainable photocatalytic H_2 evolution from water without the assistance of electron donors with STH values greater than 10% is necessary [4–6].

In general, semiconductor materials with an appropriate band gap are often used as photoelectrode for light absorption in the PEC system. Nevertheless, not all semiconductors fulfill the band gap requirements for overall water splitting, which require the conduction band (CB) to be more negative than the reduction potential of water to produce H_2 and the valence band to be more positive than the oxidation potential of water to produce oxygen [7, 8]. The wide band gap of current photoelectrode, such as zinc oxide (ZnO), which is approximately 3.37 eV, inhibits the ability to transport electrons, resulting in the recombination of photogenerated electron–hole pairs [9–11]. Hence, three-dimensional (3D) graphene with a high surface area, high conductivity, and fast charge carrier transport as a co-catalyst/support can overcome the limitations of ZnO by extending the light absorption range and improving charge separation and transportation properties [12, 13].

In this work, 3D graphene was synthesized on nickel foam (Ni-foam) using chemical vapor deposition (CVD) method, followed by hydrothermal method to synthesize ZnO on 3D graphene/Ni-foam by using two different reaction temperature (150 °C and 200 °C) for 2 hours (Figure 1). The photocatalytic performance of 3D graphene/Ni-foam hierarchical flower-like ZnO exhibits a large surface area that can increase the charge separation efficiency, resulting in excellent photocatalytic performance.

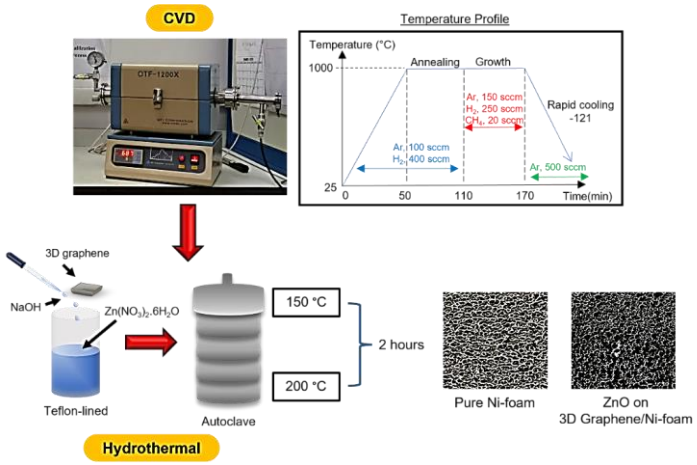

Figure 1. Schematic illustration for preparation of ZnO on 3D graphene/Ni-foam

Materials and Methods

Preparation of three-dimensional (3D) graphene

The nickel foam (Ni-foam; 1.5 cm x 1.5 cm x 0.16 cm, Brand TOB) was used as a template to grow graphene via chemical vapor deposition (CVD) method. Acetone, ethanol, and deionized water were used during ultrasonic cleaning and dried using nitrogen blow. Then, the Ni-foam was placed in the center of the quartz tube and heated up to 1000 °C for 50 min at 20 °C/min. The temperature was maintained for another 60 min with argon (Ar, 100 sccm) and H_2/Ar (400 sccm) gas flow. For 60 min of growth time, methane (CH_4) with 20 sccm gas flow was introduced as the carbon source. The sample is rapidly cooled to room temperature.

Synthesis of 3D Graphene/ZnO on nickel foam (Ni-foam)

Zinc nitrate hexahydrate ($Zn(NO_3)_2.6H_2O$), sodium hydroxide (NaOH) from Sigma-Aldrich, and deionized water were used throughout the experiment. 0.5 M $Zn(NO_3)_2.6H_2O$ solutions were prepared in 30 mL deionized water under stirring for 30 min. Simultaneously, 5 M NaOH solutions were prepared in 30 mL deionized water under stirring for the same duration. $Zn(NO_3)_2.6H_2O$ solution was transferred to a sealed Teflon-lined stainless-steel autoclave. Next, 3 drops of NaOH solution were added to the former solution to change the pH of the reactants, and the 3D graphene/Ni-foam was immersed into the reaction before being kept in a box furnace at 150 °C and 200 °C for 2 hours. Finally, the autoclave was taken outside, and the as-sample were dried for 2 hours at 80 °C.

Characterization techniques

Raman analysis was conducted using DXR2xi, Thermo Scientific, to confirm the presence of graphene on Ni foam. The morphology of the samples was examined by field emission scanning electron microscopy (FESEM) and energy dispersive X-ray (EDX) analysis to confirm the existence of graphene and ZnO (Carl Zeiss/GeminiSEM 500).

Photocatalytic measurements

UV-Vis Spectroscopy (Perkin Elmer/Lambda 35) was used to evaluate the band gap energy for ZnO on 3D graphene/Ni-foam at 150 °C and 200 °C for 2 hours. A three-electrode system was used to study the photocurrent of the as-samples, where the working electrode is ZnO on 3D graphene/Ni-foam, the counter electrode is Pt wire, and the reference electrode is Ag/AgCl (3.0 M KCl). A 0.5 M sulfuric acid (H_2SO_4) aqueous solution was used as the electrolyte, and it was purged with nitrogen before testing. 100 mW cm^{-2} Xe lamp was used as the light source, and the area of the ZnO on 3D graphene/Ni-foam exposed to light was 1.5 cm^2.

Result and Discussion

Typically, 3D graphene can be synthesized by using CVD method based on the previous study [14]. FESEM was used to study the physical and structural characteristics of the resulting 3D graphene/Ni-foam, ZnO on 3D graphene/Ni-foam, and ZnO nanoparticles, as shown in Figure 2(a). Combining 3D graphene with metal oxide like ZnO can enhance the PEC performance through shifting the band gap energy, lowering electron–hole pair recombination, increasing charge separation efficiency, and producing smaller particle size with larger surface area [15]. Figure 2(b – c) shows the FESEM image of pristine graphene taken after the CVD growth. Two different color contrasts were observed on the image where the dark contrast corresponds to graphene, which will be validated through Raman and EDX analysis. The hydrothermal method was then performed to develop ZnO on 3D graphene/Ni-foam at 150 °C and 200 °C. The morphological images of flower-like ZnO on 3D graphene/Ni-foam in Figure 2(d – e) demonstrate a high coverage area of ZnO on 3D graphene/Ni-foam. During the hydrothermal process, ZnO nanoparticles were formed (Figure 2(f – g)), and the presence of graphene influenced the growth of hierarchical flower-like ZnO structures. The mechanism of flower-like ZnO was well explained in previous study [16].

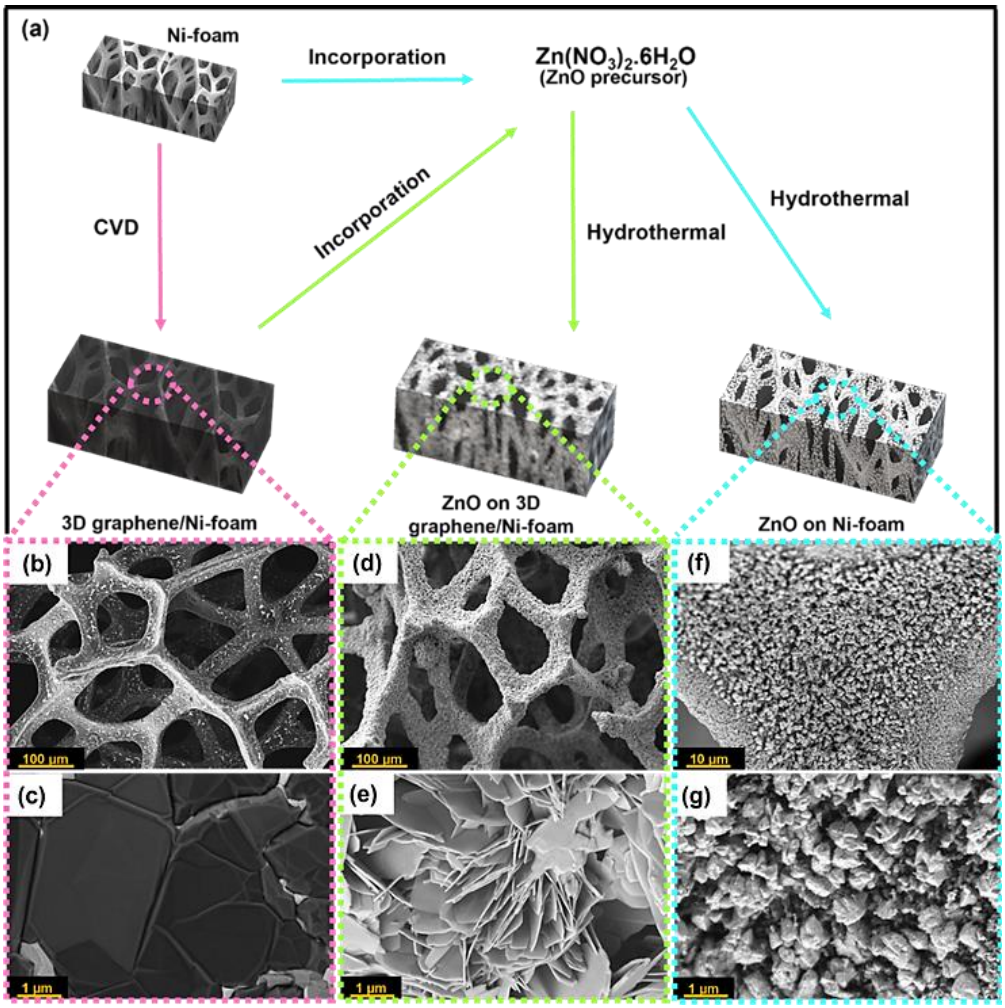

Figure 2. (a) Schematic illustration of the prepared sample. FESEM image of (b – c) 3D graphene/Ni-foam, (d – e) ZnO on 3D graphene/Ni-foam, and (f – g) ZnO on Ni-foam at the low and high magnification, respectively.

Raman spectra for 3D graphene/Ni-foam (Figure 3(a)) were determined. Two graphene fingerprint peaks, including G and 2D bands at ~1581 and ~2700 cm^{-1}, respectively, were observed (Figure 3(b)). The graphene is successfully growth with high quality as there is no D band (~1350 cm^{-1}) observed, in which the D band corresponds to the disorder and defect in graphene [17]. Thus, a sample at low temperature (150 °C) was selected to confirm the successful growth of ZnO using EDX mapping due to the good coverage and flower-like structure of ZnO. As shown in Figure 3(c – d), the existence of carbon (C), zinc (Zn), oxygen (O) and nickel (Ni) indicates the successful growth of ZnO using the hydrothermal method.

Photocatalysts with a narrow band gap can harvest visible light and generate excellent efficiency in photocatalytic applications. The reflectance spectra and Kubelka-Munk plot were used to determine the band gap energy for pure Ni-foam, 3D graphene/Ni-foam and ZnO on 3D graphene/Ni-foam at 150 °C and 200 °C at 2 hours, respectively. Figure 4(a) shows a significance

decrease around 380 nm. This decrease is related to the electron transitions occurring the optical band gap. The Kubelka-Munk function was used to convert the UV-Vis reflectance spectrum to measure the precise value of the band gap. As a result, the band gap energy of pure Ni-foam and 3D graphene/Ni-foam are E_g= 3.217 eV and ZnO on 3D graphene/Ni-foam at 150 °C and 200 °C for 2 hours are E_g= 3.218 eV, respectively (Figure 4(b)). There are no significance changes of band gap energy with the introduction of ZnO. However, the presence of ZnO enhances the photocatalytic performance, where the highest photocurrent density is achieved with ZnO on 3D graphene/Ni-foam at 150 °C, approximately 108.2 mA cm^{-2} (Figure 4(c)). Considering that the coverage of ZnO for 150 °C is larger than that for 200 °C, the structure of ZnO starts to agglomerate with the increase of temperature to 200 °C, thereby decreasing the surface area and resulting in a low photocurrent density [18]. In addition, the electron transfer rate of reaction for all samples is evaluated. Electrochemical impedance spectroscopic (EIS) analysis (Figure 4(d)) demonstrates that ZnO on 3D graphene/Ni-foam at 150 °C has the smallest arc radius of a semicircle, implying that the sample experienced faster interfacial electron charge transfer. This finding could be explained by the porous structure of 3D graphene, which has a large surface area, excellent mechanical and electrical properties, good electron transport, and electron–hole separation, making them suitable for PEC applications [7,8,14]. As shown in Table 1, ZnO on 3D graphene/Ni foam shows higher photocurrent density as compared with other conventional methods and materials for PEC water splitting.

ZnO/rGO foam	One-step hydrothermal	Nanorods	0.27 at 1.0 V vs Ag/AgCl	[20]

Figure 5 illustrates a possible mechanism for efficient electron transport in ZnO on 3D graphene/Ni-foam based on the results of the PEC test. When sunlight illuminates ZnO on 3D graphene/Ni-foam, electrons in the VB of ZnO are excited to jump to the CB using 3D graphene/Ni-foam as a co-catalyst/support. Hydrogen was produced on the surface of ZnO and 3D graphene/Ni-foam. The incorporation of 3D graphene/Ni-foam provides a good electron transport channel in the ZnO on 3D graphene/Ni-foam structure.

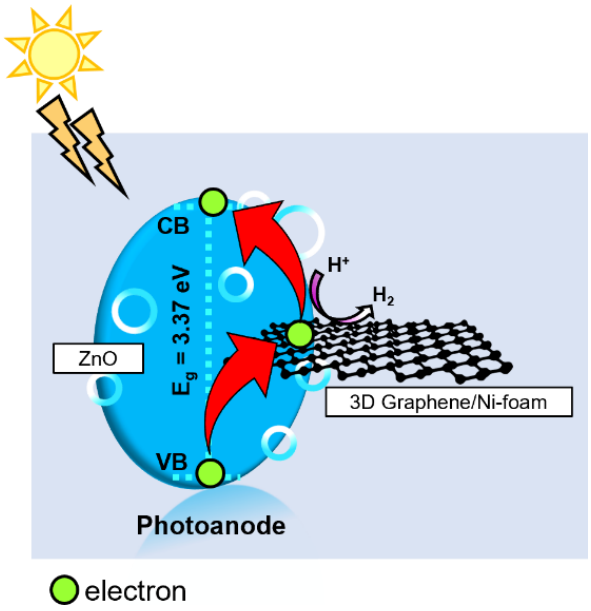

Figure 5. Schematic illustration of PEC water splitting using ZnO on 3D graphene/Ni-foam.

Conclusion

ZnO on 3D graphene/Ni-foam was successfully synthesized by a two-step approach, CVD and hydrothermal methods. The highest photocurrent density was achieved at 150 °C for 2 hours (108.2 mA cm^{-2}). Therefore, a photoelectrode with a high surface area, which provides more active sites, can enhance the photocatalytic performance by increasing charge separation efficiency. Thus, ZnO on 3D graphene/Ni-foam could be a potential photoelectrode for PEC water splitting.

Abstract

Ethanol is a renewable fuel because it can be produced from a variety of production sources that are non-toxic and environmentally friendly. Thus, the consumption of passive direct ethanol fuel cells (DEFCs) as a power supply for portable devices is intriguing and potentially marketable in the future. Unfortunately, one constraint in the application of passive DEFCs is the lack of a Nafion membrane replacement. The Nafion membrane is expensive and has high ethanol permeability. We previously synthesised a crosslinked poly vinyl alcohol/graphene oxide (PVA/GO) composite membrane for passive DEFCs using low-cost polymer materials and successfully achieved low ethanol permeability. Furthermore, the characterization and performance of a crosslinked PVA/GO composite membrane outperformed that of the Nafion membrane. In the passive DEFCs, the optimal membrane thickness is a critical parameter that influences the membrane and single-cell performance. This experimental study attempted to examine the effect of a crosslinked PVA/GO composite membrane thickness on proton conductivity, ethanol permeability, membrane selectivity, and single-cell performance. The passive DEFCs achieved a maximum performance of 7.54 mW cm^{-2} at 60 °C by using a crosslinked PVA/GO composite membrane with a membrane thickness of 0.24 mm.

Keywords: polymer electrolyte membrane, membrane thickness, passive direct ethanol fuel cells, poly (vinyl)/graphene oxide

Abstrak

Etanol merupakan bahan api yang boleh diperbaharui kerana ia boleh dihasilkan daripada pelbagai sumber pengeluaran, tidak toksik, dan mesra alam. Oleh itu, penggunaan sel fuel etanol langsung pasif (DEFCs) sebagai bekalan kuasa untuk peranti mudah alih adalah menarik dan berpotensi untuk dipasarkan pada masa hadapan. Walau bagaimanapun, satu kekangan terhadap penggunaan DEFCs pasif adalah ketiadaan penggantian membran Nafion. Membran Nafion adalah mahal dan mempunyai kebolehtelapan etanol yang tinggi. Sebelum ini, kami telah mensintesis membran komposit alkohol polivinil/grafin oksida (PVA/GO) terpaut silang untuk DEFC pasif menggunakan bahan polimer berkos rendah dan berjaya mencapai kebolehtelapan etanol yang rendah. Tambahan lagi, pencirian dan prestasi membran komposit PVA/GO silang mengatasi prestasi membran Nafion. Dalam DEFCs pasif, ketebalan membran optimum ialah parameter kritikal yang mempengaruhi prestasi membran dan sel tunggal. Kajian eksperimen ini cuba untuk mengkaji kesan ketebalan membran komposit PVA/GO terpaut silang terhadap kekonduksian

proton, kebolehtelapan etanol, selektiviti membran, dan prestasi sel tunggal. DEFC pasif telah memperoleh prestasi maksimum 7.54 mW cm^{-2} pada 60 °C melalui penggunaan membran komposit PVA/GO bersilang dengan ketebalan membran 0.24 mm.

Kata kunci: membran elektrolit polimer, ketebalan membrane, sel bahan api etanol langsung pasif, alkohol polivinil/grafin oksida

Introduction

High reliance on fossil fuel consumption tends to increase greenhouse gas emissions, resulting in impending climate change. Furthermore, as fossil fuel sources deplete, researchers and industry are attempting to boost the use of renewable fuels such as fuel cells. Fuel cells of many forms have been investigated, including proton exchange membrane fuel cells (PEMFCs), direct alcohol fuel cells (DAFCs), and solid oxide fuel cells (SOFCs). According to the fuel cell design, each type of fuel cell has a specific application based on the physical fuel condition and type of electrolyte used [1]. For example, direct ethanol fuel cells (DEFCs) are commonly utilised for portable device applications such as electrical and electronic devices due to the fact that these fuel cell systems can be manufactured on a small micrometre scale. Although methanol is more commonly used in the systems of DAFCs for portable device applications, there are numerous advantages to using ethanol in fuel cell systems over methanol. Ethanol is a low-cost, less-toxic, naturally existing, green, and renewable fuel that can be easily manufactured through the fermentation process [2]. Besides, the energy density of ethanol (i.e., 8.00 kW h kg^{-1}) is higher than that of methanol (i.e., 6.09 kW h kg^{-1}). Furthermore, ethanol is safe for human consumption (i.e., used in medicine). Thus, ethanol is easier to handle for the processes of storage, transfer, and management [3].

Passive DEFCs are appropriate for small portable device applications due to the unavailability of an external component required. For example, this fuel cell system does not require an external fuel pump or air blower to supply the fuel and oxidant needed for energy generation [4]. Passive DEFCs can be operated in the single-cell mode with a polymer electrolyte membrane (PEM) located in the centre cell and a pair of electrodes, as presented in Figure 1. PEM is a critical component that influences the overall performance of passive DEFCs. To achieve excellent long-term operating conditions for fuel cells, PEM should exhibit high chemical and mechanical stability, high proton conductivity, and low ethanol permeability to obtain high membrane selectivity [5]. Unfortunately, the conventional membrane that is widely used in fuel cell systems, which is a perfluorinated sulfonic acid electrolyte membrane (Nafion membrane, manufactured by DuPont), has significant ethanol permeability and leads to rapid ethanol crossover. As a result, the performance of the cell is degraded and damaged on the cathode side [6].

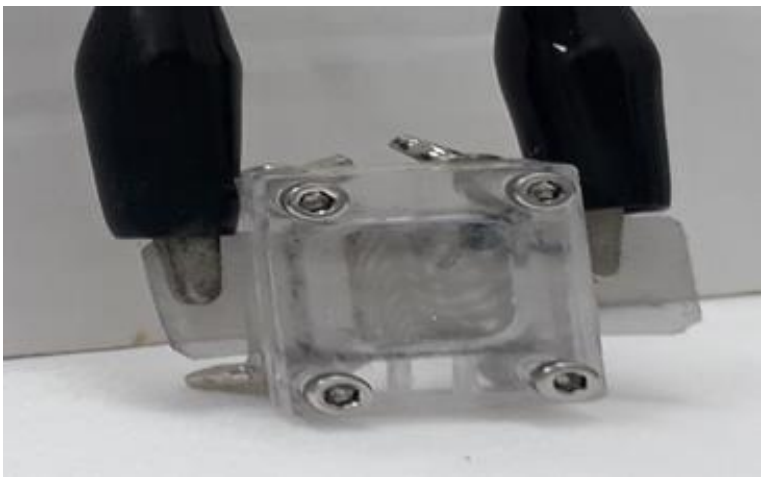

Figure 1. DIY single-cell passive DEFCs

The thickness of the membrane has a considerable effect on the membrane properties and performance of the fuel cell. Numerous studies have examined the influence of membrane thickness on fuel cell performance [7, 8]. For example, Sudaroli et al. [9] tested two distinct types of Nafion membranes with varying membrane thicknesses for fuel cell applications, Nafion 117 and Nafion 1110. According to Sudaroli et al. [9], that thicker membranes substantially decrease fuel crossover and improve single-cell efficiency. While raising the membrane thickness is efficient at decreasing fuel crossover, it has a detrimental effect on the polymeric membrane's conductivity qualities. Thus, the optimal membrane thickness is necessary to achieve the appropriate conductivity-fuel crossover balance [10].

Previously, the performance of a crosslinked poly vinyl alcohol/graphene oxide (PVA/GO) composite membrane in the use of passive DEFCs has been described. Compared to the Nafion membrane, the crosslinked PVA/GO composite membrane has a 15 wt.% loading of GO and demonstrated low ethanol permeability and good membrane selectivity [11]. In this study, the effect of the membrane thickness of a crosslinked PVA/GO composite membrane was studied to enhance the cell performance of passive DEFCs. In order to achieve the optimal membrane thickness for the crosslinked PVA/GO composite membrane, several evaluations were performed, including membrane composite self-performance and performance on single-cell passive DEFCs.

Materials and Methods

All chemicals and procedures for fabricating the membranes used in this study were previously described in our prior study utilising the simple casting solution method [11]. The GO loading was maintained at 15% by weight throughout this research. Additionally, the membrane thickness was modified according to the volume of the solution created, resulting in four distinct membrane thicknesses (i.e., 0.16 mm, 0.20 mm, 0.24 mm, and 0.28 mm). The membrane self-performance was evaluated for proton conductivity, ethanol permeability, and membrane selectivity with various membrane thicknesses. Next, the performance of single-cell passive DEFCs was measured with different membrane thicknesses of crosslinked QPVA/GO composite membranes. The cell condition was constant with 4 mg cm^{-2} of Pt/Ru catalyst (i.e., anode), 2 mg cm^{-2} of Pt catalyst (i.e., cathode), and 2 cm^2 of active cell area at 30 °C. The technical and calculation information followed the details of the experiment from our previous work [11].

Results and Discussion

The self-performance of a crosslinked QPVA/GO composite membrane, comprising proton conductivity, ethanol permeability, and membrane selectivity, is shown in Table 1. According to the self-performance results, lowering the membrane thickness substantially boosted proton conductivity. This indicated that decreasing the membrane thickness reduced the ohmic resistance slightly and shortened the proton pathway. As a result, proton transfer within the PEM was rapid. The mechanism of proton conductivity inside the crosslinked PVA/GO composite membranes is depicted in Figure 2. The proton is mostly diffused via the vehicle and hopping mechanisms. Thus, the thin membrane thickness is generated during the proton transfer process, which is accelerated due to the resistance effect, resulting in lower resistance and a shorter diffusion pathway [12].

Table 1. Self–performance of a crosslinked PVA/GO composite membrane with varying membrane thicknesses

Membrane thickness (mm)	σ, × 10^{-3} S cm^{-1}	ρ, × 10^{-7} cm^2 s^{-1}	Membrane selectivity, × 10^4 S s cm^{-3}
0.16	11.3	2.34	4.829
0.20	9.5	1.78	5.337
0.24	8.4	1.51	5.562
0.28	7.6	1.46	5.241

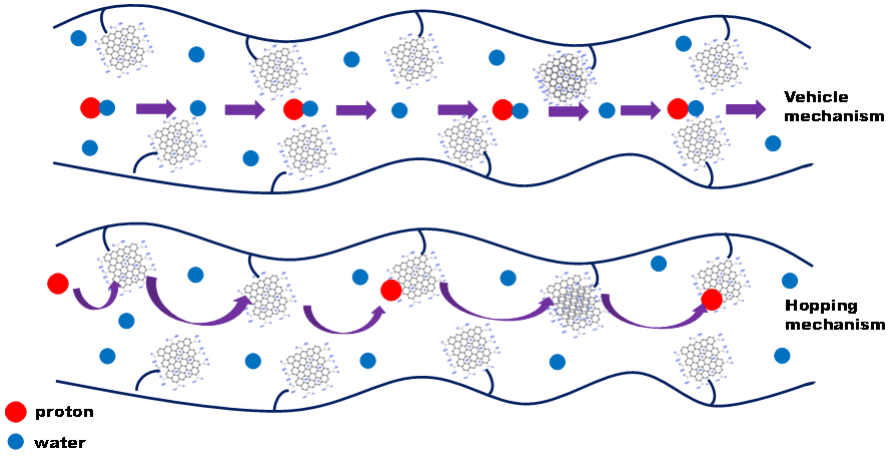

Figure 2. The mechanism of proton conductivity within the crosslinked PVA/GO composite membranes

Unfortunately, the thin membrane thickness allowed for high ethanol permeability to occur quickly due to the reduction of obstacle regions within the matrix polymer. Based on Table 1, the increasing membrane thickness is beneficial for the ethanol barrier because the fuel movement becomes more difficult to penetrate the three-dimensional matrix polymer structure between PVA, GO, and crosslinking interaction [13]. However, the proton conductivity is sacrificed due to the large membrane thickness. As a result, determining the optimal membrane thickness is critical for balancing both the membrane's self-performance and the membrane's performance. Thus, membrane selectivity is a precise metric that demonstrates the optimal membrane thickness, which balances proton conductivity and ethanol permeability [14]. According to Table 1, the maximum membrane selectivity is 5.562 $\times$ 10^4 S s cm^{-3} for a crosslinked QPVA/GO composite membrane with a membrane thickness of 0.24 mm. This indicated that the optimum membrane thickness is 0.24 mm and that the higher power density should be shown during the single-cell performance.

Overall, all membrane thicknesses have good results in terms of proton conductivity in the range of $\sim 10^{-3}$ S cm^{-1} and ethanol permeability in the range of $\sim 10^{-7}$ cm^2 s^{-1}. As illustrated in Figure 3, the characterization of a crosslinked PVA/GO composite membrane demonstrated suitable morphologies and structures for usage as a PEM in applying passive DEFCs. Figure 1 presents our previous characterization results, which include the analyses of FTIR, XRD, and FESEM [11]. As illustrated in Figure 3(a), the modification of PVA with GO and a crosslinked agent resulted in the presence of numerous oxygenic functional groups necessary for the hopping mechanism and the retention of water in the vehicle mechanism for proton transfer within the PEM. The crystalline and amorphous structures of a crosslinked PVA/GO composite membrane are then balanced to enhance the self-performance of the membrane, particularly in terms of proton conductivity and ethanol permeability, as shown in Figure 3(b). Besides, the dense morphology of a crosslinked PVA/GO composite membrane that was successfully synthesised as presented in Figures 3(c) and 3(d) has contributed to the critical function of managing the issue of ethanol crossover [15, 16].

All the different membrane thicknesses of a crosslinked PVA/GO composite membrane were evaluated in single-cell passive DEFCs with 2 M ethanol. Figure 4 shows the cell voltage and power density performance for all samples. The result has proven that the highest membrane selectivity with 0.24 mm membrane thickness obtained the highest power density with 5.71 mW cm^{-2}. Besides, the open cell voltage of 0.24 mm membrane thickness produced a maximum voltage of 0.85 V. This indicates that the minimum ethanol crossover was obtained with the optimal membrane

thickness [17]. Furthermore, the high proton conductivity of a crosslinked PVA/GO composite membrane enhanced the electrochemical properties that rapidly transferred the proton within the matrix polymer. As a result, the redox reaction occurred smoothly and produced high cell voltage and power density [18]. Hence, the optimal membrane thickness of a crosslinked PVA/GO composite membrane for this study was 0.24 mm.

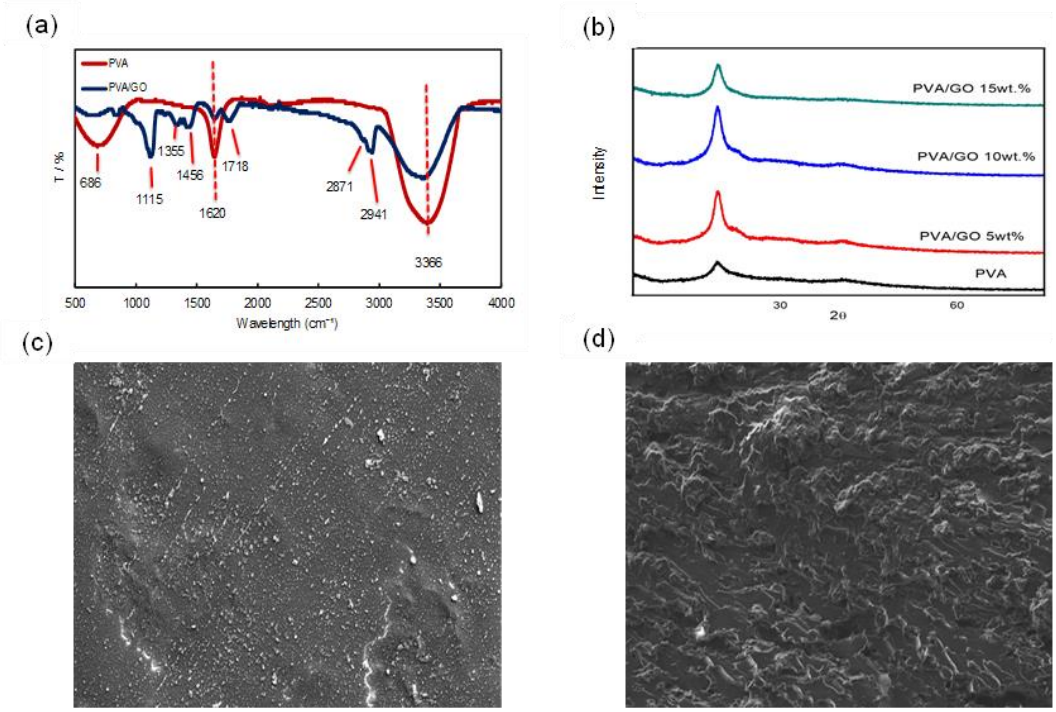

Figure 3. (a) FTIR analysis of a crosslinked PVA/GO composite membrane; (b) XRD analysis of membranes; FESEM analysis of membrane; (c) surface; (d) cross-section [11]

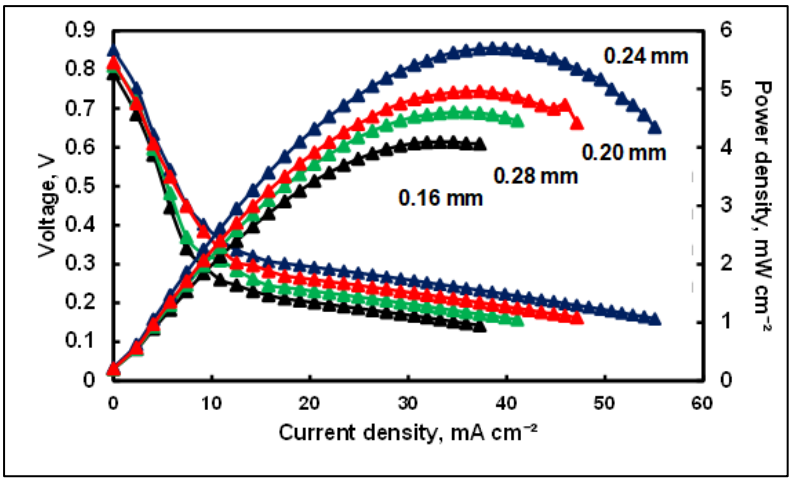

Figure 4. Cell voltage and power density of a crosslinked PVA/GO composite membrane in the passive DEFCs by varying the membrane thickness.

Finally, the optimal membrane thickness was determined using various ethanol concentrations in order to improve the cell performance of single-cell passive DEFCs using a crosslinked PVA/GO composite membrane. Three ethanol concentration values were used with the constant parameters of catalyst loading and cell operating temperature. Figure 3 presents the effect of varying ethanol concentrations, ranging from 2 M ethanol to 6 M ethanol. Obviously, the maximum power density of passive DEFCs utilising a crosslinked PVA/GO composite membrane increased from 5.71 mW cm^{-2} to 7.04 mW cm^{-2} when the ethanol concentration was changed from 2 M to 4 M. This indicates that a fuel concentration of 4 M of ethanol is a good fuel concentration to consume that can significantly improve the electrochemical activity for this investigation and boost the attainment of current density. In fact, the increment in ethanol concentration will result in a high density of ethanol molecules that can be converted to energy during the oxidation reaction at the anode [19, 20]. Unfortunately, the increment level of ethanol concentration has a limited level. Thus, this study provided a significant discovery for fuel limitation concentration. As shown in Figure 5, when 6 M ethanol was applied in passive DEFCs, the power density of a crosslinked PVA/GO composite membrane significantly decreased, going from 7.04 mW cm^{-2} to 4.45 mW cm^{-2}. This indicates that the high ethanol concentration caused the ethanol crossover to occur quickly due to the high density of ethanol molecules present at the anode. As a result, the ethanol osmotic state within the cell and ethanol transfer significantly occurred due to the different ethanol concentration conditions between the anode side and cathode side. Thus, ethanol transfers to the cathode side from the anode side through a crosslinked PVA/GO composite membrane without being affected by the oxidation process. Furthermore, this circumstance may result in both a potential problem on the cathode side and a reduction in cell performance [21, 22]. As a result, the ideal ethanol concentration was set at 4 M for this study in order to boost the performance of a crosslinked PVA/GO composite membrane in passive DEFCs.

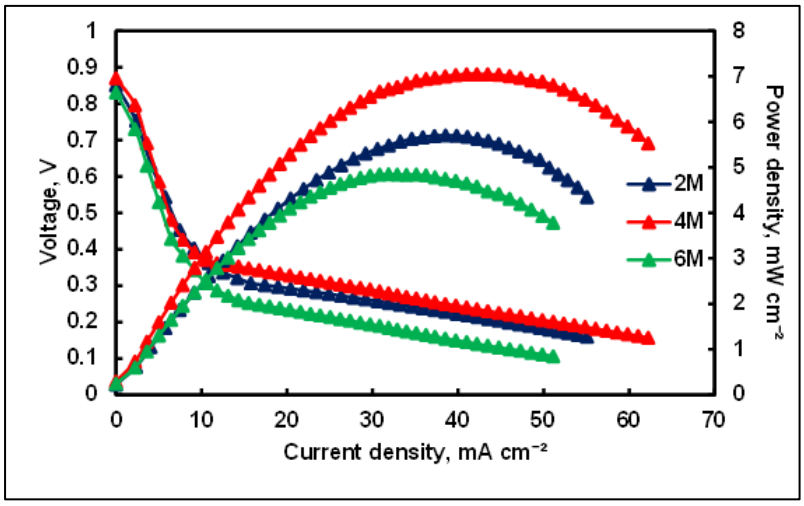

Figure 5. Cell voltage and power density of a crosslinked PVA/GO composite membrane in the passive DEFCs with optimum membrane thickness by varying the ethanol concentration

Conclusion

A simple casting solution method managed to synthesise a crosslinked PVA/GO composite membrane with good morphology and characterization. Furthermore, the thermal, mechanical, and chemical stability of this membrane has been demonstrated in our previous study, as has the excellent performance of single-cell passive DEFCs. In this study, the membrane thickness of a crosslinked PVA/GO composite membrane was manipulated to improve the cell performance of this membrane in passive DEFCs. The 0.24 mm membrane thickness demonstrated good membrane selectivity with 5.562 104 S s cm^{-3}. Thus, 0.24 mm was obtained as an optimal membrane thickness that effectively balanced

the crucial parameters of a PEM (i.e., proton conductivity and ethanol permeability). At 30 °C, the power density of single-cell passive DEFCs using a crosslinked PVA/GO composite membrane was 7.04 mW cm^{-2} at an optimal ethanol concentration of 4 M. In conclusion, the membrane thickness of a PEM significantly influences the performance of passive DEFCs.

Abstract

Gold–copper (Au–Cu) bimetallic catalysts were prepared through chemical reduction with Cu and Au precursors at the pH of 3, 5, 7 and 9 and hexadecylamine as the capping agent to produce Au–Cu bimetallic nanoparticles (Au–Cu NPs). The colloidal Au–Cu NPs were then grafted onto an anodic aluminium oxide (AAO) support through spin coating. The AAO support was fabricated via a two-step anodization method at 80 V by using oxalic acid as the electrolyte. The Au–Cu/AAO catalysts were characterized through field emission scanning electron microscopy–energy dispersive X-ray spectroscopy, Fourier transform infrared spectroscopy and inductive coupled plasma–optical emission spectroscopy. The catalytic activities of the Au–Cu bimetallic catalysts in the reduction of *p*-nitrophenol (*p*-NP) were evaluated. Results showed that the rate constant (k) varied in accordance with the pH of the Au precursor. The highest k value of 4.6×10^{-3} s^{-1} was obtained with the Au–Cu catalyst prepared at pH 7. The better performance of the investigated bimetallic catalyst than that of the monometallic Au and Cu catalysts demonstrated the promotional role of the second metal in the reduction of *p*-NP.

Keywords: Au–Cu NPs, pH, anodic aluminium oxide

Abstrak

Pemangkin dwilogam Au-Cu dengan prekursor Au pH 3, 5, 7 dan 9 disediakan dengan menggunakan prekursor Cu secara kaedah penurunan kimia dengan heksadesilamin (HDA) sebagai agen penutup untuk penghasilan nanopartikel Au-Cu (NP Au-Cu). Dwilogam NP Au-Cu telah dicantumkan pada sokongan anodik aluminium oxida (AAO) melalui kaedah salutan putaran. Sokongan AAO telah difabrikasi pada 80 V menggunakan asid oksalik sebagai elektrolit melalui kaedah anodisasi dua langkah. Pemangkin Au-Cu/AAO dicirikan oleh mikroskopi elektron pengimbasan pelepasan medan-spektroskopi sinar-X penyerakan tenaga (FESEM-EDX), spektroskopi inframerah transformasi fourier (FTIR) dan spektroskopi pelepasan plasma-optik berganding induktif (ICP-OES). Penurunan *p*-nitrofenol digunakan untuk menilai aktiviti pemangkin bimetal Au-Cu. Keputusan

menunjukkan bahawa pemalar kadar, (*k*) adalah berbeza bergantung kepada pH prekursor. Nilai *k* tertinggi iaitu 4.6 x 10^{-3} s^{-1} telah diperolehi daripada pemangkin Au-Cu yang disediakan pada pH 7. Daripada kajian ini, pemangkin dwilogam menunjukkan prestasi yang lebih baik berbanding pemangkin Au dan Cu logam mono, menunjukkan peranan promosi logam kedua ke arah penurunan *p*-nitrophenol.

Kata kunci: NP Au-Cu, pH, anodik aluminium oksida

Introduction

Gold nanoparticles (Au NPs) are small particles with diameters that range from 1 nm to 100 nm and unique optical and electronic properties. Au NPs can be easily dispersed in water to form colloidal Au, which offers many benefits for various applications. Au NPs are an excellent catalyst for the selective oxidation or hydrogenation of organic substrates. In recent years, interest in using Au NPs as catalysts for the reduction of p-nitrophenol (*p*-NP) and p-nitroaniline (*p*-NA) has grown [1-2]. Au NPs have been extensively researched as monometallic or bimetallic NPs. The performance of monometallic Au NPs is limited by particle size and manufacturing technique, but these constraints can be overcome by adding a second metal [3-6]. Au NPs mixed with other transition metals such Au-Pt, Au-Cu, Au-Pd, and Au-Ag have higher catalytic activity than monometallic Au NPs. It is highlighted that Au-Cu NPs are an excellent bimetallic alloy because they are more resistant to oxidation thus have a longer catalytic lifetime [5]. The characteristic of the NPs is highly dependent on their preparation condition such as pH, capping agent and precursor concentration.

However, the Au-Cu NPs tend to agglomerate on their own [6-15]. This can be prevented by introducing the support materials such as metal oxides to stabilize and disperse the Au-Cu NPs. Anodic aluminium oxide (AAO) was chosen as the support as it offers several advantages, such as (i) high surface area and porous structure; the reactants get easy access to the active catalytic site [16-17], (ii) prevent agglomeration of Au-Cu NPs, and (iii) this supported catalyst can easily be separated from the reaction mixture at the end of the reaction by simple filtration.

p-NP is a common pollutant that originates from agricultural, pharmaceutical and petrochemical industries; it is highly carcinogenic and tends to persist in water and soil [2,18]. *p*-NP causes the irritation and inflammation of the eyes, skin and respiratory tract. The delayed reaction of *p*-NP in the blood of people exposed to this compound causes methemoglobinemia. The symptoms of methemoglobinemia include cyanosis, confusion and unconsciousness. Therefore, this compound has prompted the development of a wide range of analytical devices by researchers for its determination and eventual removal from contaminated sites. The reduction of *p*-NP can be monitored easily by using a UV-Vis spectrophotometer at 400 nm. Therefore, in this work, we proposed the preparation of Au–Cu NPs with a Au precursor at different pH values via chemical reduction followed by immobilization on an AAO membrane through spin coating. The activities of these Au–Cu/AAO catalysts were then tested in *p*-NP reduction. *p*-NP is a pollutant that is commonly found in most water bodies; it can be upcycled for use in the production of analgesics, such as paracetamol, through reduction into p-aminophenol [1,6].

Materials and Methods

Preparation of Au-Cu NPs

The bimetallic Au-Cu NPs were synthesized based on the chemical reduction technique. An aqueous solution of $CuCl_2 \cdot 2H_2O$ (50 mM) was mixed with 0.3 mL $HAuCl_4 \cdot 3H_2O$ (50 mM) of various pH of 3, 5, 7, and 9 by using 0.5 M NaOH. The molar ratio of the Au to Cu is 2.5 to 1. The mixture was then added with 0.28 mL of glucose (0.5 M) in a glass vial containing the hexadecylamine (HDA) solution of 22.5 mg in 2 mL distilled water [3]. The vial was magnetically stirred at room temperature overnight followed by heating treatment at 100 ^{o}C for 10 mins. After the vial was cooled in an ice bath, 15 mg of HDA was added and the vial was heated again till colour changes observed.

The samples are denoted as Au-Cu pH3, Au-Cu pH5, Au-Cu pH7 and Au-Cu pH9.

Fabrication of AAO membrane

A 99.99% purity aluminium foil with a thickness of approximately 0.1 mm was cut into (2 cm x 2 cm) pieces, and an AAO membrane was formed on the aluminium foil using a two-step electrochemical anodization procedure that was previously reported [1,16]. The AAO was manufactured in multiple phases. The aluminium foils were cleaned and degreased in the first phase by sonication in acetone for 15 mins. The aluminium foils were then submerged in a chemical polishing solution (15 mL HNO_3 and 85 mL H_3PO_4) for 1 min at 70 °C. Then, using 0.3 M oxalic acid as the electrolyte, the initial anodization was performed for 1 minute at 5 °C with a constant voltage of 80 V. The anodic layer was then removed by immersing the foil for roughly 2 hours in a solution of 1.5 wt.% chromic and 6 wt% phosphoric acids. Next, the second anodization procedure was carried out for 2 hours in the conditions described above. Finally, a solution of 5% $CuCl_2.2H_2O$ and 15% HCl was used to dissolve the aluminium foils and obtain AAO membrane. The constructed AAO membrane was cleaned multiple times with generous volumes of ethanol and DI water and stored in the desiccator until further used.

Immobilization of Au-Cu NPs on AAO

The previously prepared Au-Cu NPs solution was deposited on both sides of the AAO by spin-coating at 1000 rpm for 30 s. Subsequently, the AAO was subjected to calcination at 400 °C for 4 hours at a rate of 10 °C/min. The immobilized Au-Cu NPs are denoted as Au-Cu/AAO pH3, Au-Cu/AAO pH 5, Au-Cu/AAO pH 7 and Au-Cu/AAO pH 9 correspond to the Au-Cu NPs prepared at pH 3, 5, 7, and 9, respectively.

Reduction of *p*-Nitrophenol

The *p*-NP solution was prepared by dissolving solid by *p*-NP (99%, Sigma Aldrich) in distilled water. In a cuvette, 1 mg of Au-Cu/AAO catalyst was added to a solution of $NaBH_4$ (1.5×10^{-2} M, 1.5 mL) and *p*-NP (0.05×10^{-2} M, 1.5 mL). The absorbance of the *p*-NP solution was determined at 1-minute intervals using a UV–vis spectrophotometer (Lambda 25, Perkin Elmer) set at 399 nm. At room temperature and pressure, the catalytic reduction was carried out. Depending on the catalyst, the total reaction time for complete reduction of *p*-NP would take 5 to 10 mins. Pseudo-first-order kinetics was used to get the value of the rate constant (*k*) as described by Yazid et al. [6].

Characterization

Characterization of the catalysts by Fourier Transform Infrared Spectroscopy was used to assess the surface functionalities of the produced samples (FTIR; Spectrum, Perkin Elmer). Meanwhile, the surface morphology was observed via Field Emission Scanning Electron Microscopy (FESEM: FEI Nova Nanosem 450). The elements of Au and Cu loading on the AAO membrane were determined by using an Inductive Couple Plasma-Optical Emission Spectrometer (ICP-OES: Optima 8000, Perkin Elmer).

Results and Discussion

Immobilization of Au-Cu NPs on the AAO

Figure 1 shows the photograph of AAO and Au-Cu/AAO. The change of color from yellow to light purple indicates the successful deposition of Au on AAO. The calcination process will vaporize any organic material from the previous steps and leave just the metal and metal oxide species which are Au-Cu NPs and AAO membrane. The calcination step also ensures that the Au-Cu NPs are covalently bonded to the -OH group on the AAO membrane [1,6]. This strong covalent bond prevents aggregation of the particles thus improving their catalytic performance. The spin-coating method provides homogenous distribution of the NPs on the AAO membrane. It is to note that all catalysts prepared at pH 3 to 9 show the same appearance to the naked eyes (Figure 1).

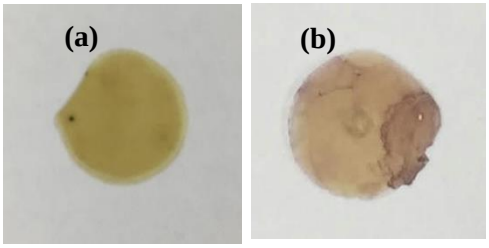

Figure 1. Photograph of (a) bare AAO (b) Au-Cu/AAO pH3

The FTIR spectra of the bare AAO (bAAO) and Au-Cu/AAO are presented in Figure 2. Some changes of peaks intensity, particularly O–H vibrations, confirm the attachment of the Au-Cu NPs on the surface of the AAO [7]. The O–H peak in bAAO at 3210 cm^{-1} is very sharp when compared to Au-Cu/AAO O-H peak at 3195 cm^{-1}. Even though the FTIR instrumentation was unable to detect the presence of gold and copper in the compound, it could be inferred through the observed peak shifting for O-H from 3210 cm^{-1} to 3195 cm^{-1}.

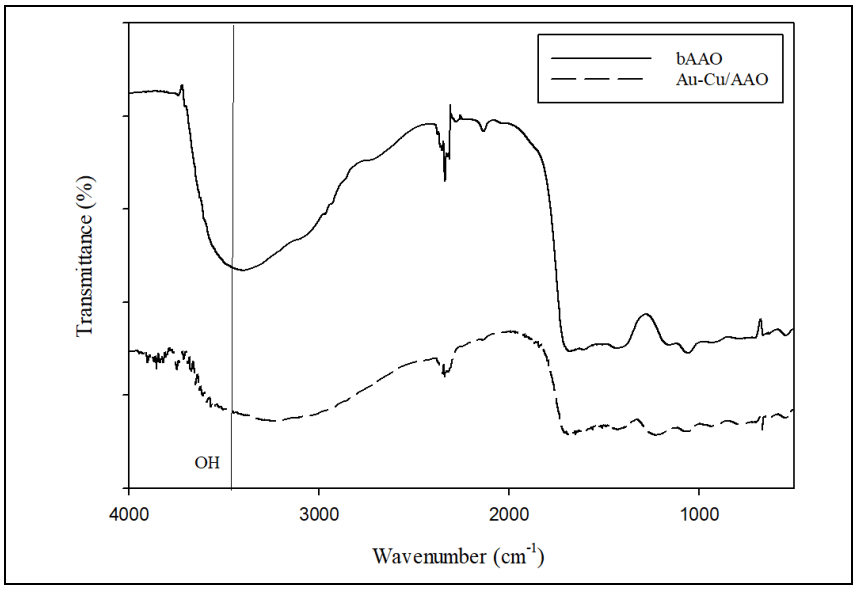

Figure 2. FTIR spectra of bAAO and Au-Cu/AAO

Figure 3 shows FESEM images of synthesized Au-Cu/AAO at pH3 to pH9. FESEM images taken from the top indicated the creation of a hexagonally aligned AAO structure via electrochemical anodization, with typical pore sizes of 100-110 nm. The pores are non-intercrossing and cylindrical in shape resulting in a high surface area. The nanostructure of the as-prepared AAO has a considerable effect on the accessibility (flow) of liquid reactants on both sites of the porous support. A good flow for the reactant to reach the active site is vital for efficient catalytic performance. It is worth noting that exact control of the AAO structure's size and interpore spacing may be accomplished by adjusting the anodization conditions and electrolyte concentration, respectively [16].

The adjustment of pH of the Au precursor has resulted in different sizes and arrangements of the NPs. On Au-Cu/AAO pH3 the size of the NPs is between 113.75 ± 85.20 nm and the NPs are clustered together as shown in Figure 3(a). Whereas, Au-Cu/AAO pH5 and pH7 demonstrated a mix of clustered and individual arrangement of the NPs with a size of 61.54 ± 96.55 nm and 32.33 ± 22.75 nm, respectively. An individually disperse NPs was shown by Au-Cu/AAO pH9 with a size of 34.33 ± 56.47 nm. Noting that the adjustment of pH of the precursor will result in various arrangement and sizes. Table 1 summarizes the characteristic of Au-Cu NPs as observed from FESEM images.

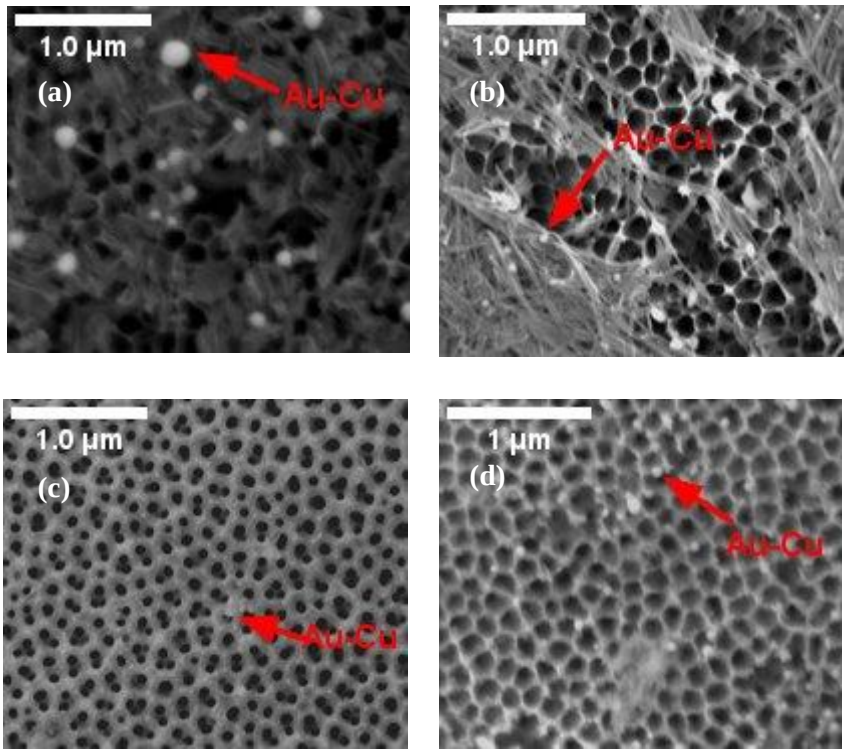

Figure 3. FESEM images of Au-Cu/AAO at different pH of (a) 3 (b) 5 (c) 7 and (d) 9

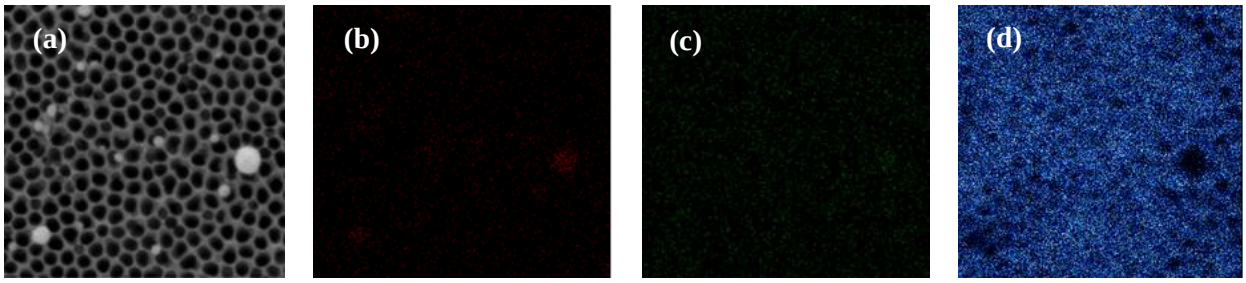
Table 1. Summary of the characteristic of Au-Cu NPs observed from FESEM images

Catalyst	Diameter Size (nm)	Distribution
Au-Cu/AAO pH3	113.75 ± 85.20	Clustered
Au-Cu/AAO pH5	61.54 ± 96.55	Mix of Clustered and Individual Dispersal
Au-Cu/AAO pH7	32.33 ± 22.75	Mix of Clustered and Individual Dispersal
Au-Cu/AAO pH9	34.33 ± 56.47	Individually Disperse

The Au-Cu pH 7 was selected for an area scan using EDX analysis (Figure 4). Figure 4(a) shows the area viewed using FESEM. Figure 4(b) depicts only large Au NPs can be detected. Small Au NPs and Cu NPs were also present but cannot be monitored clearly as seen in Figure 4(b) and (c). In contrast, the Al species from the support AAO can be seen clearly. The production of small and highly dispersed NPs on the AAO membrane resulted in reading below the EDX detection limit for small Au and Cu species. The presence of Cu species will be proved when using ICP-OES.

Based on the ICP-OES results presented in Figure 5, the Au to Cu molar ratio were determined to be 1.4: 1, 1.7:1, 2.27:1 and 1.59:1 for the Au-Cu/AAO pH3, pH5, pH7 and pH9 samples, respectively. The Au-Cu/AAO pH 7 is the closest mol to mol ratio from the experimental value of the precursor used which is 2.5 Au to 1 Cu. These results suggest that the deprotonation of the hydroxyl groups at high pH leads to the accumulation of negative charge on the surface of the Au NPs [1,18].



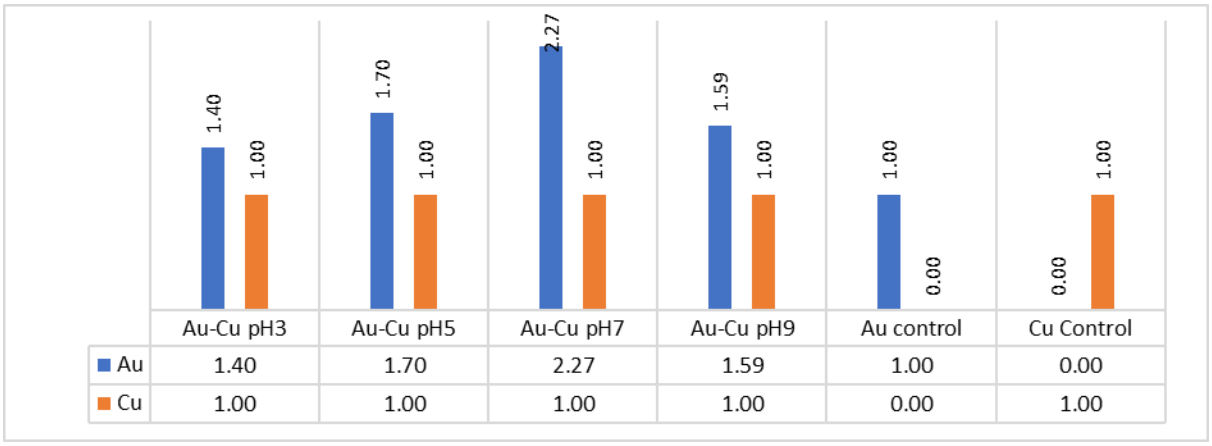


Figure 4. The Au-Cu/AAO pH 7(a) FESEM image and corresponding elemental EDX mapping of (b) Au (c) Cu and (d) Al

	Au-Cu pH3	Au-Cu pH5	Au-Cu pH7	Au-Cu pH9	Au control	Cu Control
Au	1.40	1.70	2.27	1.59	1.00	0.00
Cu	1.00	1.00	1.00	1.00	0.00	1.00

Figure 5. ICP-OES detection of Au to Cu molar ratio

Catalytic performance

The efficacy of the prepared Au-Cu/AAO catalysts were tested by catalytic reduction of *p*-NP to *p*-AP. The *p*-NP solution exhibited a high absorption peak at 317 nm under neutral or acidic conditions, but the addition of $NaBH_4$ increased the alkalinity of the solution, resulting in the creation of *p*-nitrophenolate ions and shifting the absorption peak to 400 nm [2,6]. The appearance and growth of a new peak at 300 nm corresponds to the formation of the product *p*-AP as shown in Figure 6 [1, 6, 18]. The gradual decrease in absorbance at 399 nm with time indicates that the nitro group has been reduced, while the appearance and growth of a new peak at 300 nm corresponds to the formation of the product *p*-AP [6,18]. The dark yellow colour of *p*-NP decreases with the formation of the *p*-AP, and bubbles are produced by $NaBH_4$ converting water to H_2 gas. Because the concentration of $NaBH_4$ in this reaction system far exceeds that of *p*-NP, its concentration remains constant throughout the reaction. The rate constant (*k*) for the reaction was calculated using pseudo-first order kinetics in the case of *p*-NP [6]. The absorbance at 400 nm remains constant over time in the absence of a catalyst, demonstrating that the reduction does not occur. Figure 6 depicts the gradual production of *p*-AP; two isosbestic spots are visible at 280 and 312 nm, implying that the conversion reaction is carried out by the two main species [1, 6].

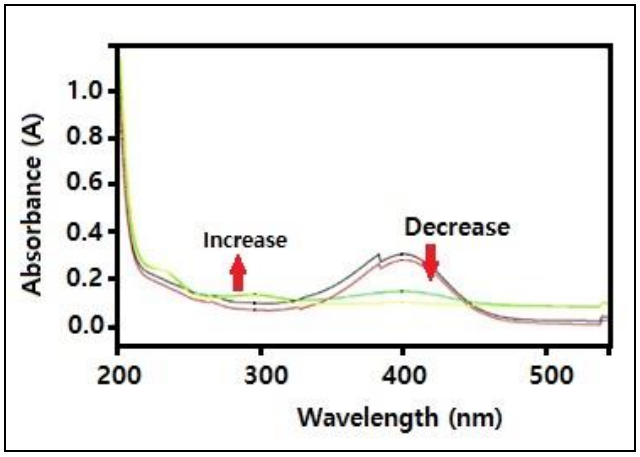

Figure 6: UV-Vis spectra of *p*-NP over time for Au-Cu/AAO pH 7

For all the studies, the graph of $\ln(C/C_o)$ vs reaction time is linear (Figure 7), showing that the catalytic reaction followed first-order kinetics. The Au-Cu/AAO pH3, pH, pH7 and pH9 samples were found to have *k* values of 4×10^{-4} s^{-1}, 2×10^{-3} s^{-1}, 4.6×10^{-3} s^{-1}, and 6×10^{-4} s^{-1}, respectively. A greater *k* value means that *p*-NP is reduced more quickly [1,6,18]. The Au control catalyst had the lowest *k* value, while Cu control had no reaction at all. These findings show that the presence of Cu had an impact in enhancing the catalytic activity of Au NPs in the reduction of *p*-NP. As previously stated, the Au-Cu/AAO pH7 catalyst possesses smaller Au NPs with a uniform distribution of clustering and individual NPs, resulting a good impact on catalytic activity. A neutral pH leads to the formation of small and a mix of individual and clustered dispersal arrangements. The various size and arrangement of Au-Cu NPs generated by grafting the NPs onto the AAO is responsible for the various *k*-values. Even though Cu shows zero catalytic activity the presence of it being with Au has increased the catalytic activity of Au when comparing Au control. Table 2 summarizes the *k*-values of all the prepared catalysts for the reduction of *p*-NP. The results indicate that the adjustment of Au precursor at pH 7 and synthesizing it with Cu has a good effect on the catalytic activity.

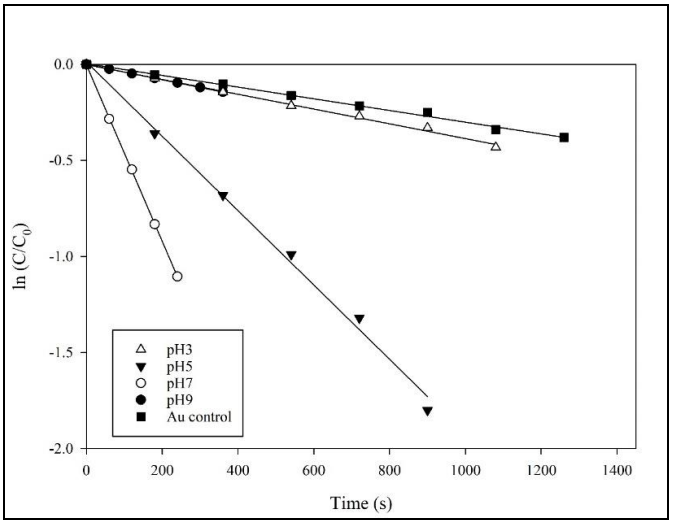

Figure 7. Plot of ln (C/C_o) versus time (min) for the catalysts Au-Cu/AAO

Table 2. Rate of reaction (*k*) of the catalysts

Catalyst	***k*-value (s^{-1})**
Au-Cu/AAO pH3	4.00×10^{-4}
Au-Cu/AAO pH5	2.00×10^{-3}
Au-Cu/AAO pH7	4.60×10^{-3}
Au-Cu/AAO pH9	6.00×10^{-4}
Au/AAO pH7 control	3.00×10^{-4}
Cu/AAO control	no reduction

Conclusion

All synthesized Au-Cu/AAOs were characterized by FESEM-EDX, FTIR, and ICP-OES. The adjustment of pH for the Au precursor during the preparation method has resulted in different Au size and arrangements. The highest activity of 4.6×10^{-3} s^{-1} was obtained for Au-Cu/AAO prepared at pH 7. Furthermore, this bimetallic catalyst exhibited higher catalytic activity than monometallic Au/AAO and Cu/AAO. Further work is underway to extend this concept by using Au NPs at pH 7 with other metals (X) to make another Au-X/AAO catalyst that can be easily recovered from liquid-phase catalytic reactions.

Abstract

Transforming waste into usable materials can protect and conserve the environment, thereby reducing the dependence on landfills, limiting the use of natural resources, and decreasing the carbon footprint. Every year, millions of tons of textile waste are sent to landfills primarily from discarded clothing. Therefore, this waste is worthwhile to convert into functional carbon product. Herein, textile waste from used clothing was converted into nitrogen-doped porous carbons (TNPC) by simple chemical activation followed by carbonisation. Urea and calcium chloride ($CaCl_2$) served as nitrogen precursor and pore forming agent, respectively. The surface area and porosity of the prepared TNPCs were affected by the activation temperature. The optimal sample (TNPC900) activated at 900 °C exhibited a large surface area (496 m^2 g^{-1}) with appropriate porosity and a reasonable amount of nitrogen doped. Remarkably, the resultant TNPC900 catalyst tested as the electrode material for oxygen reduction reaction in 0.1 M KOH exhibited an outstanding positive onset potential of 0.94 V vs. RHE. TNCP900 catalyst also demonstrated superior stability and tolerance to methanol than Pt/C. Overall, this study showed that the conversion of textile waste through a simple synthesis technique into electrocatalyst could offer a sustainable alternative to Pt for potential applications in fuel cell and energy-storage technology.

Keywords: textile waste, nitrogen-doped porous carbon, oxygen reduction reaction, metal-free catalyst

Abstrak

Mengubah sisa menjadi bahan yang boleh digunakan dapat melindungi dan memulihara alam sekitar sekaligus dapat mengurangkan kebergantungan pada tapak pelupusan sampah, mengehadkan penggunaan sumber semula jadi, dan mengurangkan jejak karbon. Setiap tahun, jutaan ton sisa tekstil dihantar ke tapak pelupusan sampah terutama dari pakaian terpakai. Oleh itu, menukar sisa ini menjadi produk karbon berfungsi adalah usaha yang berbaloi. Di sini, sisa tekstil daripada pakaian terpakai telah ditukar kepada karbon berliang terdop nitrogen (TNPC) dengan pengaktifan kimia mudah diikuti dengan langkah karbonisasi. Urea dan kalsium klorida ($CaCl_2$) bertindak masing-masing sebagai bahan sumber nitrogen dan ejen pembentukan liang. Keluasan permukaan dan keliangan TNPC yang disediakan telah dipengaruhi oleh suhu pengaktifan.

Sampel optimum (TNPC900) diaktifkan pada 900 ° C mempamerkan keluasan permukaan yang besar (496 m^2 g^{-1}) dengan keliangan dan jumlah nitrogen terdop yang sesuai. Mangkin TNPC900 yang diuji sebagai bahan elektrod untuk tindak balas penurunan oksigen (ORR) di dalam larutan 0.1 M KOH menunjukkan potensi permulaan positif yang luar biasa iaitu 0.94 V vs RHE. Selain itu, mangkin TNCP900 menunjukkan kestabilan dan toleransi yang unggul terhadap metanol daripada mangkin Pt/C. Oleh itu, kajian ini menunjukkan bahawa penukaran sisa tekstil menggunakan teknik sintesis yang mudah menjadi elektmangkin dapat menawarkan alternatif Pt yang mampan untuk aplikasi di dalam sel bahan api dan teknologi penyimpanan tenaga.

Kata kunci: sisa tekstil, karbon poros terdop nitrogen, tindak balas penurunan oksigen, mangkin bebas metal

Introduction

The growing demand of green and efficient energy has driven the exploration for new technologies because of the depletion of fossil fuels and major environmental problems associated with the usage of conventional energy sources. Fuel cells are a competitive energy device for supplying energy with promising efficiency and negligible emission levels through electrochemical reactions into electricity [1]. However, the sluggish oxygen reduction reaction (ORR) at the cathode significantly affects the overall fuel-cell performance and thus requires an efficient catalyst to accelerate the ORR. The scarce platinum (Pt) and its alloy are extensively used as ORR catalysts, but their high price, low stability, and susceptibility to methanol crossover hinder its large-scale application [2, 3]. Extensive researches have been performed for Pt alternatives that are more cost effective and sustainable with high ORR activity [4]. Metal-free nitrogen-doped carbon materials exhibit massive potential as a substitute to costly Pt-based catalysts, where it demonstrates good ORR electrocatalytic activity and durability, even in acidic electrolytes [5, 6]. Furthermore, owing to the absence of metals, these catalysts could significantly reduce the cathode cost [7].

In recent years, biomass-derived nitrogen-doped carbon materials have prompted fascination and huge consideration in various energy-related applications [8]. Since 2010, many types of biomass such as animal and plant biomass, starch, cellulose derivatives, sugar, microorganisms such as fungi and yeast, and human and industrial waste have been converted into nitrogen-doped carbon for ORR [9, 10]. Biomass materials are used because of their adequate source of carbon, relatively low cost, readily available around the world, and environment friendliness [11, 12]. In particular, the transformation of waste biomass into nitrogen-doped carbon materials reduces the use of natural resources and thus lowers the carbon footprint, eventually leading to less dependence on landfills. Over the past 15 years, the manufacture and use of textile have increased twofold owing to cheaper production cost, more efficient operation, and increasing demand caused by the fast changing fashion industry [13]. Inevitably, more textile waste is created when more textiles are produced. In the U.S only, 11.3 million tonnes of textiles are disposed in landfills, and only 14.7% (2.5 million tonnes) of the total textiles waste generated is being recycled [14]. The reason for the small amount of textiles being recycled is the complexity of segregating the blended fabric materials [15]. Therefore, the conversion of textiles waste into other usable novel materials is worth exploring.

In the present work, we developed metal-free nitrogen-doped porous carbon for ORR from discarded clothing. Urea and calcium chloride were used as nitrogen source and pore-forming agent, respectively, during synthesis. Different pyrolysis temperatures were used to explore temperature's effect on the surface characteristics and electrochemical performance of the electrocatalyst. The obtained nitrogen-doped carbon showed a comparable electrocatalytic activity to that of Pt/C, with superior stability and tolerance to methanol.

Materials and Methods

Preparation of nitrogen-doped porous carbon

TNPCs were fabricated following a previously reported procedure [16]. Typically, small textile cuts of polyester blend fabrics were impregnated in solution containing calcium chloride and urea for 12 h. Then, it

was dried at 80 °C for another 12 h prior to pyrolysis at the desired temperature (800, 900, and 1000 °C) for 1 h in N_2 environment. After cooling to room temperature, the pyrolysis products were ground using pestle and mortar into fine powder and then acid etched in 3 M HCl to remove any unstable elements. Multiple rinsing with distilled water was conducted until the eluent reached neutral pH before finally drying at 105 °C overnight. The prepared sample was denoted according to its pyrolysis temperature, i.e., TNPC800, TNPC900, and TNPC1000 for 800, 900, and 1000 °C, respectively.

Surface characterisation

The surface morphology of the TNPCs was examined by scanning electron microscopy (SEM; CARL ZEISS EVO MA 10). The Brunauer–Emmett–Teller (BET) surface area and porosity of TNPCs were determined from nitrogen adsorption–desorption isotherms evaluated by a Micromeritics 3 Flex instrument. The surface element and binding energy of the prepared TNPCs were analysed by X-ray photoelectron spectroscopy (XPS) by using an Axis Ultra DLD system (Kratos) with a monochromic Al/K-Alpha X-ray source. Background correction were performed for all peaks with carbon peaks (284.8 eV).

Electrochemical characterisation

Electrochemical tests were performed using an Autolab PGSTAT128N potentiostat (Metrohm-Autolab) with a rotating ring-disk electrode (RRDE). A typical three-electrode system comprising a platinum rod, 5 mm-diameter glassy carbon, and Ag/AgCl electrodes serving as counter, working, and reference electrodes, respectively, were used. The catalyst ink was prepared by dispersing 4 mg of catalyst powder in the mixture of deionised water, ethanol, and 5wt% Nafion solution. ORR measurements were conducted by cyclic voltammetry (CV) in N_2- and O_2-saturated 0.1 M KOH solution at a scan rate of 25 mV s^{-1}, whereas linear scan voltammetry (LSV) was performed at a sweeping rate of 5 mV s^{-1} from 100 to 1600 rotation speeds. CV and LSV were swept within the same potential range from 0.2 V to -0.9 V vs. Ag/AgCl. For comparison, 20wt% Pt/C with the same catalyst loading was used in the electrochemical measurement. Kinetic current density (j_K) was calculated according to equation (1) where j, j_K, and j_L are the measured, kinetic current, and the diffusion-limiting current densities, respectively.

$$j_K = \frac{j \cdot j_L}{j_L - j} \quad (1)$$

The electron-transfer number (n) was calculated from the Koutecky–Levich (K-L) equations (2) [17].

$$\frac{1}{j} = \frac{1}{j_K} + \frac{1}{j_L} = \frac{1}{B}\omega^{-1/2} + \frac{1}{j_K} \quad (2)$$

where ω is defined as the angular velocity (rad s^{-1}), and the proportionality coefficient B is defined as equation (3) [17].

$$B = 0.62D^{2/3}\nu^{-1/6}nFC^{*} \quad (3)$$

where D is the diffusion coefficient of O_2 in 0.1 M KOH (1.9×10^{-5} cm^2 s^{-1}), ν is the kinematic viscosity of the electrolyte (0.01 cm^2 s^{-1}), F is the Faraday constant (96485C mol^{-1}), and C^* is the concentration of O_2 in 0.1 M KOH (1.2×10^{-6} mol cm^{-3}) [18]. Electron-transfer numbers (n) and H_2O_2 (%) yield were calculated from the RRDE curves using equations (4) and (5), respectively [19].

$$n_{RRDE} = 4 \times \frac{i_d}{i_d + i_r/N_c} \quad (4)$$

$$H_2O_2\ (\%) = 200 \times \frac{i_r/N_C}{i_d + i_r/N_c} \quad (5)$$

where i_r is the ring current, i_d is the disk current, and N_c is the disk-current collection efficiency of ring electrode. (N_c= 0.256). For stability test, we compared the LSV curves of before and after a continuous 1000 CV cycle of 100 mV s^{-1} scan rate in O_2-saturated 0.1 M KOH of TNPC and Pt/C. The ring potential was set at 1.4 V vs. RHE during the RRDE measurement, which was within the recommended potential window of inducing H_2O_2 oxidation to O_2 [17].

Results and Discussion

Surface characterisation of TNPCs

The SEM images of TNPC800, TNPC900, and TNPC1000 are shown in Figure 1, respectively. All three samples had pore-like morphology on the TNPC surface. For TNPC800 and TNPC900, the pores were

more visible and had depth (Figures 1a and 1b, respectively), whereas the pores on TNPC1000 were larger and seemed shallower as if the pores had collapsed (Figure 1c). This finding indicated that the development of pore structures on TNPCs was affected by pyrolysis temperature. An electrocatalyst with porous structure is desirable as it could accommodate abundant active sites and transport channels for ions [20, 21].

N_2 adsorption–desorption isotherm was used to determine the porosity properties of the TNPC samples. As shown in Figure 1(d), all TNPCs demonstrated type-IV isotherm curves with a clear hysteresis loop (parallel adsorption and desorption branches) at $P/P_o \approx 0.45–1.0$, signifying the existence of mesopores in all samples [22]. Furthermore, the BJH pore-size distribution plot (Figure 1d inset) also confirmed that all samples contained mesopores within their distribution. The surface areas calculated based on BET for all TNPCs are listed in Table 1. TNPC900 had the largest surface area of 495.97 m^2 g^{-1} and the highest pore volume within the range of the pyrolysis temperature studied. Furthermore, the surface area increased with increased temperature from 800 °C to 900 °C but significantly dropped when the pyrolysis temperature was 1000 °C with decreased surface area to 207.76 m^2 g^{-1}. The pore volume also followed the same trend as the surface area. However, the ratio of S_{meso}/S_{micro} increased with increased pyrolysis temperature. This finding indicated that with increased temperature to 1000 °C, the micropore structures collapsed and created larger pores. Consequently, the surface area decreased, as supported by the higher average pore size obtained at 1000 °C. The increase in pore diameter well agreed with the morphology observed by SEM. Given that ORR occurs at the interfacial/surface of a catalyst, the micro- and mesoporous structure of a catalyst with high surface area and pore volume can serve as abundant active sites influencing the mass-transport properties and diffusion of the electrolyte [23, 24]. Therefore, the porosity structure of these TNPCs is expected to affect ORR performance.

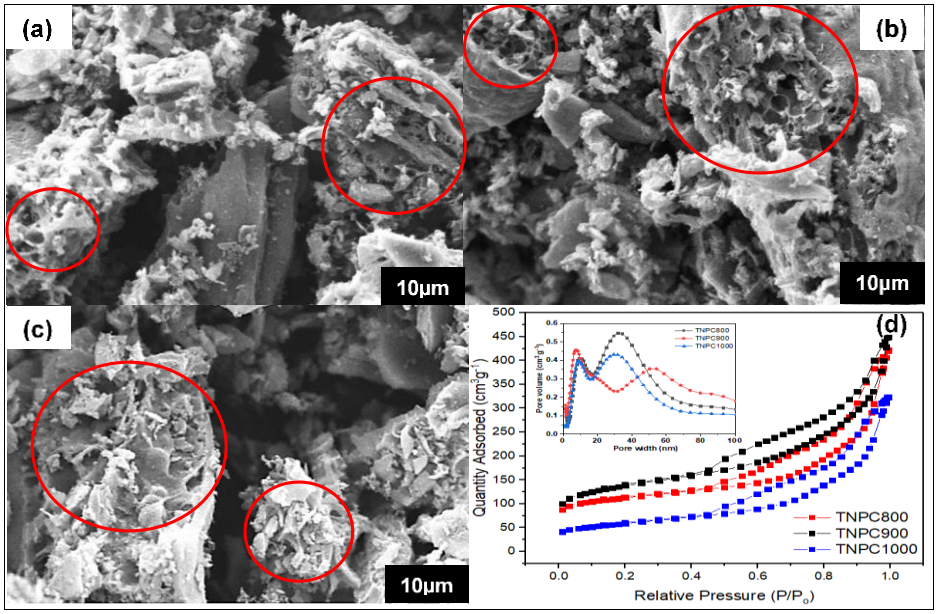

Figure 1. SEM images of (a) TNPC800, (b) TNPC900, (c) TNPC1000 (1k magnification respectively), and (d) N_2 adsorption–desorption isotherms of TNPCs (inset, corresponding pore-size distribution)

N_2 adsorption-desorption isotherm was used to determine the porosity properties of the TNPC samples. As shown in Figure 1 (d), all TNPCs demonstrate type IV isotherm curves with a clear hysteresis loop (parallel adsorption and desorption branches) at P/P_o ~0.45 – 1.0, signify the existence of mesopores in all samples [22]. Furthermore, the BJH pore size distribution plot (Figure 1d inset) also corroborates that all samples contain mesopores within their distribution. The surface area calculated based on Brunauer-Emmett-Teller (BET) for all TNPCs are tabulated in Table 1. As we can see, TNPC900 has the largest surface area of 495.97 m^2 g^{-1} and the highest pore volume in the range of the pyrolysis temperature studied. Furthermore, the surface area enlarge as the temperature was increased from 800 to 900 °C but drop significantly when the temperature of pyrolysis was at 1000 °C as the surface area reduced to 207.76 m^2 g^{-1}. The pore volume also follows the same trend as surface area. However, the ratio of S_{meso}/S_{micro} increase with the increment in pyrolysis temperature. This might indicate that as the temperature raised to 1000 °C, the micropore structures had collapsed which creating larger pores thus decreasing the surface area and this is supported by the higher average pore size obtained at 1000 °C. The increase in pore diameter is in agreement with the morphology observed by SEM. Since ORR occur at the interfacial/surface of a catalyst, the micro- and mesoporous structure of a catalyst with high surface area and pore volume can serve as abundance active sites that influence the mass transport properties and diffusion of the electrolyte [23,24]. Therefore, it is expected that the porosity structure of these TNPCs will affect the ORR performance.

Table 1. Surface properties of TNPCs

Sample	S_{BET} (m^2 g^{-1})	S_{micro} (m^2 g^{-1})	S_{meso} (m^2 g^{-1})	S_{meso} / S_{micro} ratio	Pore Volume (cm^3 g^{-1})	Average Pore Size (nm)	C (at%)	N (at%)	O (at%)
TNPC800	416.1	235.55	180.55	0.43	0.64	6.12	92.96	3.54	2.88
TNPC900	495.97	214.77	281.20	0.57	0.67	5.43	91.85	2.80	3.99
TNPC1000	207.76	54.36	153.40	0.74	0.49	9.43	93.39	1.54	3.86

The surface compositions and bonding states of all samples were analysed by XPS. Figure 2(a) displays the survey scans of TNPC samples. C 1s, N 1s, and O 1s were identified at binding energies around 284, 400, and 532 eV. The presence of a small N 1s signal indicated that nitrogen was successfully doped into carbon. The estimated elemental content is listed in Table 1. The nitrogen content can be as high 3.54 at% for TNPC800 and as low as 1.54 at% for TNPC1000, indicating that increased temperature significantly affected nitrogen doping. High-resolution scans of N 1s were further performed to investigate its chemical structure and deconvoluted into three peaks, as exemplified in Figure 2(b). The peaks at 398.4, 400.0, and 401.5 eV corresponded with pyridinic-N, pyrrolic-N, and graphitic-N, respectively [25, 26]. Pyridinic-N is when two carbon atoms located at the edge of graphitic planes are bound to the nitrogen atom, whereas pyrrolic-N is the nitrogen atom incorporated into the pentagonal ring. Meanwhile, graphitic-N is when a nitrogen atom replaces a carbon atom and bonded with three carbon atoms in the graphene layer [27, 28]. As shown in Figure 2(c), pyridinic-N was the highest for TNPC900 followed by TNPC1000. Furthermore, the rise in temperature from 900 °C to 1000 °C reduced the contents of pyridinic-N slightly but significantly reduced pyrrolic-N. By contrast, the graphitic-N content rose to almost 50 at% at 1000 °C, which was attributed to the transformation of pyrrolic-N and fractional conversion of pyridinic-N into

graphitic-N from the condensation of graphite rings at 1000 °C [29]. Recent studies have reported that pyridinic-N and graphitic-N played important roles in enhancing ORR performance [30, 31]. Pyridinic-N provided active sites and facilitated the dominant 2e⁻ to 4e⁻ process in the ORR mechanism, whereas graphitic-N promoted the reduction of oxygen to hydrogen peroxide by adsorbing OOH intermediates through a 2e- pathway [32].

Electrochemical performance of TNPCs

To investigate the possible application of the prepared catalysts for fuel-cell or energy-storage systems, the electrochemical activity of TNPCs was evaluated using a three-electrode system. RRDE or a glassy carbon electrode was loaded with the as-prepared catalyst ink with 0.285 mg cm^{-2} loading. As shown in Figure 3 (a), all three catalysts showed no reduction peak observed in N_2-saturated 0.1 M KOH solution but obvious peaks in a solution of O_2 saturated with the same electrolyte, indicating that these TNPCs were catalytically active towards ORR. However, TNPC900 illustrated a stronger cathodic peak at 0.76 V vs. RHE, and it was more positive than TNPC800 and TNPC1000. Figure 3(b) shows the LSV plots for TNPCs and the commercial Pt/C (20wt%) at 1600 rpm in O_2-saturated electrolyte. Amongst the three TNPCs, TNPC900 had the highest ORR activity based on the most positive onset potential E_o and half-wave potential $E_{1/2}$ at 0.94 and 0.78 V vs. RHE, respectively. The E_o and $E_{1/2}$ of TNPC800 (0.92 and 0.74 V, respectively) and TNPC1000 (0.93 and 0.75 V, respectively) were more negative than those of TNPC900. The E_o of TNPC900 was slightly inferior to that of commercial Pt/C but comparable with values obtained in previous studies using a different biomass, such as coconut mesocarp [26], but higher than those of waste lotus seedpod [12] and cotton stalk [33]. The ORR activity of the TNPCs can also be assessed by their kinetic current densities (j_K) [34]. The j_K values at 0.8 V vs. RHE were in the order TNPC900 (1.82 mA cm^{-2}) > TNPC1000 (0.55 mA cm^{-2}) > TNPC800 (0.46 mA cm^{-2}), consistent with E_o and $E_{1/2}$.

To further investigate the kinetic information of ORR for TNPC900, LSV curves were collected at different rotating speeds from 100 rpm to 1600 rpm in O_2-saturated 0.1 M KOH solution (Figure 3(c)). With increased rotation, the limiting current density increased because of the shorter distance of diffusion [12]. The K-L plot (Figure 3(c) inset) illustrated a linear trend for the potential range of 0.2 V to 0.6 V vs. RHE, signifying similar electron-transfer number (3.5–3.8) around these potentials. The corresponding electron-transfer number calculated from the ring current and disk current of RRDE (3.55–3.73) curve also agreed with the K-L results (Figure 3d) suggesting a dominant 4e⁻ pathway in ORR for TNPC900 catalyst. Conversely, the electron-transfer number calculated for TNPC800 (3.35–3.53) and TNPC1000 (3.48–3.58) was slightly lower than that for TNPC900, indicating that ORR occurred through a combined 2e⁻ and 4e⁻ transfer pathway. The yield of H_2O_2 shown in Fig. 3d indicated lesser H_2O_2 formation on TNPC900, further validating

a higher catalytic efficiency of TNPC900 in 0.1 M KOH solution.

The superior ORR performance of TNPC900 may be largely influenced by the highest surface area, proper ratio of mesopores over micropores, and the role of pyridinic-N. Given that pyridinic-N served as the active sites for the adsorption and dissociation of oxygen [35], TNPC900 exhibited superior ORR activities than the other TNPCs. However, despite TNPC800 having a slightly lower surface area than TNPC900 and the highest nitrogen content (Table 1), its effect was not as important to ORR as the E_o and $E_{1/2}$ were the lowest for TNPC800. This finding may be due to the higher proportion of micropores (56.6%) dominating the effect to ORR because the restricted active sites such as micropores were difficult to be wet by liquid electrolyte [36]. This finding was further supported by the higher ORR characteristics of TNPC1000 that even though the surface area and the nitrogen content were the least (Table 1), the larger proportion of mesopores was assumed to facilitate a better ORR activity than TNPC800.

(c) LSV of TNPC900 at different rotation speeds (inset, K-L plots of TNPC at 0.2 V to 0.6 V vs. RHE). (d) Plots of number of electron transfer; n and H_2O_2 yield of TNPC900 calculated from RRDE currents

Stability of TNPC900

To evaluate the durability of TNPC900, stability test particularly CV was performed in O_2-saturated 0.1 M KOH at a scan rate of 100 mV s^{-1}. After 1000 potential cycles, the E_o and $E_{1/2}$ of TNPC900 remained unchanged (Figure 4a), whereas a significant negative shift was observed for Pt/C (Figure 4(a) inset) under the same condition. Pt/C also experienced 11% loss of the limiting current density. These results indicated TNPC900 had a relatively better stability than Pt/C under alkaline condition. TNPC900 also showed good tolerance to methanol (Figure 4(b)) as the CV curve was similar before and after adding 3 M methanol. Conversely, a visible oxidation peak emerged for Pt/C (Figure 4(b) inset), which was typical owing to the higher selectivity of Pt for methanol oxidation reaction than ORR [37]. Therefore, the superior stability and methanol tolerance of TNPC900 over Pt/C signified possible application in direct methanol fuel-cell application.

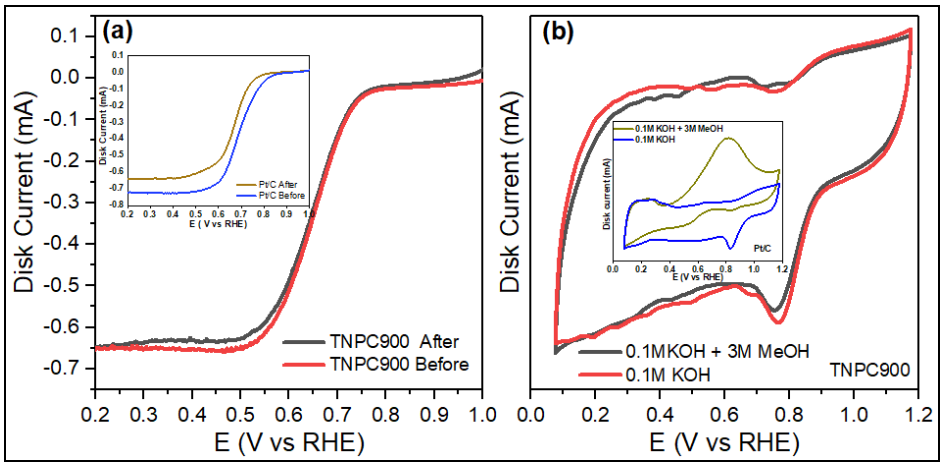

Figure 4. (a) LSV plots for TNPC900 (inset: Pt/C) before and after 1000 CV cycle in O_2-saturated 0.1 M KOH. (b) CV curves for TNPC900 (inset: Pt/C) before and after 3 M methanol addition

Conclusion

We successfully fabricated nitrogen-doped porous carbon from textile waste through chemical activation and pyrolysis. Calcium chloride-induced pore formation and urea served as the nitrogen precursor. Different pyrolysis temperatures (from 800 °C to 1000 °C) impacted the surface characteristics and ORR performance of the TNPCs produced. Among the TNPCs prepared, TNPC900 catalyst exhibited the highest ORR activity with the least H_2O_2 formation. The excellent electrocatalytic activity may be attributed to the collusion of high surface area, proper ratio of mesopores and micropores, and high pyridinic-N. Although ORR performance was slightly inferior to that of Pt/C, TNPC900 is a good potential Pt substitute because of its abundantly available resource and simple production method. TNPC900 also showed better stability and methanol immunity than commercial Pt/C catalyst, making it potentially suitable for direct methanol fuel-cell application.

Abstract

Titanium dioxide (TiO_2) is one of the most studied materials as photocatalyst of water splitting for hydrogen generation. However, TiO_2 has a large band gap of around 3.2 eV, limits its absorption energy to visible light, and the photoexcitation products, such as electron and hole, are recombined rapidly. One method to overcome this problem is by creating a composite heterojunction with other semiconductor materials. In this study, the photocatalytic hydrogen generation of water splitting by TiO_2/Co_3O_4 composite photocatalyst was evaluated. The composite was prepared through hydrothermal synthesis assisted by ball mill crushing, and the powder was annealed at 550 °C. The percentage of Co_3O_4 loading on the TiO_2 varied at 0.5% w/w (TC-05), 1% w/w (TC-1), and 2% w/w (TC-2) to study the suitable amount of Co_3O_4. The surface morphology of the composites was investigated through field emission scanning electron microscopy (FESEM) analyses. Results showed that nanosphere and cubic–shaped morphologies were obtained. For the hydrogen performance analysis, two different conditions of photocatalytic hydrogen generation, which are in pure water and water with addition of 10 vol% of methanol solution as the sacrificial reagent, were measured by using a hydrogen sensor (UNISENSE). TC-1 showed the highest hydrogen production in the pure water, which is 6.75 μmol h^{-1} g^{-1} compared with others. The addition of 10% methanol enhanced the hydrogen production by three times compared with pure water (20.22 μmol h^{-1} g^{-1}. The superior heterojunction of TiO_2 and Co_3O_4 performance can be used in practical applications to enhance the photocatalytic properties of TiO_2.

Keywords: cobalt oxide, hydrogen production, PEC, titanium dioxide

Abstrak

Titanium dioksida (TiO_2) adalah salah satu bahan yang paling banyak dikaji sebagai fotomangkin pembelahan molekul air untuk penjanaan hidrogen. Walau bagaimanapun, TiO_2 mempunyai jurang jalur yang besar sekitar 3.2 eV, yang mengehadkan tenaga

penyerapannya kepada cahaya nampak, dan hasil fotopengujaan, iaitu, elektron dan lubang mengakibatkan bergabung semula dengan cepat. Salah satu cara untuk mengatasi masalah tersebut ialah dengan mencipta gabungan komposit dengan bahan semikonduktor lain. Dalam kajian ini, untuk penjanaan hidrogen bagi pembelahan molekul air fotomangkin gabungan komposit TiO_2/Co_3O_4 telah dinilai. Kaedah sintesis hidroterma dibantu oleh proses penghancuran penggilingan bebola yang digunakan untuk menyediakan komposit berikutan penyepuhlindapan serbuk pada 550 °C. Peratusan pengabungan Co_3O_4 pada TiO_2 telah divariasi pada 0.5% w/w (TC-05), 1% w/w (TC-1), dan 2% w/w (TC-2) untuk mengkaji kadar Co_3O_4 yang sesuai. Morfologi permukaan komposit telah disiasat menggunakan analisis FESEM. Berdasarkan FESEM menunjukkan nanosfera dan berbentuk kubik. Untuk analisis prestasi hidrogen, dua keadaan berbeza penjanaan hidrogen fotokatalitik iaitu dalam air tulen dan air ditambah 10 vol % larutan metanol sebagai reagen, dan telah diukur menggunakan sensor hidrogen (UNISENSE). Hasilnya, TC-1 menunjukkan pengeluaran hidrogen tertinggi dalam air tulen iaitu 6.75 μmol h^{-1} g^{-1} berbanding yang lain. Penambahan 10% metanol meningkatkan pengeluaran hidrogen 3 kali lebih tinggi berbanding dengan air tulen 20.22 μmol h^{-1} g^{-1}. Gabungan komposit TiO_2 dan Co_3O_4 boleh digunakan dalam aplikasi praktikal meningkatkan sifat fotomangkin TiO_2.

Introduction

The growth in global population and quality of life has caused a remarkably increase in energy consumption, where fossil-based fuels are the primary energy contributors to date. Given the nonrenewable nature of fossil fuels, they will be depleted if humans do not undertake steps to safeguard these resources. Alternative fuels are necessary to fulfil future energy demands if fossil fuels are no longer available, particularly for the transportation sector, which consumes around 60% of global energy [1, 2]. Hydrogen was identified four decades ago as a fundamental element of a feasible future energy framework for giving safe, savvy, and ecologically harmless energy. The Energy Policy Act of 1992 classifies hydrogen as an alternative fuel. The ability to power fuel cells in zero-emission cars and the fuel cell's rapid filling time and high efficiency have sparked interest in hydrogen as an alternative transportation fuel. A fuel cell with an electric motor is two to three times more efficient than a gasoline-powered internal combustion engine. Internal combustion engines may use hydrogen as a fuel [3, 4].

The availability of H_2 has become a new barrier because it is not naturally accessible on earth. Hydrogen may be found in a variety of forms, including hydrocarbons, water molecules, and acid and base molecules. Thus, H_2 must be eliminated from all of the abovementioned sources [5]. Coal gasification, steam reforming of natural gas, cryogenic distillation, and water splitting are the methods used for producing commercial hydrogen [6]. Coal gasification and steam reforming of natural gas processes can produce significant quantities of hydrogen. However, these approaches need a strong and safe system due to the tremendous energy consumption (temperatures > 1000 °C) necessary to perform reactions [7]. Electricity generated from renewable energy sources, such as hydropower, wind power, and solar power, might be used to electrolyze water molecules. However, these procedures are inefficient and costly [8]. Photocatalytic water splitting technologies have gained considerable interest for producing green and sustainable hydrogen energy from water. The intrinsic features and architectures of semiconductor-based photocatalysts and photoelectrodes have a large influence on the efficiency of solar-to-hydrogen conversion in photocatalytic and/or PEC catalysis [9].

Titanium dioxide (TiO_2) became the most widely used photocatalyst in the 1970s when water splitting drew the attention of researchers. This condition is due to the low cost, chemical stability, Earth abundance, and nontoxicity of TiO_2. Unfortunately, the potential of TiO_2 is limited because of its high band gap width, poor conductivity, and problematic excited dissociation and electron transport. Thus, many studies have focused on improving the TiO_2's photocatalytic efficacy by changing its surface and microstructure, adding cocatalysts, and creating heterojunctions with metals or other semiconductors [10]. Engineered heterojunctions in photocatalysts were revealed to be a viable approach for increasing catalyst activity by allowing

photogenerated electron–hole pairs to be separated spatially. Co_3O_4 is a good choice for fabricating TiO_2-based hybrids for water splitting because Co_3O_4 is one of the most well-known p-type semiconductors, with incredible substance dependability, low solvency, and solid electrical, attractive, and reactant attributes. The cost-effectiveness and availability of Co-based chemicals may simplify large-scale applications [11-13]. Compared with the typical hydrogen electrode, Co_3O_4 has conduction band (CB) and valence band (VB) areas of 0.97 and 1.23 eV, respectively, thereby resulting in a p–n heterointersection with TiO_2. The performance of a combination of varying weight percent of TiO_2/Co_3O_4 thin films in PEC and photocatalytic water splitting was investigated in this work. TiO_2 P25 was used to make a heterojunction with Co_3O_4 by using a hydrothermal technique.

Materials and Methods

Materials

Cobalt nitrate hexahydrate Co $(NO_3)_2.6H_2O$ and TiO_2 P25 were obtained from Sigma-Aldrich. Urea (analytical grade), polyethylene glycol, and ethanol were purchased from Chem-Supply. All chemicals were used without further purification.

Preparation of TiO_2

Ethanol (1 mL) was mixed with 0.2 g of TiO_2 P25 and 0.05 g of polyethylene glycol, and the mixture was crushed. Blade coating was used to coat the slurry on the fluorine-doped tin oxide (FTO) surface at 0.5 mm thickness, which was then annealed at 500 °C for 2 h.

Synthesis of cobalt oxide

In accordance with prior research, cobalt oxide was produced by using a hydrothermal technique [11]. Cobalt nitrate hexahydrate (1.74 g) and urea (0.72 g) were dissolved in 50 mL deionized water. A stainless-steel autoclave was used to transfer the homogenous solution. The autoclave was placed in a furnace for 6 h at 100 °C. The autoclave was turned off and allowed to cool to ambient temperature. The sample was washed with deionized water before being dried in an oven. Cobalt oxide produced by hydrothermal technique was ball milled for 2 h before being mixed with TiO_2.

Synthesis of the composite heterojunction of TiO_2 and Co_3O_4 as a sample

TiO_2, Co_3O_4, polyethylene glycol, and ethanol were ball milled for 20 min, coated over the FTO surface, and annealed for 2 h at 550 °C. TC-05 (0.5% $Co_3O_4.TiO_2$), TC-1 (1% $Co_3O_4.TiO_2$), and TC-2 (2% $Co_3O_4.TiO_2$) were the three weight variants of TiO_2:Co_3O_4. The sample was characterized and used as a working electrode.

Characterization

A field emission scanning electron microscopy (FESEM) model of ZEISS MERLIN was used to examine the surface morphology with 10k magnification and signal A intense duo.

Electrochemical study

In a three-electrode setup with 0.5 M Na_2SO_4 electrolyte solution, linear sweep voltammetry (LSV) analysis was performed by using an Ametek Versastat 4 under a 100 mW/cm^2 xenon light. The working electrodes were TiO_2/Co_3O_4 thin films, the counter electrodes were platinum wires, and the reference electrodes were Ag/AgCl electrodes.

Photocatalytic H_2 generation measurements

The sample (100 mg) was weighed and placed in a reactor to conduct the photocatalytic H_2 generation measurements. The sample was added with 100 mL of sodium sulfate and placed under solar AM 1.3 illumination (100 mW cm^{-2}) using 75 W Xenon light at 500 nm bandwidth for 2 h, and hydrogen readings were taken every 20 min. The steps were repeated by adding methanol as scavenger, and the readings were taken. In this study, a hydrogen sensor was used to measure the hydrogen produced through a photochemical process.

Figure 1. Photoreactor set up for the photocatalytic H_2 generation measurements

Results and Discussion

Characterizations of catalysts

Figure 2 displays the FESEM images of the as-prepared (a) TiO_2 (b) TC-05, (c) TC-1, and (d) TC-2 samples. From Figure 2a, the TiO_2 shows well-defined nanocubic morphology, with the width of 1.011 µm. Figures 2b–c shows that the loaded Co_3O_4 is finely dispersed on the TiO_2 surface with a diameter of approximately 7.14 nm. Figure 2d shows that an obvious agglomeration occurs during the introduction of Co_3O_4 species. The result is mostly similar to a previous study [12]. However, the different weight percentages of composite heterojunction show different sizes of loaded Co_3O_4 [12].

LSV analysis was used to study the potential of the photocatalyst, and the overpotentials of TC-05, TC-1, and TC-2 were calculated. Figure 3a shows the photocurrent responses of (a) TiO_2, (b) TC-05, (c) TC-1, and (d) TC-2 samples. TC-1 had the highest photocurrent density (70 µA cm^{-2}) among the composites, implying that coating TiO_2 with Co_3O_4 nanoparticles (NPs) improved the photogeneration performance. However, the photocurrent decreased when the Co_3O_4 composites increased to 2 wt.%. This condition occurred because of the agglomeration of the photocatalyst, as shown in the FESEM image (Figure 2d). The agglomeration of the photocatalyst decreased the active site and surface area. EIS analysis was used to test the charge carrier transport capabilities of the composites (Figure 3b), The Nyquist plot of TC-1 was less than that of TC-05 and TC-2. This finding revealed that the TC-1 sample had the lowest electron migration resistance among the samples, indicating that it had a high photocatalytic hydrogen evolution reaction (HER) performance. These findings suggested that the TC-1 sample had the best charge detachment behavior of photogenerated carriers among the photocatalyst samples. The amount of active free radicals available for photocatalytic H_2 creation will rise if charge carrier separation was effective [14].

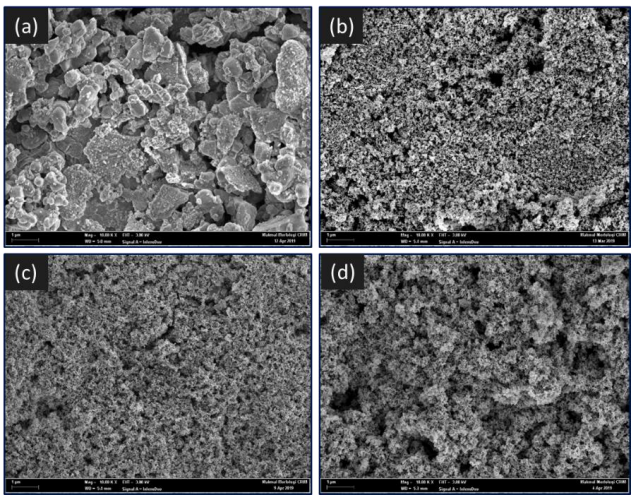

Figure 2. FESEM image of (a) TiO_2 (b) TC-05, (c) TC-1, and (d) TC-2

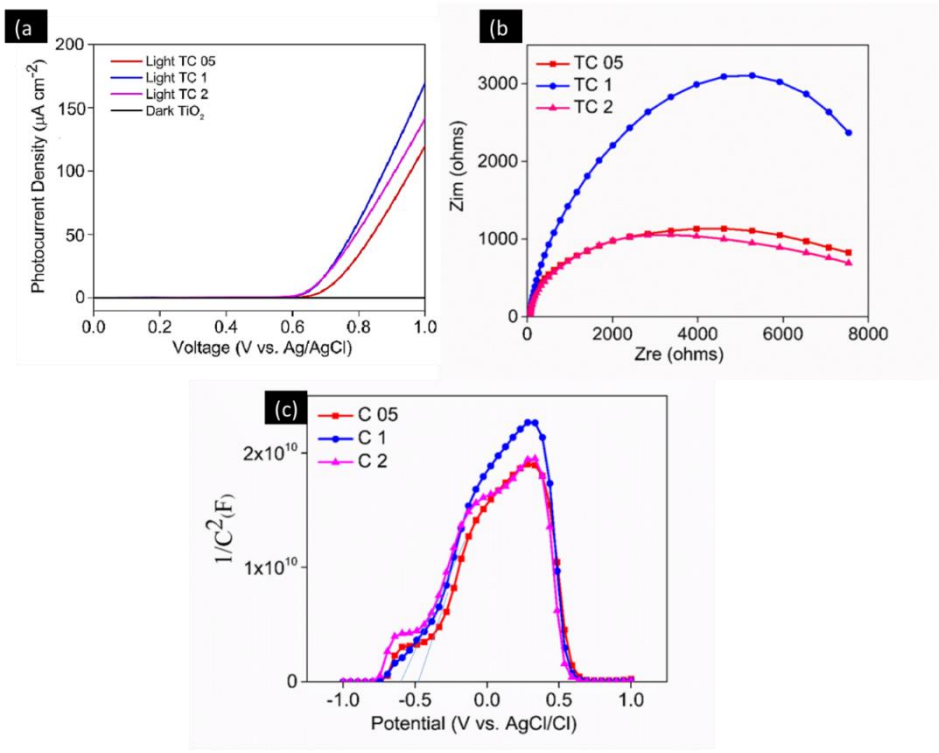

Figure 3. (a) Photocurrent density (b) Electrochemical impedance spectroscopy (EIS), and (c) Mott–Schottky plot of TC-05, TC-1 and TC-2

Photocatalytic hydrogen generation

The photocatalytic hydrogen evolution of the prepared samples was evaluated under artificial sunlight irradiation by using a hydrogen sensor. The photocatalytic hydrogen evolution was tested in two different solutions, and the results were compared. The first analysis (Figure 3a) was tested by using only pure water, and the second analysis (Figure 4b) was tested by using pure water with the addition of 10 vol% of methanol solution as the sacrificial reagent. The comparison of Figures 4a and b showed that the sample with methanol exhibited three times excellent photocatalytic hydrogen evolution as compared without methanol. As shown in Figures 4a and b, the TC-1 sample exhibited the highest H_2 advancement rate (6.75 μmol $g^{-1}h^{-1}$) in pure water and (20.22 μmol $g^{-1}h^{-1}$) in methanol among all the prearranged Co_3O_4/TiO_2 tests. The H_2 production in methanol is higher compared with pure water because methanol effectively separates the hole charges, and the hole–electron pair recombination is reduced [15]. The H_2 advancement rate of TC-2 diminished to 5.70 μmol $g^{-1}h^{-1}$ in pure water and 16.71 μmol $g^{-1}h^{-1}$ in methanol.

The photocatalytic HER of the proposed TiO_2/Co_3O_4 heterojunctions is shown in Figure 5 to analyze the composite heterojunction of TiO_2/Co_3O_4. A previous study [11] provided the specifics of the Co_3O_4 band structure. TiO_2 has a higher Fermi level than Co_3O_4 before they come into contact in the heterojunction. Negative charges migrated from TiO_2 to Co_3O_4 after the heterojunction because p-type Co_3O_4 NPs developed on the surface of n-type TiO_2. This condition caused the Fermi level alignment between TiO_2 and Co_3O_4, resulting in a *p–n* Co_3O_4/TiO_2 junction. According to Wang et al. (2022), a space charge region with a strong built-in electric field in the TiO_2 to Co_3O_4 direction occurs at the TiO_2/Co_3O_4 interface when the energy bands of TiO_2 and Co_3O_4 are bent up and down, resulting in a drift of the

photogenerated charge carrier for heat transfer until a balance thermal equilibrium is reached [16]. The charge transfer mechanism is shown in Figure 5. Under solar AM 1.3 illumination, photogenerated electrons migrated from TiO_2 and Co_3O_4 VBs to the corresponding CBs. The photogenerated electrons were guided from the p-type Co_3O_4 CB to the n-type TiO_2 CB by the induced built-in electric field, resulting in the spatial detachment of photogenerated electron–hole sets. Similarly, Co_3O_4 NPs filled in as a cocatalyst in this *p–n* Co_3O_4/TiO_2 intersection, assisting in expanding the charge partition. Therefore, more photogenerated electrons might focus on TiO_2, which can then be used in the water reduction cycle to produce H_2.

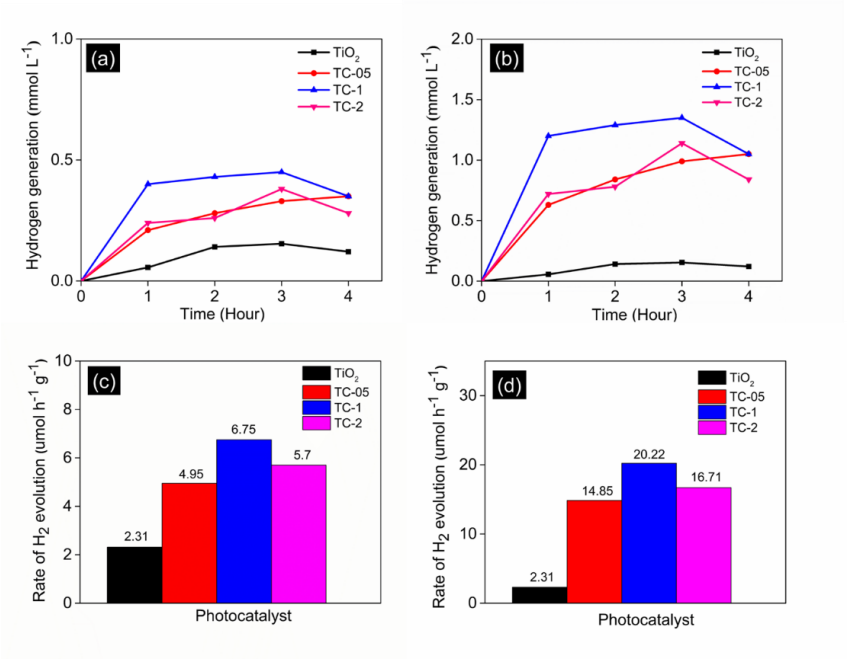

Figure 4. Photocatalytic hydrogen evolution of sample with (a) pure water (b) pure water and methanol, and hydrogen evolution rate of sample with (c) pure water and (d) pure water and methanol.

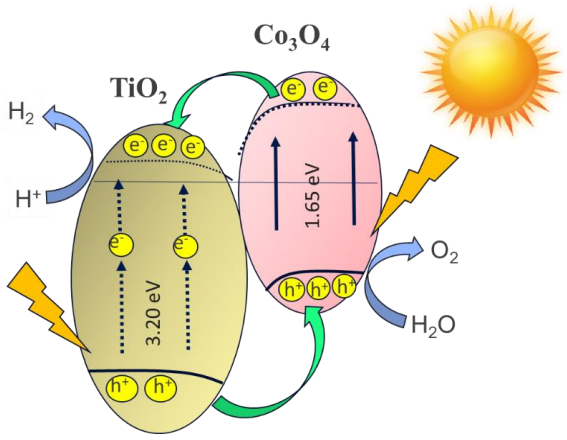

Figure 5. Schematic of the photocatalytic HER mechanism and photogenerated electron–hole separation route of Co_3O_4/TiO_2 *p–n* junction.

Conclusion

In this study, hydrothermal synthesis was used to efficiently construct a Co_3O_4/TiO_2 *p–n* heterojunction. With a photocatalytic H_2 development pace of 20.22 mol $g^{-1}h^{-1}$, the enhanced Co_3O_4/TiO_2 heterojunction had the best photocatalytic H_2 advancement rate. This study used the catalytic effect of Co_3O_4 to distinguish photogenerated electron–hole pairs. A unique Co_3O_4/TiO_2 contact interface and a *p–n* heterojunction was utilized for fast charge carrier transport pathways to enhance the photocatalytic performance. This study may help in the future development and production of *p–n* heterojunction photocatalyst with high visible light-driven energy conversion efficiency.

THE THERMAL STABILITY AND PRELIMINARY PERFORMANCE OF SODIUM ALGINATE AND POLYVINYL ALCOHOL-BASED MEMBRANE IN DMFC: MONTMORILLONITE AS A FILLER

(Kestabilan Haba dan Prestasi Awal Membran Berasaskan Natrium Alginat dan Polivinil Alkohol untuk DMFC: Montmorillonit sebagai Pengisi)

Abstract

Biopolymer-based membranes have emerged vastly in recent years for fuel cell applications. Polymer electrolyte membranes (PEM) have become a major component in DMFC stacks that have gone through many studies beforehand. An improvement has been made to PEM, especially using biopolymers like alginate based. Sodium alginate (SA) has significant characteristics such as being too hydrophilic, which is its biggest weakness as a PEM. Blending it with another polymer of polyvinyl alcohol (PVA) and adding a clay filler of montmorillonite (MMT) would be a great solution, in this work. From TGA-DSC analysis, SA/PVA-MMT achieved different thermal stability as the filler content differed. The glass transition temperature of the membrane had increased as the MMT content increased, at a maximum range of 240-260 °C at 15 wt.% of MMT content. The membrane's thermal stability ranking was then followed by 10 wt.% (250 °C) and 2 wt.% (240 °C) of filler content. The higher the glass transition temperature, the greater the thermal stability due to the greater mass loss after being exposed to a later heating. Meanwhile, for the proton conductivity test, a hybrid membrane of SA/PVA-MMT with SVM 20 (20 wt.% MMT) obtained the highest value of 8.0510 mS/cm, followed by SVM 10, SVM 2, SVM 15 and SVM 5 with values of 6.5025, 2.6429, 2.0332 and 1.6083 mS/cm respectively. Higher proton conductivity enables the potential of the hybrid to conduct electricity in DMFC. The lowest methanol uptake was shown by the membrane with 20 wt.% MMT content, with a value of 53.00%, followed by 15 wt.% (97.46%), 10 wt.% (121.59%), 5 wt.% (132.23%) and 2 wt.% (203.30%), respectively. Low methanol uptake of the membrane indicated that the DMFC stack could operate with high efficiency. This study showed that SA/PVA-MMT could be a promising choice of PEM with an optimum MMT content of 10 wt.% for a better performance produced by a cheaper hybridized membrane.

Keywords: alginate, polyvinyl alcohol, montmorillonite, copolymer membrane, thermal stability

Abstrak

Membran berasaskan biopolimer telah muncul secara meluas sejak kebelakangan tahun ini, dalam aplikasi sel fuel. Membran polimer elektrolit (PEM) telah menjadi komponen utama dalam tindanan DMFC, yang mana telah menjadi objek kajian berkali ganda sebelumnya. Satu penambahbaikan PEM telah dibuat khususnya menggunakan biopolimer alginat. Natrium Alginat (SA)

mempunyai sifat signifikan iaitu terlalu hidrofili, yang mana ianya merupakan kelemahan terbesar sebagai PEM. Di dalam kajian ini, Natrium alginat (SA) akan dicampur bersama polivinil alkohol (PVA) dan montmorillonit (MMT), sejenis pengisi berasaskan tanah liat. Campuran ini telah menghasilkan prestasi yang amat baik. Daripada analisis TGA-DSC, SA/PVA-MMT telah mencapai kestabilan haba yang berbeza apabila kandungan pengisi turut berbeza. Suhu peralihan kaca membran tersebut bertambah apabila kandungan MMT dalam sampel juga bertambah, pada 15 wt.% MMT, maksima julat suhu dicapai ialah 240-260 ℃. Kestabilan haba membran ini kemudiannya diikuti dengan 10 wt.% (250 ℃) dan 2 wt.% (240 ℃) konten pengisi. Semakin tinggi suhu peralihan kaca, semakin tinggi kestabilan haba membran disebabkan jisim mula berkurang banyak pada suhu pemanasan yang tinggi (lebih lewat). Manakala untuk kekonduksian proton, SVM 20 (20 wt.% MMT) mendapat nilai tertinggi iaitu, 8.0510 mS/cm, diikuti dengan SVM 10, SVM 2, SVM 15 dan SVM 5 dengan nilaian 6.5025, 2.6429, 2.0332 dan 1.6083 mS/cm masing-masing. Tingginya nilai kekonduksian proton, semakin besarlah potensi membran hibrid tersebut untuk mengalirkan elektrik dalam DMFC. Ambilan metanol terendah dibuktikan oleh SVM 20 (20 wt.% MMT) dengan nilaian 53.00%, diikuti dengan 15 wt.% (97.46%), 10 wt.% (121.59%), 5 wt.% (132.23%) dan 2 wt% (203.30%) masing-masing. Hasil ambilan metanol yang rendah menunjukkan tindanan DMFC boleh beroperasi pada tahap keberkesanan yang tinggi. Kajian ini menyimpulkan bahawa SA/PVA-MMT boleh menjadi pilihan PEM yang terbaik, dengan kandungan MMT optimum pada 10 wt% beserta kos yang rendah untuk prestasi yang lebih baik.

Kata kunci: alginat, polivinil alkohol, montmorillonit, membran dwipolimer, kestabilan haba

Introduction

A polymer electrolyte membrane (PEM) that contains additives is normally able to enhance performance when operating in a fuel cell system. There are many polymers, such as sulfonated poly(ether ether) ketone [1], polybenzimidazole [2], polyvinyl alcohol [3], sulfonated polyimide [4] and polyether sulfone [5], that have been utilized in previous studies to develop non-Nafion based membranes. These polymers are claimed to be capable of replacing Nafion owing to their polysaccharide backbone, which is able to act as both hydrophilic and hydrophobic domains. However, with the high production costs needed for polymer materials, an alternative innovation has been constructed, using biopolymers that are PEM-based.

Recent studies have discovered that chitosan [6], carrageenan [7] and alginate [8] are PEM-based. These biopolymers have the potential to conduct protons as they are mostly in an amorphous state. The highly amorphous condition of the materials resulted in high proton conductivity as there are more proton pathways in amorphous mediums [9]. Charradi et al. worked on SiO_2-montmorillonite filled membranes (9% content) for PEMFC and obtained 0.158 S/cm proton conductivity, which was higher than the pristine polymer at 120 ℃ and 100% relative humidity [10]. Sainul Abidin et al. achieved the highest proton conductivity of 0.0706 S/cm by using modified montmorillonite at 10 wt.% loading, under 70 ℃ conditions, using a polyimide based PEM [11]. Wang et al. synthesized chitosan-based PEM that was filled with solvent-free carbon nanotube fluids and was able to perform maximum proton conductivity at a value of 0.044 S/cm at 80 ℃ [12]. Since biopolymers are highly amorphous, by blending them with other semi-crystalline polymers such as PVA, the resulting membrane could have better flexibility and a firmer structure. Zakaria et al. and Yang et al. worked on PVA-based membranes, each achieving the highest proton conductivity of 0.0095 S/cm and 0.0368 S/cm respectively, both at 30 ℃ [13, 14]. Nevertheless, these works were unable to figure out the hidden potential of blending membrane composites of sodium alginate and polyvinyl alcohol together with an inorganic filler – montmorillonite. Montmorillonite is a clay-type filler, that contains silica tetrahedral, an octahedral layer of aluminum, and exchangeable cations like magnesium and potassium.

Montmorillonite (MMT) has been studied previously, modified with additional protons like H^+, Na^+, Mg^{2+} Ca^{2+} and K^+. Wu et al. achieved high proton conductivities at 38.5 mS/cm with balanced water uptake, 24.26% when developed cloisite sodium montmorillonite [15]. Wang et al. reported 5wt% of

MMT-PBI-O exhibited 0.5 mS/cm proton conductivities at 80 ℃ and losing weight easily (under TGA analysis) compared to pure PBI-O membrane [16]. This was because the insertion of MMT facilitates water absorption thus allowing proton channel formation; 5 wt.% was better than 3wt% MMT. When blending MMT with SPEEK polymer, the water uptake reached 35% which was lower than pure SPEEK, contributing to 0.057 S/cm of ionic conductivity at ambient condition, which was a good finding from Ata et al. [17].

These reports potentially bring up this study to show how MMT involvements can improve proton conductivity of polymer matrix besides its thermal stability could be maintained as well. To distinguish, additional polymer – PVA was included together with biopolymer sodium alginate for developing a novel hybrid membrane electrolyte for direct methanol fuel cell application. This work highlighted on membrane performance tests relating to the thermal degradation analysis.

Materials and Methods

The membranes comprising of sodium alginate, polyvinyl alcohol and montmorillonite as the hybridized membrane of SA/PVA-MMT, were simply named as SVM in this work. The variation of MMT loadings in each sample were differentiated as shown in Table 1.

Table 1. The notation for each sample

MMT Loadings (wt.%)	Notation
0	SV0
2	SVM2
5	SVM5
10	SVM10
15	SVM15
20	SVM20

Membrane preparation

The SVM blended solution was prepared using the solution casting method. Sodium alginate (SA, Acros Belgium) and polyvinyl alcohol (PVA, R & M Chemicals) were mixed together at a concentration ratio of 40:60. The SA and PVA solutions were prepared separately, then dispersed in deionized (DI) water, at 70 ℃ and 90 ℃ respectively. Both polymer solutions were mixed in a beaker and stirred for 1 hour, adding 1 mL of 10% glutaraldehyde (GA, Nacalai Tesque Japan) for internal crosslinking, dropwise, until homogenized. Then solutions of 2 wt.%, 5 wt.%, 10 wt.%, 15 wt.% and 20 wt.% Montmorillonite (MMT, Acros Belgium) were prepared in 5 mL DI water each, which were dispersed overnight at ambient temperature. The SA/PVA solutions and MMT solutions were blended altogether, stirring for 5 hours, to create a homogenized mixture. The mixture was then cast in a petri dish and dried for 12 hours at 60 ℃, followed by 1 hour at 80 ℃ using a box furnace (Carbolite chamber) to become a membrane film. The membrane film was externally crosslinked with 1.5 wt.% $CaCl_2$ and 10% GA by soaking it for 30 minutes under ambient conditions, before further testing.

Thermal analysis

The film samples were characterized using the Simultaneous Thermal Analyzer-Differential Scanning Calorimetry (STA-DSC), NETZSCH Proteos Software, to determine their thermal stability based on the glass transition temperature (T_g). The analysis was run under a nitrogen atmosphere, within the temperature range of 30-800 ℃, with a heating rate of 10 ℃/min.

Membrane performance tests

The membrane film was proceeded to the liquid uptake performance test and proton conductivity test. The membrane film was cut according to a 2 cm x 2 cm dimension for both water and methanol uptake. The film was weighed after 24 hours of being soaked in DI water and 10 % methanol for respective tests, which is denoted as W_{wet} (g). The films were weighed again after drying for 24 hours at room temperature, denoted as W_{dry} (g). The weights recorded were calculated using the liquid uptake equation formula (1) to obtain the percentage of water uptake and methanol uptake.

$$\frac{W_{wet}-W_{dry}}{W_{dry}} \times 100 \quad (1)$$

For proton conductivity testing, the membrane film (4 cm x 1 cm dimension) must be in a fully hydrated

state; it was immersed in DI water for an hour before being placed in a four-electrode conductivity cell that was connected to a potentiostat/galvanostat (WonATech) for 60 seconds, over a frequency range of 1 MHz–50 Hz. This potentiostat would produce a linear trend of voltage versus the current graph, producing a membrane resistance from the slope. The in-plane proton conductivity value (σ) can be calculated by using the in-plane proton conductivity equation (2) [5]:

$$\sigma = \frac{L}{RWT} \quad (2)$$

where L is the length of the film in cm, R is the average resistance (Ω), W is the film width (cm) and T is the thickness of the film (cm).

Results and Discussion

FESEM

For micrographs images, only four samples were observed, because the morphology analysis demand was required just to emphasized on the homogeneity of the surfaces as clay loadings increased – SV0, SVM5, SVM10, SVM20. These desired membranes were proven having carbon, oxygen and sodium elements as observed in EDX in Figure 1(c), (f), (i), (l). Figure 1 (a), (d), (g), (j) were the surface morphology of the membranes while Figure 1 (b), (e), (h), (k) were showing the cross sectional of the membranes. based on Figure 1 (a), which resembling SV0, the present surface image seemed to have pores, as well as could be seen in the cross-section image (Figure 1(b)). Too many porosities were undesirable because it creates channel for water absorption which then leading to excessive membrane swelling. When introduce a little amount of MMT, the surface image for SVM5 looked rougher than SV0, as illustrated in Figure 1(d). The cross-sectional image for SVM2 looked rougher as well, implying the successful intercalation of MMT, with proven EDX elemental peak based on the rising of Mg, Al, Si, K peaks. However, the declining peak of Na, was due to the well-blend of MMT with the polymer chain, interrupting the structure of polymer consisting Na.

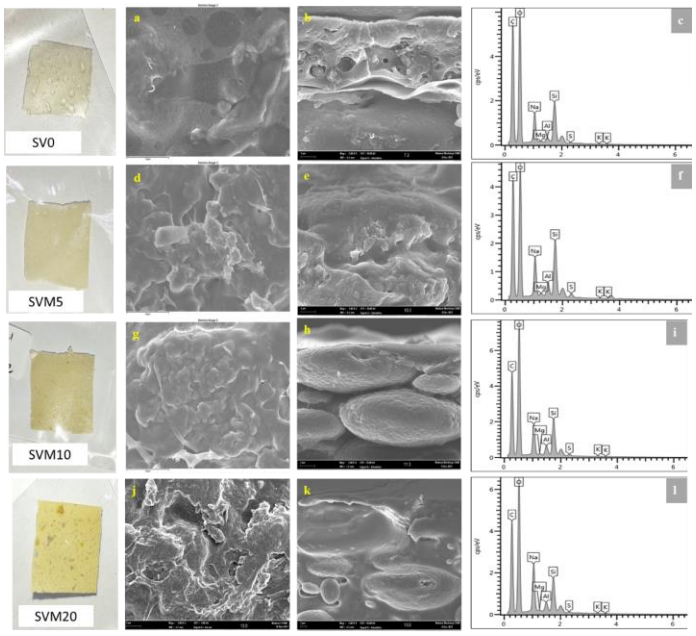

Figure 1. FESEM images of membrane samples, followed by the physical sample on the left-handside, surface images, cross-sectional images and elemental peaks EDX on the right-handside. SV0 (a, b, c), SVM5 (d, e, f), SVM10 (g, h, i) and SVM20 (j, k, l)

As MMT increased higher, SVM10 membrane surface looked much rougher and compact cross-sectional area as shown in Figure 1(g, h). This indicating that water molecules had fully evaporated from the polysaccharide matrix [18], as white tiny particle were visible in Figure 1(h) depicting the successful intercalation of MMT into the SA/PVA copolymer matrix. Nevertheless, the agglomeration presented in SVM20 because of excessive MMT addition resulting it to concentrate at one point, that further discussed in liquid uptake part.

TGA-DSC

For thermal stability analysis, only four samples were involved since we just insisted to compare the obvious trend among the expected significant MMT loadings in the membranes – SV0, SVM2, SVM10, SVM15. The membrane film obtained good thermal stability, with an increased temperature phase of degradation as MMT loadings increased. Referring to Figure 2, the polymer blend started to degrade at 220–240 ℃ and proved to be better than previous studies, which indicated that the first stage began at 80 ℃ [19] and 198 ℃ [20] with only PVA and SA. This first degradation phase was attributed to solvent evaporation [21]. By adding MMT, the membrane has a combination of amorphous and crystalline phases, making the degradation phases a bit slower. The polymer must have a semi-crystalline phase since high amorphous properties might result in a low strength structure of the film. The presence of semi-crystalline properties of the PVA could strengthen the interaction bond between the polymer chain and the filler bond. The interaction bond involved was a strong hydrogen bond, which is difficult to break apart. The weight loss of the membranes was around 50.4–55.2%, which began at a range of 259.8–263.5 ℃, which was dominated by SVM 15. In comparison, the second degradation phase of these MMT-filled membranes had slightly lower thermal stability than the SP/PVA membrane at 307 ℃ [19]. This was due to the presence of MMT, which has hydrophilic properties that cause it to easily degrade. The hydrophilicity enables the membrane to retain water molecules in the matrix, thus degrading at lower temperatures [20, 22]. However, the presence of PVA and MMT in a sodium alginate-based membrane was much better as this blended membrane took higher ranges of the third degradation phase (470–800 ℃) to fully depolymerize the polysaccharide backbone owing to the interfacial connections and improvised crystallinity.

The thermograms of DSC shown in Figure 3, indicating that the glass transition phase changed as MMT loading increased. The glass transition temperature increased from SV0 to SVM10 which was owing to the dipole interaction declining that happened within the homopolymers [23]. This is simultaneous phase to the TGA thermogram whereby the hybridized membranes facing phase changes to rubbery state at a later temperature as the clay fillers added. However, when reaching 15 wt.% of MMT in the hybridized membrane, the glass transition temperature decreased to complex peak value of 123.6 ℃, which could be seen overlapping peak with the control membrane, SV0 in the thermogram. This indicating that backbone polymers became soften at certain higher loading point. In relation to the water uptake performance, SVM15 absorb more water molecules than SVM10 by 10.84%, deducing it has voids for water binding. The voids presence turned up SVM15 membrane to be easily degraded and change phase. Therefore, SVM10 was much preferable type of membrane in this case because it possessed the greater thermal stability with peak value glass transition temperature at 196.7 ℃.

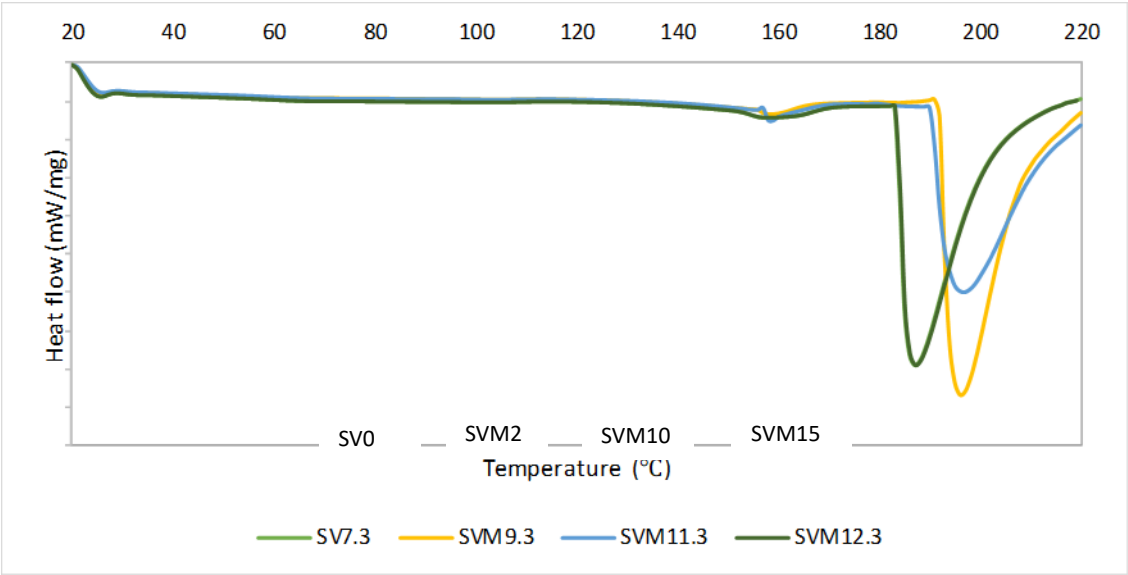

Figure 3. DSC thermogram of the membranes

Membrane performance tests

From Figure 4, the graph trend fluctuated as the MMT content increased. The maximum value of proton conductivity was achieved at 8.0510 mS/cm by using SVM20 (at 20 wt.% MMT loadings). During the conductivity testing, the prominent functional groups involved were H^+, H_3O^+ and ^-OH ions, where H^+ dissociated from the water molecules, hopping from one molecule to another. The insufficiency of single electrons causes the H^+ to react actively with the ^-OH free ions from the MMT, which also contributes to transporting the protons throughout the medium. The hydration state of the membrane was crucial as it would produce more H^+ to actively bind with lone pairs of electrons in H_2O, thus forming a highly reactive ion, H_3O^+. The cycle of transporting protons through

negatively charged ions was repeated simultaneously with the protons hopping. In this study, both mechanisms could potentially occur - the proton hopping mechanism, namely, the Grotthuss mechanism, and the proton being transported, namely the Vehicular mechanism [24]. As shown by SVM15, the existence of free volumes in the membrane decreased when a higher MMT filling was introduced, which resulted in difficulties for the protons to be transferred. The tendency of the proton conductivity to increase at 20 wt.% MMT was due to the presence of active sites at the MMT, which enabled the transport of the proton to pass through. The values were lower at SVM5 and SVM15, most probably caused by the activation of the inhibition properties of MMT when extra loading produced an aggregated effect on the membrane [25, 26].

For water uptake performance, according to Figure 5, the membrane began to reduce absorbing water at 2 wt.% MMT. Then, the trend started to decline again at 15 wt.% MMT after a slight increase at 10 wt.% MMT. The increment of water absorption was due to the introduction of MMT to the pure SAPVA membrane, slightly induced by the hydrophilicity of MMT, which provides a high water content to the membrane [22].

This hydrophilic property, owing to its oxygenated functional group (-OH) [27], through the abundance of water, creates a continuous transferring channel and facilitates ion movement [22]. These functional groups interact with each other (polymer and fillers) via strong hydrogen bonding or polar-polar interaction [27]. The lowest water uptake point was at 20 wt.% (SVM20), after 10 wt.% (SVM10) of MMT. The water uptake level dropped from 162.46% to a value of 129.65% at 10 wt.%, before it decreased even further to 74.89%, with the addition of SVM20.

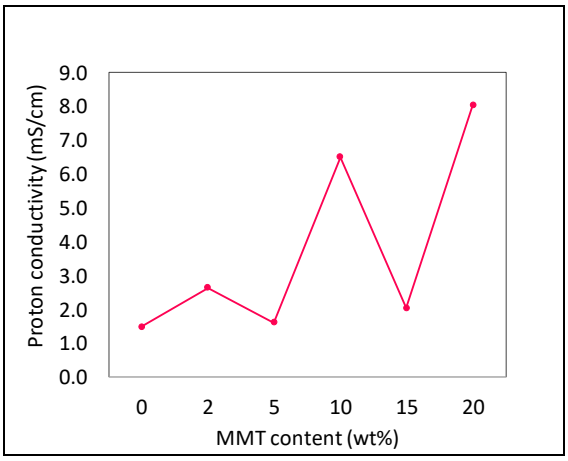

Figure 4. Proton conductivity for SVM2 (2 wt.%), SVM5 (5 wt.%), SVM10 (10 wt.%), SVM15 (15 wt.%) and SVM20 (20 wt.%)

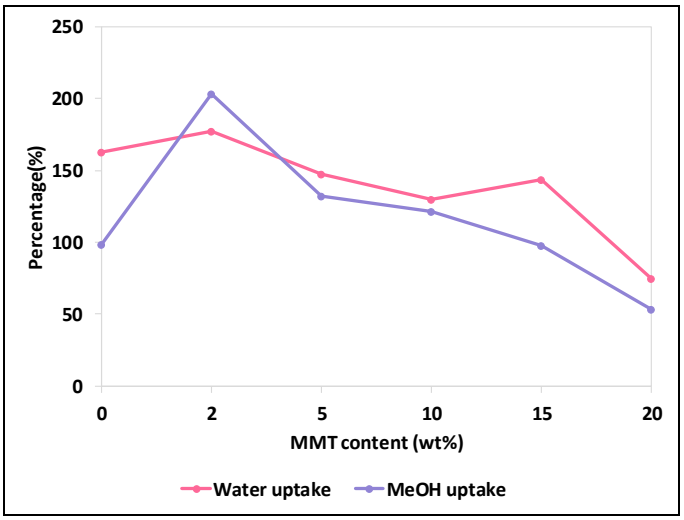

Figure 5. Water uptake and methanol uptake performances for SVM2-20

Table 2. The comparison of previous membrane hybridized studies

Membrane Composite	**Filler Loadings (wt.%)**	**Proton Conductivity (mS/cm)**	**References**
Pure SA	0	0.48	[18]
PVA/SA(6/4)	0	91.0	[19]
PVA/TiO_2	15	48.0	[28]
SA/TiO_2	25	17.3	[8]
SA/Alumina	15	13.0	[20]
PVA/MMT	10	36.8	[14]

The additional MMT filler had partially reduced the size of the ion channels because of agglomeration, hence blocking the absorption of water. Figure 6 and Figure 7 illustrate the plausible figures of how MMT filled up the polymers' matrix. The matrix inside the membranes was homogenously distributed, thus decreasing the free voids of the resultant matrix [27]. The mobility of the SA/PVA chains was reduced then, thus leading to a decrement of water content. Based on the experimental results as shown in Table 3 and Figure 5, the methanol uptake value dropped after reaching its peak at 2 wt.% MMT, from 203.30%, to 53% at 20 wt.% MMT. The explanation for methanol uptake was similar, since the graph trend also decreased as MMT loading increased. The same trend showed that there was good networking and bonding between the alginate polymer and MMT, which prevented fuel crossing [22].

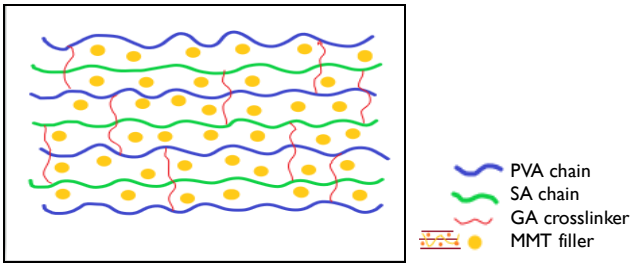

Figure 6. The plausible figures for blended SVM membranes [29]

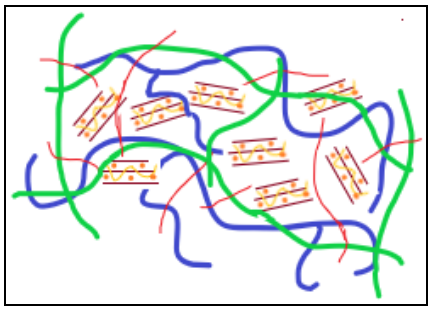

Figure 7. The another version of plausible figures [3]

Table 3. Proton conductivity and liquids uptake of the membranes according to the MMT loadings

Sample	MMT Loadings (wt.%)	Proton Conductivity (mS/cm)	Water Uptake (%)	Methanol Uptake (%)
SV 0	0.0	1.4828	162.46	98.55
SVM 2	2.0	2.6429	177.50	203.30
SVM 5	5.0	1.6083	147.10	132.23
SVM 10	10.0	6.5025	129.65	121.59
SVM 15	15.0	2.0332	143.70	97.46
SVM 20	20.0	8.0510	74.89	53.00

Conclusion

Sodium alginate-based membranes are biopolymers that have a high potential to be used in conducting protons. By blending it with semi-crystalline PVA, the membrane is more thermally stable when the depolymerization phase occurs at a higher temperature. The addition of the inorganic filler, MMT, to the PEM could have a more powerful impact in terms of the liquid uptake. The study proves that 10 wt.% of MMT is the most preferable to obtain a balanced water uptake and reduce methanol uptake, hence suggesting SVM10 as the best composite PEM with improved proton conductivity. Overall, further research might require functionalizing MMT or PVA to enhance the conductivity value in order to be the most promising alternative PEM.

Abstract

A cathode component solid oxide fuel cell (SOFC) is important in the manufacturing of the cells. This study evaluated two dual composite cathodes, namely, $(La_{0.6}Sr_{0.4})_{0.97}Co_{0.2}Fe_{0.8}O_3$ (LSCF)/$Y_{0.8}Zr_{0.92}O_{1.96}$ (YSZ)-$Sm_{0.2}Ce_{0.8}O_{1.9}$ (SDC) and LSCF/YSZ-SDC carbonate (SDCC). The dual composite cathodes with different compositions were developed through high-energy ball milling (HEBM) for the production of dual composite powder and screen-printing method for the fabrication of symmetrical cells. The properties of the dual composite cathodes were studied. Phase identification was carried out via X-ray diffractometry (XRD), and the electrochemical performance of the symmetrical cells was measured by impedance test. The physical morphologies of LSCF/YSZ-SDC and LSCF/YSZ-SDCC were slightly different. The XRD patterns of the LSCF/YSZ-SDC cathode powder showed no secondary peak, whereas the LSCF/YSZ-SDCC cathode powder had $SrCO_3$ as an impurity. Microstructure and powder homogeneity are considered essential in addition to the good formulation of the dual composite's cathodes. The particle sizes of LSCF/YSZ-SDC and LSCF/YSZ-SDCC as analyzed by ImageJ software were in the range of 130–160 nm. The printed cathode was investigated under heat treatment from 700 °C to 500 °C. The electrochemical performance of LSCF/YSZ-SDCC was slightly better compared with that of LSCF/YSZ-SDC because of the addition of the carbonate; however, the polarization resistance obtained did not meet the standard range. The electrochemical performance obtained from this study was not favorable because of severe problems, such as the technique applied during cell fabrication and the presence of impurity after the HEBM process.

Keywords: dual composite cathodes, intermediate temperature, screen printing, solid oxide fuel cell

Abstrak

Komponen katod untuk sel bahan api oksida pepejal (SOFC) adalah penting dalam pembuatan sel. Dalam kajian ini, penilaian katod komposit dwi (LSCF)/(YSZ)-(SDC) and (LSCF)/(YSZ)-Karbonat (SDCC) dibentangkan. Komposisi yang berbeza bagi katod komposit dwi telah dibangunkan melalui teknik pengisaran bebola tenaga tinggi untuk penghasilan serbuk komposit dwi dan kaedah percetakan skrin telah digunakan untuk fabrikasi sel simetri. Pencirian sifat katod komposit dwi telah dikaji. Pengenalpastian fasa melalui kaedah pembelauan sinaran-X telah dijalankan dan prestasi electrokimia sel simetri diukur dengan

menggunakan ujian impedans. Perbandingan antara morfologi fizikal LSCF/YSZ-SDC and LSCF/YSZ-SDCC menunjukkan sedikit perbezaan dengan penambahan karbonat. Corak sinar-X untuk komposit dwi campuran LSCF/YSZ-SDC katod serbuk tidak memaparkan puncak sekunder. Bagaimanapun, Komposit dwi campuran LSCF/YSZ-SDCC katod serbuk memaparkan kehadiran sebagai bendasing. Kehomogenan struktur mikro dan serbuk dianggap pentiing sebagai tambahan kepada perumusan katod dwi komposit yang baik. Purata saiz zarah purata bagi LSCF/YSZ-SDC and LSCF/YSZ-SDCC dwi komposit selepas dianalisis oleh perisian Image J didedahkan berada dalam julat antara 130-160. Filem bercetak katod telah disiasat di bawah suhu rawatan haba dari 700 ℃ hingga 500 ℃. Prestasi elektrokimia LSCF/YSZ-SDCC menunjukkan lebih baik sedikit berbanding LSCF/YSZ-SDC kerana penambahan karbonat namun keputusan yang diperoolehi tidak mencapai julat piawai rintangan polarisasi. Prestasi elektokimia yang diperoleh daripada kajian ini adalah tidak memberangsangkan kerana masalah yang teruk seperti teknik yang digunakan semasa fabrikasi sel dan kehadiran bendasing selepas proses HEBM.

Kata kunci: katod komposit dwi, suhu pertengahan, percetakan skrin, sel bahan api oksida pepejal

Introduction

Solid oxide fuel cells (SOFCs) are still highly investigated because they have the highest potential for future power-generating devices in fuel cell technology. The capability of SOFCs to convert chemical energy from hydrogen or versatile fuels, particularly hydrocarbon fuels, into electrical or thermal energy made SOFCs a potential renewable energy source. Recent developments in SOFCs have focused on limiting the operating temperature and selecting a stable material for SOFC components. Although many cathodes have been developed and studied in detail, dual composite cathodes are barely reported. Dual composite cathodes are introduced to create an ideal cathode microstructure that can help improve phase contiguity and interfacial coherence by selecting suitable materials as cathode components [1-4]. Several studies have development of dual composite cathode was investigated. According to Ko et al. [3], $(La_{0.6}Sr_{0.4})_{0.97}Co_{0.2}Fe_{0.8}O_3$ (LSM)-$Y_{0.8}Zr_{0.92}O_{1.96}$ (YSZ) composite cathodes struggle to achieve a high electrochemical performance because their effective surface area is small for electrocatalytic reactions. As a solution, an LSM/YSZ-YSZ dual composite cathode was created with LSM and YSZ particles conjugated together on YSZ-based particles. Based on the reported analysis, the LSM/YSZ-YSZ dual composite cathode had improved cathodic performance and also improved the durability of the cell by enhancing the phase contiguity and interfacial coherence between cells. Several dual composite cathodes were created for the further investigation of dual composite cathode materials. For example, LSM/YSZ-gadolinium-doped ceria (GDC), LSCF/YSZ-GDC and LSCF/GDC-YSZ were developed. The cell performances of these dual composite cathodes were investigated by comparing with a single composite cathode (LSCF-GDC), and the results showed that LSCF/GDC-YSZ had a lower polarization resistance (0.075 Ωcm^2) than LSCF-GDC (0.195 Ωcm^2) [3-4]. However, the operating temperatures of previously developed dual composite cathodes for SOFCs are high.

In this study, two new dual composite cathodes, namely, LSCF/YSZ-$Sm_{0.2}Ce_{0.8}O_{1.9}$ (SDC) and LSCF/YSZ-SDC carbonate (SDCC), were developed in an attempt to investigate their electrochemical performances in limited operating temperatures. Previous research developed and evaluated two different dual composite cathodes, namely, LSM/GDC-YSZ and LSCF/YSZ-GDC. The electrochemical performances of these cathodes were investigated at high operating temperatures [3-4]. In the present study, the operating temperature was limited to 700–500 °C. YSZ was added to the LSCF-SDC composite cathode as an electrolyte material because YSZ can help increase the performances of cell components [5]. Moreover, SDC was used instead of GDC in this research. Both doped ceria are good oxygen ion conductors [6], but SDC is preferred because of its excellent ionic conductivity, which is related to oxygen vacancy [6]. Samarium causes a remarkable increase in oxygen vacancies, which help increase ionic conductivity [6]. Additionally, incorporating carbonate salts (Li_2CO_3 and Na_2CO_3) can improve ionic conductivity [7]. For these reasons, two

new dual composite cathodes were developed and examined in this study.

The present work aimed to investigate the electrochemical performances of dual composite cathodes in an operating temperature between 700 °C and 500 °C. The dual composite cathodes were prepared by mixing LSCF with YSZ-SDC and YSZ-SDCC with different weight percentages. The symmetrical cells were prepared by screen printing method using LSCF/YSZ-SDC and LSCF/YSZ-SDCC as the inks. Moreover, the phase microstructure and electrochemical performances of the dual composite cathode symmetrical cells were evaluated in depth in this study.

Materials and Methods

Preparation and characterization of dual composite powders

YSZ-SDC and YSZ-SDCC composite powders were prepared using high-speed ball milling technique. SDCC electrolyte was prepared using low-speed ball milling method with 80 wt.% raw SDC powder (Kceracell, South Korea) mixed with 20 wt.% binary carbonates, which comprise 67 mol.% Li_2CO_3 and 33 mol.% Na_2CO_3 (Sigma Aldrich, USA) [7]. YSZ-SDC and YSZ-SDCC composite powders were prepared by mixing commercial YSZ powder (Kceracell, South Korea) with commercial SDC and SDCC electrolyte powders, respectively, via high-energy ball milling (HEBM) (Fritsch Pulveristte, Germany) at 550 rpm for 2 h in zirconia jars. Three different weight ratios (50 wt.%:50 wt.%, 60 wt.%:40 wt.% and 70 wt.%:30 wt.%) for YSZ-SDC and YSZ-SDCC were selected as inspired from a previous research [8]. The resultant YSZ-SDC and YSZ-SDCC wet mixtures were dried and calcined.

In the second step, a commercial LSCF powder (Kceracell, South Korea) was added into the obtained YSZ-SDC and YSZ-SDCC composite powders with a 50:50 ratio to form dual composite cathode powders. HEBM was applied to produce homogenous mixtures of the dual composite cathode powders. Lastly, both dual composite cathode powders were dried overnight and heat treated at 750 °C for 1 h [8]. Table 1 shows the compositions of the prepared composite powders and dual composite powders.

All the fabricated powders were characterized by X-ray diffractometry (XRD; D8 Advanced Bruker, Germany) to identify the crystalline phases and the formation of any secondary phases. Then, the microstructure and element composition distribution were characterized using field-emission scanning electron microscopy (FESEM) with electron-dispersive spectroscopy (EDS; JSM 6380-Jeol, Japan). The particle sizes of all the resultant powders were estimated through the ImageJ software using the micrographs obtained by FESEM.

Table 1. Weight ratio compositions of composite and dual composite powders

Composite Powder	Weight Ratio Composition (wt.%)	Dual Composite Powder	Designated samples	Weight Ratio Composition (wt.%)
YSZ-SDC	50:50	LSCF/YSZ-SDC	LYS1	50/50:40
YSZ-SDC	60:40	LSCF/YSZ-SDC	LYS2	50/60:40
YSZ-SDC	70:30	LSCF/YSZ-SDC	LYS3	50/70:30
YSZ-SDCC	50:50	LSCF/YSZ-SDCC	LYSC1	50/50:50
YSZ-SDCC	60:40	LSCF/YSZ-SDCC	LYSC2	50/60:40
YSZ-SDCC	70:30	LSCF/YSZ-SDCC	LYSC3	50/70:30

Electrical performance analysis of LSCF/YSZ-SDC and LSCF/YSZ-SDCC dual composite cathodes

The dual composite symmetrical cells (LSCF/YSZ-SDC//YSZ electrolyte//LSCF/YSZ-SDC and LSCF/YSZ-SDCC//YSZ electrolyte// SCF/YSZ-SDCC) were prepared for the evaluation of the electrical performances of the dual composite cathodes. YSZ electrolyte pellet was prepared using a uniaxial press (Bench Top 3851, Carver, USA). Commercial YSZ powder (0.5 g) was mixed with a drop of polyethylene glycol to produce 13 mm-thick YSZ pellets. LSCF/YSZ-SDC and LSCF/YSZ-SDCC were screen printed on both sides of the YSZ electrolyte pellet. The dual composite powder was merged with terpineol (solvent; Merck kGaA, Germany), ethyl cellulose (binder; Sigma Aldrich, USA) and oleic acid (dispersant; Sigma Aldrich, USA) to create the screen-printing ink [9]. All the chemicals were mixed and agitated for several hours in an agate mortar until the suitable ink viscosity was achieved. Samples of the dual composite cathode symmetrical cells were placed in alumina boats and sintered at 600 °C for 90 min at a heating rate of 5 °C/min using a furnace (PLF 130, Protherm, Turkey) [10]. The surface morphologies of the dual composite cathodes were examined by scanning electron microscopy (SEM; Jeol, Japan). The electrical performances of symmetrical cells were tested using AC impedance spectroscopy (Metroahm Autolab Potentiostat and Galvanostat) in the frequency range of 0.1–1 MHz and AC voltage amplitude of 500–700 °C. Figure 1 shows the schematic diagram for the dual composite cathode symmetrical cell with its characterization, which will be discussed later in this paper.

Results and Discussion

Characterization of dual composite powders

The XRD patterns of LSCF/YSZ-SDC and LSCF/YSZ-SDCC powders with different electrolytes and electrolyte contents (YSZ-SDC and YSZ-SDCC) are shown in Figures 2(a) and (b), respectively. Both dual composites cathodes were compared with commercial LSCF, YSZ, SDC and SDCC. As shown in Figure 2, only three primary phases of the standard peaks of LCSF perovskite (JCPDS No 01-089-5720), SDC (JCPDS No 01-075-0157) and YSZ (JCPDS No 00-030-1468) were detected. The carbonate (Li/Na) peaks in the SDCC composite shown in Figure 2(b) yielded the crystallite peak of the pure fluorite structure of SDC, which is equivalent to the pure SDC structure. This result indicates that carbonates form an amorphous form, whereas SDC forms a well-defined fluorite crystal structure [8]. The SDCC peak was similar to the SDC pattern, as the addition of binary carbonates did not affect the shape and size of the original structures of the SDC particles. Li_2CO_3 and Na_2CO_3 were in molten amorphous states because the calcination temperature was over their melting temperatures [10]. Secondary phases were detected in the LSCF/YSZ-SDCC dual composite. Figure 2(c) shows the enlarged XRD pattern of the secondary phase identified as strontium carbonate ($SrCO_3$, JCPDS No. 00-005-0418). According to Rahman et al. (2020), this phenomenon is normally due

to excessive power generated during the milling process of commercial LSCF powders, which caused the minor phase of $SrCO_3$ to form [11]. The formation of $SrCO_3$ impurity might be one of the reasons that caused the degradation of the electrochemical performances of the dual composite cathode cells owing to its incompatibility with the electrolyte material. A further analysis between the formation of impurities and the performances of dual composite cells need to be addressed more in the future.

Microstructure analysis of dual composite cathode powders

The effect of various weight compositions (YSZ-SDC and YSZ-SDCC) on powder morphology after the incorporation with LSCF were further investigated via FESEM. Figures 3 and 4 show the FESEM micrographs of the LSCF/YSZ-SDC and LSCF/YSZ-SDCC dual composite cathodes. Well-distributed and fine particles were obtained in all dual composite cathode powders after HEBM. Fine particles in the range of 130–160 nm were observed. HEBM is a well-known technique used to synthesise nanocrystalline perovskites that exhibit an improvement in response ratios at low operating temperatures [12]. The particle sizes of the commercial

powders of LSCF,YSZ and SDC, as well as those of the developed dual composite cathodes, are tabulated in Table 2. LYSC1 (159 nm) had the largest particle size, followed by LYSC2 (145 nm) and LYSC3 (135 nm). Similarly, amongst the LSCF/YSZ-SDC dual composites, LYS1 (147 nm) displayed a slightly larger particle size compared with LYS2 (138 nm) and LYS3 (126 nm). The prepared LSCF/YSZ-SDC and LSCF/YSZ-SDCC dual composite powders had smaller particles compared with commercial LSCF, YSZ and SDC powders. The decrease in size can be affected by the calcination process, as the calcination temperature directly influences the parameters [14]. The decrease in the average particle size of the dual composite powders was expected because the milling process creates mechanical energy to breakdown the particles into smaller size and creates a uniform mixture of solid contents [15]. However, a slight agglomeration was seen in the LYS3 dual composite powders. This finding indicates that the composition 70YSZ:30SDC is not suitable for the development of dual composite cathodes. As a result, the total polarisation resistance of LYS3 was the highest amongst the compounds. Parwaiz et al. reported that the improper selection of a sample parameter will induce unwanted phase transformation and undesirable material properties [16].

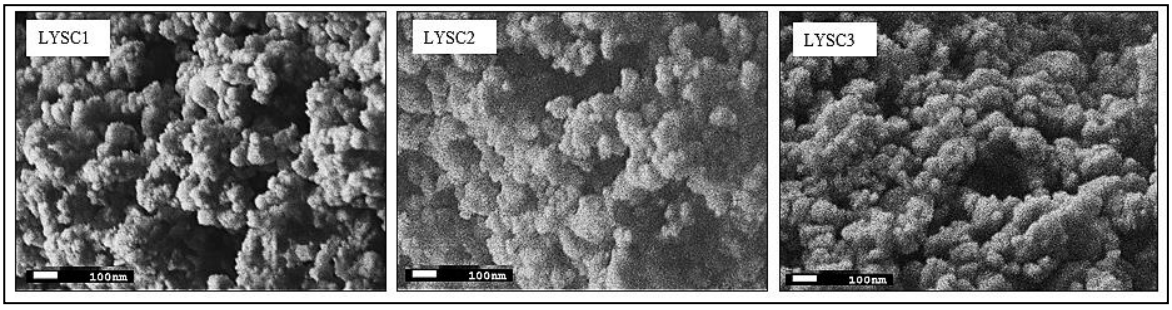

Figure 4. FESEM micrographs of the LSCF/YSZ-SDCC dual composite cathode after HEBM and calcination at 50,000× magnification

Table 2. Average particle sizes of the commercial and prepared dual composite powders

Powders	Average Particle Size (nm)
Commercial Powder LSCF	567
Commercial Powder YSZ	379
Commercial Powder SDC	130
Prepared LSCF/YSZ-SDC (50/50:50 wt.%)	147
Prepared LSCF/YSZ-SDC (50/60:40 wt.%)	138
Prepared LSCF/YSZ-SDC (50/70:3 0wt.%)	126
Prepared LSCF/YSZ-SDCC (50/50:50 wt.%)	159
Prepared LSCF/YSZ-SDCC (50/60:40 wt.%)	145
Prepared LSCF/YSZ-SDCC (50/70:30 wt.%)	135

Microstructure analysis of dual composite cathode symmetrical cells

The printed surfaces and cross-sections of the LSCF/YSZ-SDC and LSCF/YSZ-SDCC pellets were observed through SEM and EDS as illustrated in Figure 5, Figure 6 and Figure 7. Figure 5 shows the secondary (SE) SEM images of the printed surfaces of the dual composite cathodes in the same magnification. Small pores were seen in all LSCF/YSZ-SDCs, whereas large pores were detected in the LSCF/YSZ-SDCCs. This outcome was probably because the binary carbonate reached the melting point as the sintering temperature (600 °C) during the preparation of the symmetrical cells was fixed. In addition, the porosity of the cathode should lie in the range of 20%–40% to achieve a better electrochemical performance [17]. The estimated average porosity for both dual composite cathodes was determined using SEM. The maximum porosity percentages of all LSCF/YSZ-SDC and LSCF/YSZ-SDCC dual composite cathodes were kept within the acceptable range. Table 3 shows the estimated averages porosity for the different compositions of the dual composite cathodes. The morphology of the pellets showed a regular distribution; however, the addition of carbonate as the solid content increased the roughness of the printed surface. The addition of a solid content helps increase the surface roughness by improving the elastic properties of the screen-printing ink [18]. As shown in Figure 5, a small crack was observed on the surface of the printed cathode films in the LYS3 and LYSC3 dual composite cathodes. Carbonate degradation might have led to the cracking phenomenon. Besides, a weak adhesion to the surface of the substrate during the deposition of the printed material is perhaps one of the reasons that caused the cracking surface [19].

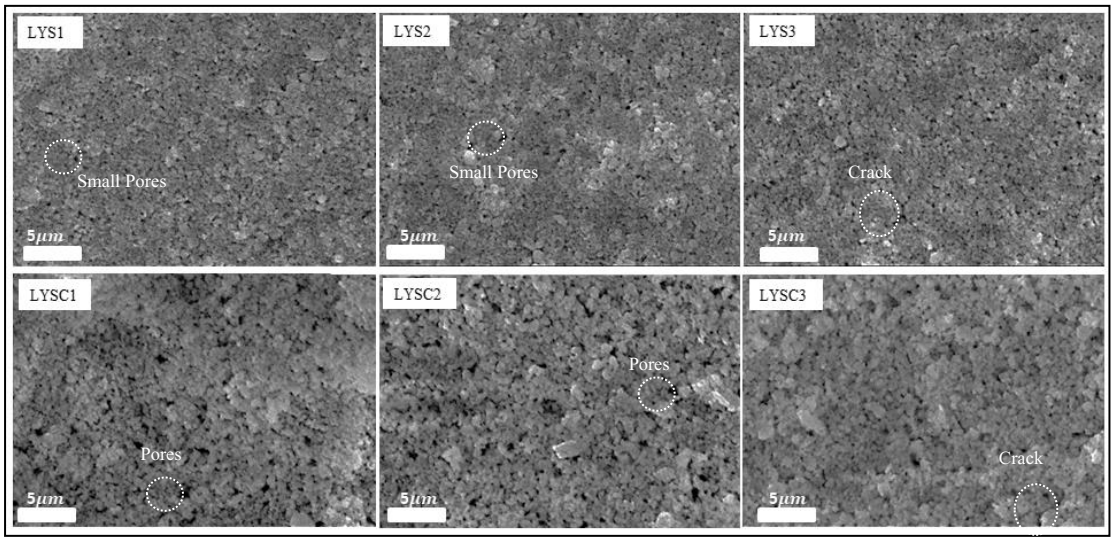

Figure 5. SEM micrographs for of the printed surfaces of (above) LSCF/YSZ-SDC and (below) LSCF/YSZ-SDCC at 10,000× magnification

Table 3. Average porosity of dual composite cathode symmetrical cells

Dual Composite Cathode	Average Porosity (%)		
	50/50:50	50/60:40	50/70:30
LSCF/YSZ-SDC	20.22	25.91	25.07
LSCF/YSZ-SDCC	23.85	26.29	25.86

Figure 6 and Figure 7 show the cross-section micrograph view and EDS spectra of LSCF/YSZ-SDC and LSCF/YSZ-SDCC dual composite cathode layer on YSZ electrolyte pellet by 10 times repetition using screen printing method. The EDS spectra presented all the elements consist of La, Sr, Co, Fe, Sm, Ce, Y, Zr, O and C from LSCF/YSZ-SDC dual composite cathode. Na element was detected from LSCF/YSZ-SDCC as the addition of the Na_2Co_3 carbonate existing in melting amorphous state however due to a very low energy characteristics radiation, element Li were not detected in EDS spectra analysis region

The screen-printing thickness of the dual composite cathode layer was uniform thickness for 10 times repetition for each layer. Table 4 shows the total thickness of each LSCF/YSZ-SDC and LSCF/YSZ-SDCC after the printing of 10 layers. The average thicknesses of the dual composite cathodes per printing are presented in Table 4. The thickest screen-printed layer was 45.6 μm for the LYSC3 composition. The thickness of the cathode layer using the LSCF/YSZ-SDCC ink seen wider compared with that of the LSCF/YSZ-SDC ink. The increase in thickness using the LSCF/YSZ-SDCC inks may be related to the improved elastic properties caused by the addition and increase in solid content [18]. The formulations for dual composite cathode ink are non-identical for each composition as the weight compositions (YSZ-SDC and YSZ-SDCC) are different. The powder volume of the final dual composite ink was <30 vol.% as suggested from a previous research to obtain good quality cathode inks [18]. Thus, the thickness of the screen-printing layer and the production of cathode inks are important as it can help improve cell performance [20].

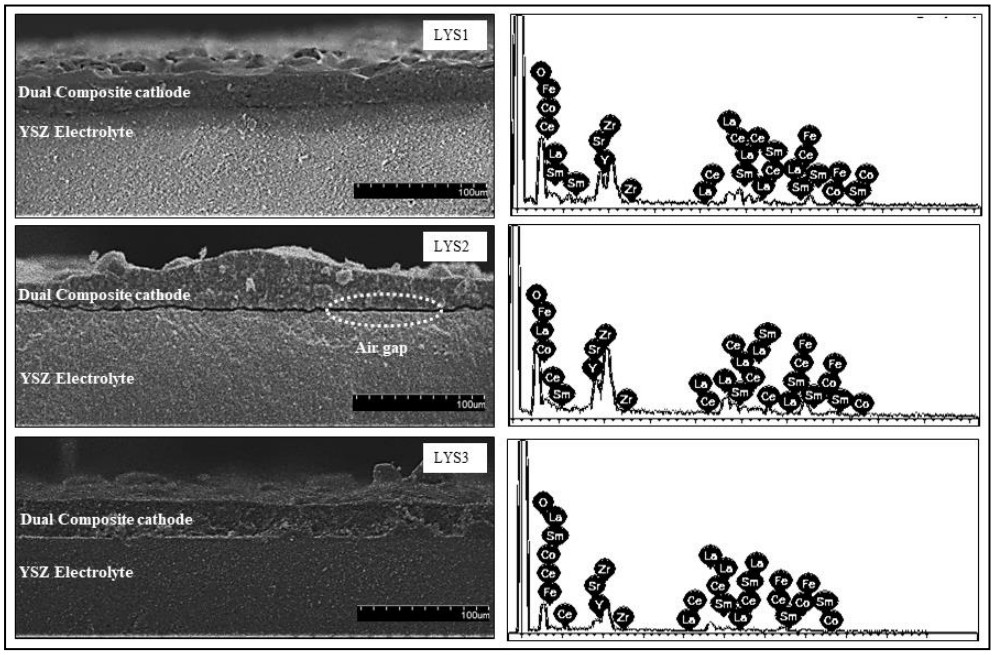

Figure 6. Cross-sectional micrographs and EDS spectra of screen-printed LSCF/YSZ-SDC cathode films

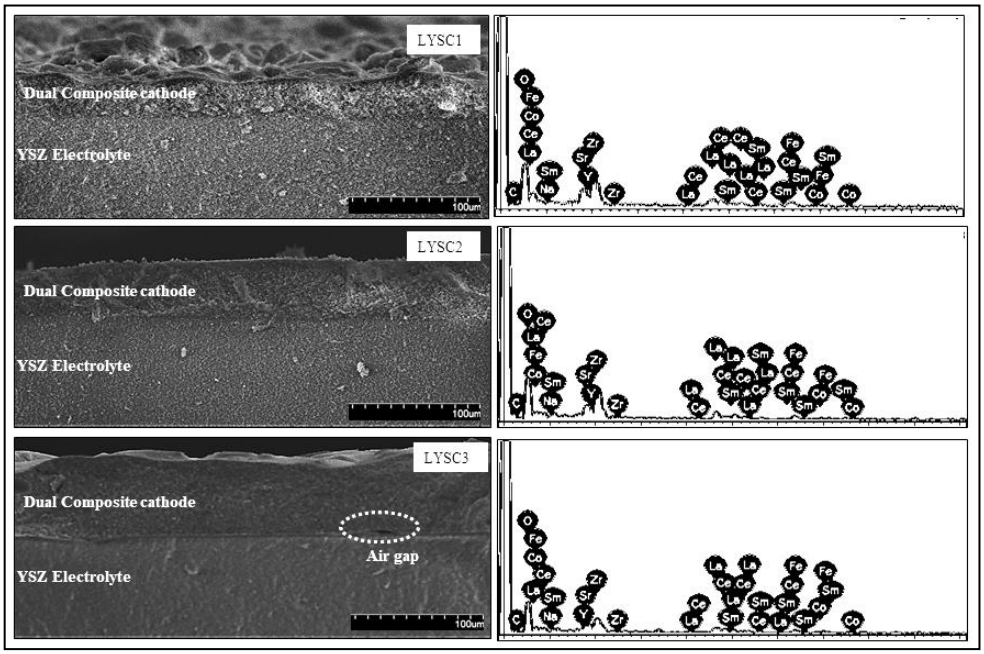

Figure 7. Cross-sectional micrographs and EDS spectra of screen-printed LSCF/YSZ-SDCC cathode films

Table 4. Screen printing thickness of the cathode layer

Dual Composite Cathode	Total Thickness (µm)	Average Thickness per Printing (µm)
LYS1	17.9	1.79
LYS2	16.3	1.63
LYS3	15.1	1.51
LYSC1	23.8	2.38
LYSC2	32.5	3.25
LYSC3	45.6	4.56

Electrochemical performance of the dual composite cathodes

The ionic conductivities of the symmetrical cells of LSCF/YSZ-SDC and LSCF/YSZ-SDCC were measured. Figures 8 and 9 show the impedance spectra of LSCF/YSZ-SDC and LSCF/YSZ-SDCC in an open circuit condition with a firing temperature from 700 °C to 500 °C in air. The impedance spectra were fitted, and the fitting results are shown in Table 5. The total polarization resistance of all cells showed a decrement with the increment in operating temperature (500–700 °C). In addition, the ionic conductivities of the dual composite cathodes were calculated using equation below.

Ionic conductivity formula:

$$\sigma = \frac{1}{\rho} = \left(\frac{1}{R}\right) x \left(\frac{A}{d}\right) \quad (1)$$

where: σ: Conductivity, d: Thickness of the sample (cm), R: Resistance (Ω), A: Effective area (cm^2), and ρ: Resistivity (Ωm).

LYS2 (0.080×10^{-5} S cm^{-1}) yielded the highest ionic conductivity for the LSCF/YSZ-SDC parameter, whereas LYSC1 (0.410×10^{-5} S cm^{-1}) attained the greatest ionic conductivity for the LSCF/YSZ-SDCC parameter. Both dual composite cathodes yielded the best ionic conductivity at 700 °C. LYSC1 (307 kΩ) showed the lowest polarization resistance, followed by LYSC2 (37.90 kΩ) and LYSC3 (39.20 kΩ), at 700 °C. Unfortunately, the recorded polarization resistance values were not favorable, as the resistance was too high, and the ionic conductivity was extremely low. Nonetheless, this finding proved that the conductivity and polarization resistance of LSCF/YSZ-SDCC was slightly better compared with those of the dual composite cathodes without the addition of binary carbonate. This finding was also coherent with the findings of previous research, which reported that binary carbonates are able to enhance the electrochemical performances. [11-12] .

The high ionic conductivity for excellent fuel cell performance at the intermediate- to low-temperature region is in the range of 0.01–1 S cm^{-1}[21]. The data gathered in this study show that the obtained ionic conductivity is not within the acceptable range. Some factors possibility affected the performances of the LSCF/YSZ-SDC and LSCF/YSZ-SDCC cells. The first factor was the selection of sintering temperature during the preparation of the symmetrical cells. The sintering temperature for a YSZ material is 1300–1600 °C;

therefore, 1400 °C was chosen as the sintering temperature for SOFC application [22]. In addition, selecting the appropriate temperature for a material is crucial, as high conductivity is achieved when the operating temperature is above the melting point of the material [23]. Besides the selection of sintering temperature, the development of symmetrical cells is considered one of the reasons for the low ionic conductivity. For example, during the cross-sectional analysis, the dual composite ink was not well screen printed on the surface of the YSZ pellet. This poor application may trap air between the cathode and electrolyte layers. During the printing process, parameters, including printing repetition layer, squeegee-related parameters, printing angle and forces exerted during the screen-printing process, influence the quality of the printed layer [20].

Conclusion

The current study presented the development of new dual composite cathodes, namely, LSCF/YSZ-SDC and LSCF/YSZ-SDC carbonate, for use in intermediate-temperature SOFC application. The main objective was to enhance the electrochemical performances of LSCF/YSZ-GDC and LSM/GDC-YSZ, which remains a challenge owing to the poor ionic conductivities of LSCF/YSZ-SDC and LSCF/YSZ-SDCC. However, this study proved that the addition of the Li/Na binary carbonate helped increase the ionic conductivity and showed a better electrochemical performance compare with LSCF/YSZ-SDC.

Abstract

The catalyst support is typically implemented to improve the catalytic activity in direct methanol fuel cells (DMFCs). Thus, this study focused on the novel support of 3D hierarchical porous TiO_2-graphene aerogel which was established via a combination of hydrothermal method and freezing drying method. XRD, Raman spectra, and FESEM were used to study the PtRu/TiO_2-GA. The estimated particle size of PtRu/TiO_2-GA determined from the XRD analysis was less than composite TiO_2-GA. The existence of the carbon support material was confirmed by the Raman spectra in all generated samples. Within the electrocatalyst and TiO_2-GA, the ratio value of the D band to the G band (I_D/I_G) was not significantly different. The computed I_D/I_G values for TiO_2-GA and PtRu/TiO_2-GA electrocatalysts were 0.99 and 1.02, respectively. The best TiO_2-GA was doped with PtRu catalyst for the electrochemical test and DMFC performance based on FESEM characterization. PtRu/ TiO_2-GA exhibited better electrocatalytic activity, as well as improved PtRu usage efficiency stability and methanol oxidation reaction. Notably, the ECSA value was around 76.01 m^2g^{-1}, and the mass activity (957.15 $mAmg^{-1}$) was higher than commercial with the same loading (20%) PtRu/C (110.79 $mAmg^{-1}$). Interestingly after the 2000s, the current density of PtRu/TiO_2-GA was consistently higher than that of PtRu/C. The superior electrocatalytic performance of PtRu/TiO_2-GA towards methanol oxidation demonstrates its use in practical application as a promising anode material for DMFCs

Keywords: 3D titanium dioxide-graphene aerogel, platinum-ruthenium nanoparticles, electrocatalysis, methanol electro-oxidation

Abstrak

Sokongan mangkin biasanya dilaksanakan untuk meningkatkan aktiviti pemangkin dalam sel bahan api metanol langsung (SFML). Oleh itu, kajian ini memberi tumpuan kepada novel sokongan pada TiO_2-grafin aerogel berliang hierarki 3D telah ditubuhkan dengan gabungan kaedah hidroterma dan kaedah pengeringan beku. XRD, spektrum Raman dan FESEM digunakan untuk mengkaji PtRu/TiO_2-GA. Anggaran saiz zarah PtRu/TiO_2-GA yang ditentukan daripada analisis XRD adalah kurang daripada komposit TiO_2-GA. Kewujudan bahan sokongan karbon telah disahkan oleh spektrum Raman dalam semua sampel yang dihasilkan. Dalam elektromangkin dan TiO_2-GA, nilai nisbah jalur D kepada jalur G (I_D/I_G) tidak berbeza dengan ketara. Nilai

I_D/I_G yang dikira untuk elektromangkin TiO_2-GA dan PtRu/TiO_2-GA ialah 0.99 dan 1.02, masing-masing. TiO_2-GA terbaik akan didop dengan mangkin PtRu untuk ujian elektrokimia dan prestasi SFML berdasarkan pencirian FESEM. PtRu/ TiO_2-GA mempamerkan aktiviti elektrokatalitik yang lebih baik, serta peningkatan kestabilan kecekapan penggunaan PtRu dan tindak balas pengoksidaan metanol. Terutama, nilai ECSA adalah sekitar 76.01 m^2g^{-1}, aktiviti jisim (957.15 $mAmg^{-1}$) adalah lebih tinggi daripada komersial dengan pemuatan yang sama (20%) PtRu/C (110.79 $mAmg^{-1}$). Menariknya selepas minit ke-2000 saat, ketumpatan semasa PtRu/TiO_2-GA sentiasa lebih tinggi daripada PtRu/C. Prestasi elektrokatalitik unggul PtRu/TiO_2-GA terhadap pengoksidaan metanol boleh digunakan dalam aplikasi praktikal sebagai bahan anod yang menjanjikan untuk DMFC.

Introduction

Direct methanol fuel cells (DMFCs) have gained traction recently due to their technological advances through a variety of characteristics: low emissions, excellent energy conversion efficiency, liquid fuel handling convenience, and low operating temperature. These are the results of the increasing use of mobile devices and the prerequisite of affording sufficient energy and power for the application [1, 2]. The electrochemical reaction in a direct methanol fuel cell is represented as follows:

$CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^-$
$E° = 0{:}016V$ (vs: SHE) (Anode reaction)

$3/2O_2 + 6H^+ + 6e^- \rightarrow 3H_2O$
$E° = 1{:}229V$ (vs: SHE) (Cathode reaction)

$CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^-$
$E° = 1{:}245V$ (vs: SHE) (Overall reaction)

The need for highly active catalysts for the oxidation process of hydrogen-rich liquid fuels is one of the major driving forces behind the development of DMFC technology. The electrocatalyst selection is critical for DMFC because the quality of the reaction kinetics of catalyst influences current density and cell lifespan. Improved catalyst activity and durability can be achieved through the development of novel support materials or the use of innovative catalytic metals [3]. Due to their increased catalytic activity in the electrooxidation of methanol, platinum group metals (PGMs) are the most used anode catalysts in DMFCs [4-8]. Platinum is costly, thus finding a replacement catalyst will necessitate further research. The best catalyst for DMFCs right now is bimetallic platinum-ruthenium (PtRu). Pt loading can be lowered by reducing the electrocatalyst costs in DMFC using only the corresponding ratio of 1:1. Additionally, bimetallic Ru catalyst works in catalytic operations by eliminating carbon monoxide (CO) from the active site for HOR, where this catalyst can reduce CO poisoning [11, 12]. PtRu demonstrated a higher catalytic activity in the DMFC according to research by Bock et al. [4], and it was evident that the catalytic performance was significantly dependent on the distribution of Pt and Ru sites at the atomic level. However, the PtRu catalyst cannot solve the problem of low methanol oxidation. Further catalyst modifications are required to help the fuel cell sector.

The DMFC has been in progress for a decade with the creation of several catalyst-based solutions. Alternative support materials are stable and cost-effective, and they have been identified and developed with great effort [28–30]. Novel carbon supports, for example carbon nanotubes [5], mesoporous carbon [6], graphene [7], noncarbon materials, and nonconductive whiskers, due to their strong corrosion-resistance, have been explored as carbon alternatives. Graphene is the best candidate for catalyst support in fuel cells because of its chemical resistance, large and sufficient porosity, high conductivity, and diversity of topologies (network, aerogel, foam, etc.) [8, 9]. In general, the graphene aerogel (GA), which has a three-dimensional (3D) structure, has received a lot of attention due to its extensive macroporosity and multidimensional electron transport pathways, making it ideal for catalysis and energy storage devices [10, 11]. In the advancement of DMFCs, applying additional materials to the catalyst, including the formation of new hybrid catalysts, has become a trend [4–6]. However, issues such as

electronic and protonic functioning, poor catalytic activity, stability, and conductivity are still persistent.

The most used materials to improve the electrocatalysis of DMFCs are metal oxides. Titanium dioxide (TiO_2) is a type of inorganic substance, non-flammable, corrosion-resistant, and fundamentally stable. Furthermore, TiO_2 crystal structures are thermodynamically stable, contributing to the production of a composite material that is thermally and electrochemically stable [12]. Anatase stimulates charge carriers deeper within the bulk material, leading more in surface reactions and rising catalytic activity with time [13]. Additionally, when the TiO_2 metal oxide interacts with another component, the electrical behaviour of the materials improves as well. Instead of lowering CO oxidation potentials, this material can also support to increase oxidation activity [14]. The metal catalyst is supported by TiO_2, which impacts the reaction kinetics and mechanism [15]. TiO_2 has all the advantages recorded above and it can be used in a variety of industries. Despite these benefits, the low conductivity of material prevents it from being widely used in fuel cell applications.

Significant loading of a Pt catalyst on TiO_2 made from an electrically conductive substance like N-doped carbon, as well as the use of sub-stoichiometric TiO_2, is necessary to overcome this obstacle [16]. In 2018, Abdullah et al. [16] developed PtRu alloys on a nanofiber catalyst structure with metal oxide as the catalyst support; PtRu/TiO_2-embedded carbon nanofiber (CNF) (PtRu/TECNF) was designed by Ito et al. [17], and Ercelik et al. [18] demonstrated PtRu/ C-TiO_2 as an electrocatalyst in DMFC technology; the result indicated that the performance of this new composite electrocatalyst was superior to PtRu catalyst. The above-mentioned performance is due to the homogeneous dispersion of PtRu nanoparticles on the support material. Consequently, combining a powerful PtRu catalyst with a rational TiO_2 and graphene aerogel structure has unique properties and high surface area, it has developed as the latest support material, with the possibility to increase electrocatalytic activity in MOR.

Materials and Methods

Preparation of TiO_2-GA and electrocatalyst

TiO_2-GA was produced hydrothermally, then freeze-dried in a typical experiment. Firstly, 20 mg of TiO_2 were homogeneously disseminated into 10 mL of GO solution (2 mg/mL) using moderate ultrasonication for 2 hours. After that, the solution was placed in a 50mL of Teflon-lined autoclave and kept at 200°C for 12 hours. To make a TiO_2-GA composite, the produced TiO_2-graphene hydrogel was thoroughly rinsed with deionized water before being freeze-dried for 24 hours. The steps of TiO_2-GA production are depicted schematically in Figure 1.

For electrocatalyst synthesis, a microwave-assisted alcohol reduction approach was used. The optimal TiO_2-GA support doped with PtRu catalyst was chosen specifically for this study. On TiO_2-GA support, 20 wt.% Pt-Ru with an atomic ratio of 1:1 was loaded. To begin, Ethylene Glycol (EG) solutions were combined with ruthenium chloride precursors and chloroplatinic acid precursors, and were homogenized for 15 minutes. After that, the TiO_2-GA powder that had been produced was mixed into the cooperation precursor solutions and agitated for 30 minutes to ensure that everything was well mixed. After that, the pH of the solution was adjusted to 10 using a 1 M NaOH solution. In addition, the mixture was microwaved for 1 minute, and was left to accomplish the reduction process for 1 minute twice. Finally, before being dried in a 120 °C oven for 3 hours, the sample was filtered and rinsed a few times with ethanol and DI water to remove the impurities.

Characterizations

To prove crystallinity in the manufactured tests for characterization uses, X-ray Diffraction (XRD) is a powerful physical description method. Using a D8 Advance/Bruker, AXS Germany model, all fabricated tests were examined at 2θ from 5° to 100°. Moreover, the degree of graphitization was described using Raman spectrum analysis. The surface morphology and forms of the samples were explored using a Field Emission Scanning Electron Microscope (FESEM).

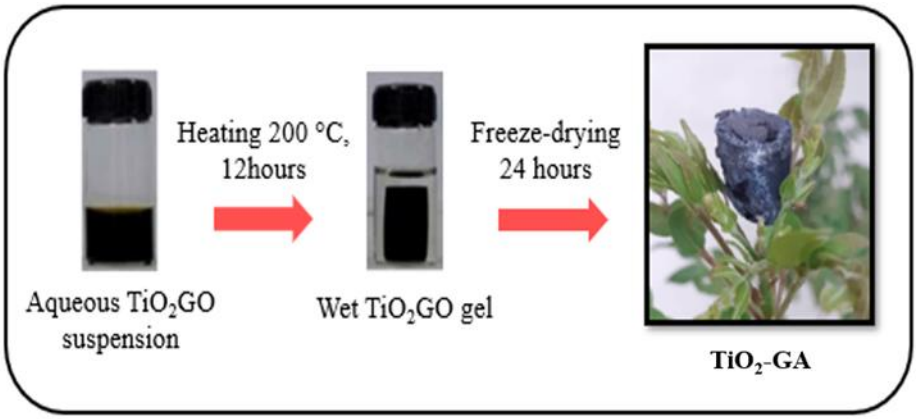

Figure 1. Design of the preparation of TiO_2-GA composite

Electrochemical characterization and performance test

In a 0.5 M H_2SO_4 the electrocatalyst performance was estimated by determining the electrochemical surface area, ECSA, cyclic voltammetry (CV), and catalyst stability measured with a chronoamperometry (CA) test. Three-electrode cell systems were used at room temperature: a working electrode with a glassy carbon electrode (3 mm Ø), reference electrodes noted as Ag/AgCl electrodes, and counter platinum-based electrode. Furthermore, 3 mg of electrocatalyst of PtRu/TiO_2-GA and commercial catalyst were dispersed in 150 mL DI water, 150 mL IPA, and 50 mL Nafion (5 wt.%) solution to make the electrocatalyst ink for the working electrode. On the glassy electrode, there was a catalyst loading of 0.0503 mg cm^{-2}. The CV was measured at a 50 mVs^{-1} scan rate with potentials ranging from -0.2 to 1.0 V vs. Ag/AgCl. Note that in this analysis, the potentials ranged from -0.2 to 1.0 V vs. Ag/AgCl, while CV was recorded at a 50 mVs^{-1} scan rate. The long- term performance of all electrocatalysts was assessed using chronoamperometry (CA) in the electrolyte solution at a potential of 0.6 V for 2000 s.

Results and Discussion

The crystal structure and pattern of the built catalyst support and electrocatalyst were investigated using XRD analysis. As a result, the TiO_2-GA support was synthesized by hydrothermal at 200 °C. The microwave-assisted alcohol reduction approach was used to make the PtRu/TiO_2-GA and PtRu/C marketable. The analysis of the diffraction peak for the associated sample and comparative samples of XRD pattern for PtRu/TiO_2-GA electrocatalyst is shown in Figure 2(a). Peaks at 25.3°, 37.8°, 48.0°, 53.9°, 55.1°, 62.7°, 68.8°, 70.3°, and 75.0° are indexed to (101), (004), (200), (105), (211), (204), (116), (220), and (215) crystal planes of TiO_2 anatase, respectively based on XRD examination for TiO_2-GA support sample [19, 20]. The TiO_2-GA hydrothermal at 200 °C was chosen as the best-produced TiO_2-GA and was doped with PtRu catalyst. The XRD results for the synthesized PtRu/TiO_2-GA showed the presence of all particles, PtRu, and C support. The Pt particles peaked at 39.7° (111), 46.2° (200), 67. 5° (220), and 81.3° (311). The diffraction peaks for Ru were 40.7° (111), 47° (200), 69° (220), and 83.7° (311). The structure of both metals was cubic, and in the electrocatalyst sample, high Bragg angles were detected in the range of 25°–60°, indicating that the catalyst possessed bimetallic or alloy interaction [21]. Additionally, the estimated crystallite size of PtRu was computed using Scherrer's equation, which revealed that PtRu/TiO_2-GA particles were smaller than PtRu/C particles [22]. As shown in Table 1, the particle size of Pt and Ru can also be predicted using the crystallite size. In general, smaller particles perform better in MOR electrocatalysis reactions than larger particles, since smaller catalyst particles contribute to a higher particle surface area. Furthermore, the smaller catalyst particle size may allow for a reduction in the use of Pt in electrocatalyst, as well as a reduction in the overall cost of DMFC production. The decreased size of PtRu particles found in the

electrocatalyst sample could potentially be due to the lower crystalline structure.

In terms of the chemical and structural information offered by the shift in wavelength of inelastically scattered radiation, the D and G bands were 1350 and 1590 cm^{-1}. The two separate peaks in the Raman spectra for the samples in Figure 2(b) indicated that the D band was linked to crystal boundary vibrations and the G band reflected perfect sp2 vibrations of graphitic crystals. From the Raman spectrum analysis, the intensity ratio of the D to G band (I_D/I_G) had a descending order: TiO_2-GA (1.02), PtRu/ TiO_2-GA (0.99) and PtRu/C (0.98). The band fluctuated depending on the relative intensity of the D and G bands on the type of graphite material, and it could be used to estimate the degree of graphitization. The I_D/I_G ratio observed in this work showed that the aerogel was successfully achieved after the catalyst was disseminated at TiO_2-GA [23], [24]. Ultimately, in the disintegrated region and structure of TiO_2-GA, the carbon layer in these electrocatalysis samples was not significantly different. The weak Raman shift bands at 152 cm^{-1} and 154 cm^{-1} were identified in TiO_2-GA and PtRu/TiO_2-GA, respectively, and were linked to unique characteristics of TiO_2 anatase [25].

FESEM was used to analyze the dispersion surface, morphologies, and sizes of PtRu/TiO_2-GA and PtRu/C produced using a microwave-assisted alcohol-reduction technique. PtRu/TiO_2-GA had a 3D-porous cellular structure, exhibiting constant porosity of sizes ranging from micrometres to sub micrometres as seen in Figure 3. Furthermore, the tight inspection revealed an evenly adorned PtRu nanoparticles in a 3D porous cellular structure, demonstrating a strong interaction among the PtRu-carbon building block. Interestingly, the PtRu/C images revealed that these carbon-supporting materials were spherical. [26]. The findings indicated that the samples were agglomerated with a diameter of 120-150 nm, which was available in the nanoscale range. The Van der Waals interaction surrounded by the particles could be causing the aggregation [27].

Table 1. Estimated crystallite size of TiO_2-GA and PtRu/TiO_2-GA on XRD analysis

Samples	XRD/Crystallite Size (nm)
TiO_2-GA	7.9
PtRu/TiO_2-GA	3.8
PtRu/C	3.9

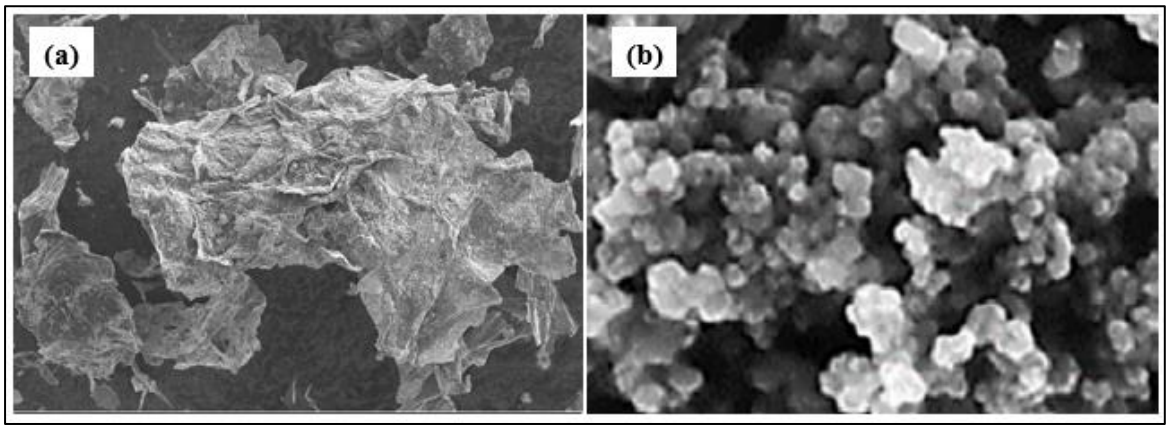

Figure 3. FESEM image of the prepared (a) PtRu/TiO_2-GA and (b) PtRu/C Electrocatalytic performance

In recent decades, DMFCs have been intensively explored and gained increasing attention in the electrooxidation by methanol. For the methanol oxidation in acid media, the electrochemical efficiency of the PtRu/TiO_2-GA catalyst has been explored. The PtRu/TiO_2-GA CV curves and PtRu/C catalysts in N_2 with 0.5M H_2SO_4 saturated solutions are displayed in Figure 4(a). In the area from -0.2 V to 1.0 V vs Ag/AgCl, both electrics demonstrated the characteristics of hydrogen adsorption-desorption. The ECSAs computed for PtRu/TiO_2-GA and PtRu/C amount was about 68.44 m^2 g^{-1} and 20.44 m^2 g^{-1}, respectively. The ECSA for PtRu/TiO_2-GA was 3 times that of PtRu/C and 30 % greater than that for commercial PtRu/C. This finding demonstrates that retaining a bimetallic 3D structure in TiO_2-GA helps to increase the ECSA of PtRu nanoparticles and improve catalyst utilization. This is owing to the differences in crystallite size between PtRu/TiO_2-GA and PtRu/C as shown in Table 1 from the XRD analysis: the PtRu/TiO_2-GA crystallite size for TiO_2-GA was the lowest and it had a superior ECSA value. Hence, the catalyst and reaction surface area can be increased by using the smallest crystallite size.

Figure 4(b) illustrates that the peak mass activity PtRu/TiO_2-GA is greater than PtRu/C. The CV values are indicated in Table 2 for the PtRu/TiO_2-GA and PtRu/C electrocatalyst. For PtRu/TiO_2-GA catalyst, the value for mass activity was 957.15 mA mg^{-1} PtRu, 12 times greater than that of the commercial PtRu/C catalyst. This reveals that the support for TiO_2-GA is a superior replacement for carbon catalyst support. Throughout the carbonization process, the aerogel mixture can boost the electrical and thermal leads of the catalyst [28].

In a composite electrocatalyst, using an aerogel structure can increase the overall surface area as well as the active reaction site on the surface of the electrocatalyst. An additional benefit is the high anatase TiO_2 composition, as determined by the XRD measurements. Anatase has a higher electrocatalytic activity than rutile TiO_2. Besides increasing peak current density, the metal-support interaction also shows a favourable effect, and the material combination of PtRu and TiO_2-GA is an effective electrocatalyst in DMFCs. The performance of PtRu/C is significantly poorer than that of PtRu agglomeration, where the ECSA value as well as the crystallite size as determined by XRD are emphasized. Such state reduces the possibility of the electrocatalyst surface to be an active site and lowers the performance of the electrocatalysts.

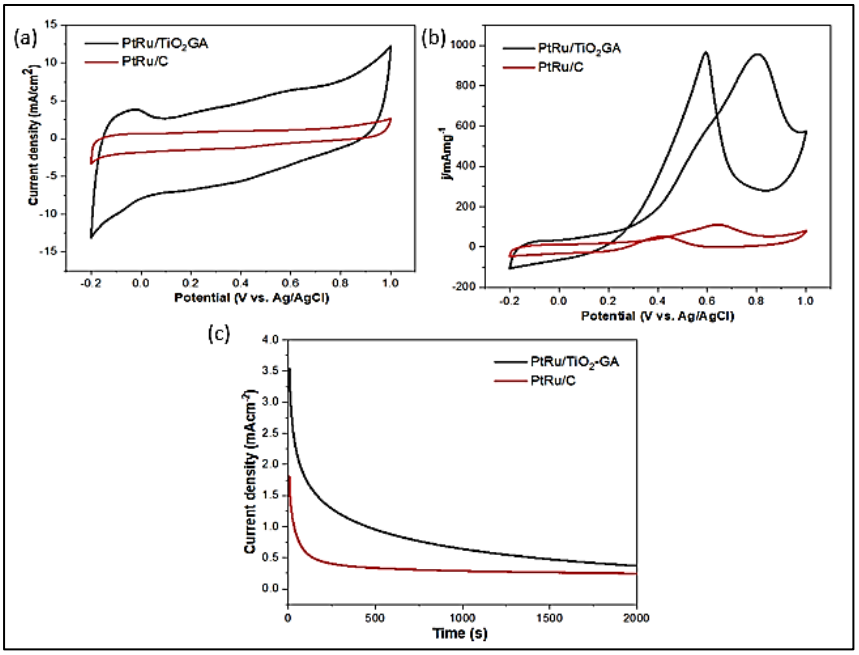

Figure 4. (a) CVs of PtRu/TiO_2-GA and PtRu/C in N_2 saturated 0.5 M H_2SO_4 solution at scan rate 50 mVs^{-1}, (b) CVs of PtRu/TiO_2-GA and PtRu/C in N_2 saturated 0.5 M H_2SO_4 solution containing 1 M CH_3OH at scan rate 50 mVs^{-1}, and (c) Chronoamperometric curves of H_2SO_4 in N_2 saturated containing 1 M CH_3OH

Table 2. Assessment of the performance outcomes with the previous research

Research	**Type of Catalyst**	**ECSA (m^2/g_{PtRu})**	**Mass ativity (mA/mg_{PtRu})**
This study	PtRu/TiO_2-GA	68.44	957.15
This study	PtRu/C	20.44	79.11
Abdullah et al. [16]	PtRu/TiO_2-CNF	10.4	345.64

Ramli et al. [30]	PtRu/CNC	16.23	427.00

CA tests were carried out to verify the stability of electrocatalyst and endurance for long-term MOR performance in a 1M methanol solution containing 0.5 M H_2SO_4 for 2000 seconds. At 0.6 V, the potential was kept constant. The CA curves electrocatalysts for the PtRu/TiO_2-GA and PtRu/C are shown in Figure 4(c). The current density of electrocatalysts indicates a dramatic decline at the beginning of the experiment probably due to methanol oxidation mediation poisoning. The limiting current PtRu/TiO_2-GA was higher than PtRu/C across the entire duration, indicating better stability. The result demonstrated that the PtRu/TiO_2-GA catalyst showed higher stability than PtRu/C. Consequently, it is assumed that the synergistic effects of combining Pt and Ru help to reduce poisoning rates [16]. Hence, the 3D hierarchical porous TiO_2-graphene aerogel encapsulation structure is important in enhancing the durability. This unique structure can be extensively applicable to commercial catalytic products. It was also shown that TiO_2-GA as support was a better alternative to bimetallic support since the mesoporous

structure of TiO_2-GA could improve the total surface area on the electrocatalyst surface area.

Conclusion

The novel 3D hierarchical porous TiO_2-graphene aerogel (TiO_2-GA) was synthesized using hydrothermal technique and then freeze-dried before being used as a catalytic support for an anodic catalyst in the DMFC. Therefore, the catalytic activity of electrocatalyst was determined by comparing it to that of commercial PtRu/C. The maximal mass activity of the manufactured electrocatalyst PtRu/TiO_2-GA was 12 times that of the PtRu/C commercial electrocatalyst. The catalyst support of TiO_2 and the graphene aerogel catalyst structure resulted in the maximum catalytic activity. The reaction between the PtRu and TiO_2-GA catalysts at the metal-support interface serves to advance the characteristics of catalyst layers. Therefore, PtRu/TiO_2-GA is a viable choice for anode catalyst support in DMFCs.

Abstract

Various types of promising proton exchange membrane (PEM) are based on thermoplastics due to their excellent conductivity, good thermal and chemical stability, high durability as well as low fabrication and material cost. Sulfonated poly (ether ether ketone) or SPEEK is one of the examples of thermoplastic polymer that has been sulfonated to enhance its fundamental properties. These properties can be altered and improved through the fabrication process and modifications of the membranes. Thus, current researches on combining SPEEK with other polymers and inorganic particles through various fabrication methods are discussed in this review. The characterization of SPEEK-based membrane in terms of its water uptake, methanol permeability, proton conductivity, thermal and mechanical stability are also included in the discussion. The impact of membrane modifications on the fundamental properties and comparison of different membrane preparation methods are addressed. In addition, the advantages and drawbacks of modified membranes are summarized.

Keywords: SPEEK; polymer electrolyte membrane; fuel cell

Abstrak

Pelbagai jenis polimer elektrolit membran yang diyakini adalah daripada termoplastik disebabkan oleh kekonduksian yang cemerlang, kestabilan terma dan kimia yang baik, ketahanan yang tinggi dan kos bahan dan pembuatan yang rendah. Poli (eter eter keton) tersulfonat atau SPEEK adalah satu contoh polimer termoplastik yang telah disulfonasi untuk mempertingkatkan ciri asas seperti pengambilan air dan ketertelapan metanol yang rendah, meningkatkan kekonduksian proton dan mempunyai ketahanan dan kestabilan yang tinggi. Ciri-ciri ini boleh diubahsuai dan dipertingkat melalui proses fabrikasi dan pengubahsuaian ke atas membran. Oleh yang demikian, para penyelidik menggabungkan SPEEK dengan polimer jenis lain dan bahan tak organik melalui pelbagai cara fabrikasi telah dibincangkan dalam ulasan ini. Kesan daripada pengubahsuaian membrane k etas ciri-ciri asanya dan perbandingan cara penyediaan membrane turut dibincangkan. Seterusnya, kelebihan dan kekurangan membran terubahsuai turut diringkaskan.

Kata kunci: SPEEK, membran elektrolit polimer, sel fuel

Introduction

As of September 2021, the current world population is 7.9 billion, according to the most recent United Nations estimates as elaborated by Worldometer. It is estimated that the population will reach up to 10 billion in another 30 years [1]. In line with the increase in the world population, the demand for energy also increases. Conventional fossil fuels are the primary sources of power to meet the world's energy demands. However, the depletion of fossil fuel sources and the rise of environmental issues, i.e., global warming due to the excessive releases of greenhouse gases have shifted the interest into the environmentally sustainable energy research [2]. One of the alternative energies that can solve this issue is through the utilization of natural sources such as hydrogen.

Hydrogen is one of the most abundant elements in the universe. For instance, the sun consists mainly of hydrogen. While on earth, hydrogen combines with other elements either in liquid, gas, or solid form as it does not exist freely in nature. As it only exists in a compound form, specific processes are required to split and obtain hydrogen, such as reforming, hydrolysis, and electrolysis [3]. Hydrogen can be utilized in many applications such as petroleum refining and fertilizer production, and for the past decades it has been widely used in fuel cell to generate electricity.

Fuel cell technology

Fuel cell is an electrochemical device that converts fuel and oxidant into electricity [4]. Basically, hydrogen is supplied as fuel at the anode and oxygen (oxidant) at the cathode. At the cathode, oxygen is reduced, and oxygen ions are produced. These oxygen ions will pass through the electrolyte and move towards the anode. When reaching the anode, they react with the protons that are broken down from hydrogen [5]. Electrons that are obtained from hydrogen molecules travel at the outer circuit and generate electricity. The half-reactions of this process at both sides are shown by the following equation:

$$\text{Cathode} : \tfrac{1}{2} O_2 + 2H^+ + 2e^- \rightarrow H_2O \quad (1)$$

$$\text{Anode} : H_2 \rightarrow 2H^+ + 2e^- \quad (2)$$

$$\text{Overall reaction} : H_2 + \tfrac{1}{2} O_2 \rightarrow H_2O \quad (3)$$

As it generates electricity through an electrochemical reaction, the by-products from the reaction are basically water and heat, which do not contribute to the environmental pollution. In fact, the water can be reused in the system, and the heat that is generated can be recycled into another system, such as a water heater system. These reused and recycled processes eliminate energy wastes and yield high energy efficiency of fuel cells up to 90% [6]. Correspondingly, there are various types of fuel cells depending on the types of electrolytes that are used. They are further sub-categorized by the types of fuel (hydrogen, reforming hydrogen-rich fuels, i.e., methanol, ethanol, and hydrocarbon), and operating temperature- low temperature (LT), intermediate temperature (IT), high temperature (HT). For example, direct methanol fuel cell (DMFC) and direct ethanol fuel cell (DEFC), also known as direct liquid fuel cell (DLFC), are the extension study to the proton exchange membrane fuel cell (PEMFC). While for microbial fuel cell (MFC), some improvements are being made where glucose is employed on-non enzymatic noble metal electrode to overcome certain drawbacks of the conventional MFC, which is known as direct glucose fuel cell (DGFC). Whereas a direct borohydride fuel cell (DBFC) is a sub-category of an alkaline fuel cell (AFC), and the latest research has reported that the anionic exchange membrane fuel cell (AEMFC) possesses great potential in replacing the traditional liquid electrolyte AFC [7]. In SOFC, there are three sub-categories, which are differentiated by the range of operating temperature, i.e., LT-SOFC, IT-SOFC and HT-SOFC. Each temperature range requires different types of material to be used as electrolytes. All existing fuel cells and their characteristics, including the efficiency, are summarized in Table 1.

Table 1. Types of fuel cells and their characteristics

Electrolyte	Types of Fuel Cells	Sub-Category	Operating Temperature (°C)	Fuel/Oxidant	Efficiency (%)
Phosphate buffer	MFC	DGFC	25-30	Organic load/Oxygen	-
Alkaline solution	AFC	DBFC	50-90	Sodium or potassium borohydride/Oxygen or hydrogen peroxide	50-70
		AEMFC		Hydrogen/Oxygen	
Solid polymer membrane	PEMFC	DMFC DEFC	50-120	Methanol/Oxygen Ethanol/Oxygen	40-50
Acidic solution	PAFC		175-220	Hydrogen/Oxygen	40-45
Molten mixture	MCFC		600-650	Hydrogen/Oxygen	50-60
Ceramic oxides	SOFC	LT-SOFC IT-SOFC HT-SOFC	400-600 600-800 800-1000	Hydrogen or hydrocarbon/Oxygen	60-90

Among the types of fuel cells, DMFC which is the sub-category of PEMFC has been widely used in various applications- covering small-scale appliances to mobile usage such as transportation. These broad applications are due to the advantages of low operating temperature, which lead to rapid start-up and a long-life span. Besides that, the DMFC system yields high power density and through its compact design, provides superior transportation facilities compared to other existing fuel cells. Although it has a compact design, complex heat and water management are unavoidable. Also, it uses expensive materials as a catalyst, such as Platinum, Pt, and Palladium, Pd to speed up the chemical reaction, and Nafion® for membrane materials. However, owing to its vast advantages, DMFC has generated an interest among researchers to find a way to overcome the drawbacks.

Development of proton exchange membrane (PEM) for DMFC

DMFC is a type of fuel cell that uses methanol as fuel to replace hydrogen in a typical fuel cell. As methanol is a non-volatile liquid fuel, it does not easily evaporate into gas at room temperature. In fact, this type of fuel cell does not require any fuel processing equipment as the mixture of methanol and water are directly fed into the cell. Therefore, it is easy to store and handle compared to the volatile hydrogen gas. Other advantages of using methanol in fuel cell systems are the high energy density that is obtained; due to its abundant resources, the price of methanol is relatively cheap and affordable. The reactions that take place in both electrodes are as follows:

Anode : $CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^-$ (4)

Cathode : $3/2\ O_2 + 6H^+ + 6e^- \rightarrow 3H_2O$ (5)

Accordingly, the overall cell reaction is

Overall : $3/2\ O_2 + CH_3OH \rightarrow CO_2 + 2H_2O$ (6)

One of the key components in fuel cells, especially for DMFC, is the proton exchange membrane (PEM). PEM is needed to complete the electrochemical reaction to fulfill the energy requirement in which it serves to transfer H^+ within itself from anode to cathode [8]. The high and outstanding PEM must meet specific criteria such as having good oxidative and hydrolytic stability, possessing high mechanical and thermal stability, and

yield a high proton conductivity as well as being cost effective in the fabrication of membrane electrode assembly (MEA). As it is located between the electrodes, the PEM must also have good barrier properties to avoid the mixing of fuel (methanol) from the anode and oxidant (oxygen) coming from the cathode. The permeability of the membrane is an unresolved issue that is still under ongoing research. The high permeability membrane or leakage of the MEA (consisting of PEM) can contribute to a serious methanol crossover issue, which eventually will deteriorate the performance of fuel cell. Therefore, a high durability membrane is needed to overcome this issue.

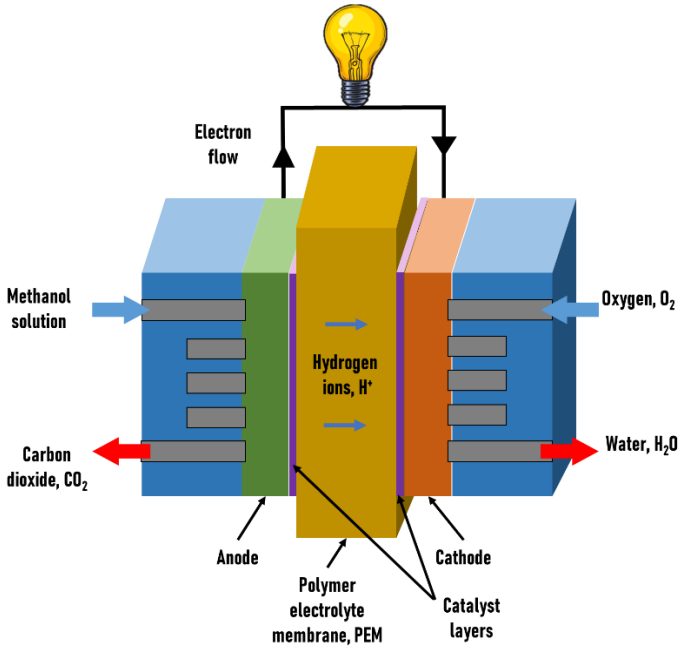

Figure 1. Working principle of DMFC

Table 2. Target requirement for an ideal PEM [9]

Criteria	**Target Requirement**
Proton conductivity	0.1 – 1 S cm^{-1}
Oxygen crossover	2 mA cm^{-2}
Fuel crossover	2 mA cm^{-2}
Electrical resistance	1000 Ω cm^{-2}
Durability	20,000 cycles
Chemical stability	More than 500 h

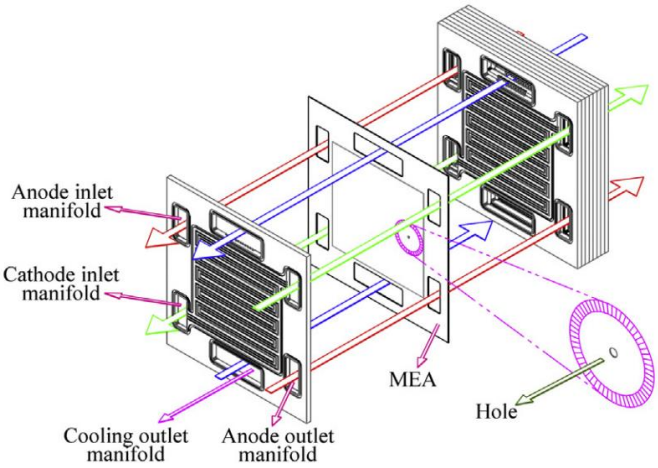

Figure 2. The leakage passing through the PEM [10]

Classification of polymeric membranes

Polymeric membranes can be classified into fluorinated and non-fluorinated polymers. Fluorocarbon-based ion-exchange membrane or Nafion® is the most common and readily available membrane in the market. Nafion® possesses unique structures that contribute to stability in terms of mechanical and chemical aspects as well as imparts high proton conductivity [11]. However, the presence of (approximately 4 nm) ionic clusters which are considerably large in size compared to methanol molecules, make them penetrate easily from anode to cathode. The methanol crossover is also being contributed by the separated nanophase of hydrophobic and hydrophilic domains of Nafion®. This methanol crossover will create a mixed potential that includes methanol and performance loss at cathode and anode, respectively. It will simultaneously affect the oxygen reduction reaction (ORR) and methanol oxidation reaction (MOR), which lead to a lower cathode potential and decrease in the cell voltage (as much as 0.15-0.2V)[12]. Besides that, electrocatalyst poisoning might occur at the cathode due to methanol oxidation from the crossover [13].

The ways to overcome these problems are (a) synthesizing new polymeric membranes (non-fluorinated polymers) such as poly ether sulfone (PES), polyphenyl sulfone (PPSU), poly benzimidazole (PBI)[14, 15], poly ether ether ketone (PEEK), polyvinyl alcohol (PVA)[16] and polyimide (PI); (b) sulfonation of aromatic polymers; and (c) incorporating the existing polymer membrane with other materials which are also known as filler. Filler can consist of inorganic particles such as titanium dioxide, iron titanate, zirconium phosphate, silica, heteropolyacid, and zeolites. The incorporation of this filler into the polymer produces a composite or hybrid membrane. This composite or hybrid membrane with control structure and outstanding properties for DMFC is attracting significant attention among researchers. This is proven by the number of papers that have been published in high-impact journals for the past ten years. Using the keywords search of 'composite membrane' or 'hybrid membrane' and 'direct methanol fuel cell' in the ScienceDirect website, the increasing trend of published papers that are related to the keywords is observed in Figure 3.

Due to the shortcomings and drawbacks of the perfluorosulfonic acid membrane as stated, non-fluorinated polymers, specifically poly arylene ether ether type-polymers such as PEEK, PES, PS, PI, PBI, and their derivatives have the potential to replace it. Besides having good thermal and mechanical stability, these alternative polymers also possess good cost-effective properties as well as high proton conductivity.

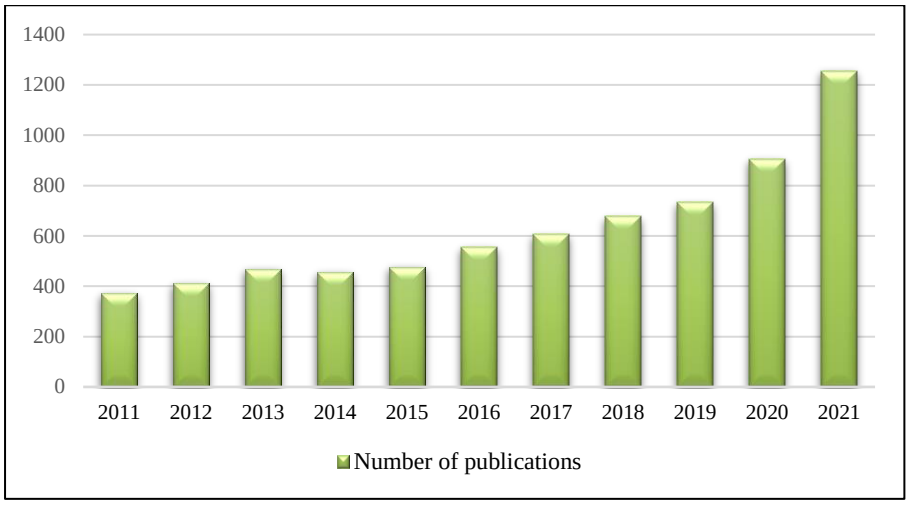

Figure 3. The trend of publication of composite membrane in high impact journals for the past 10 years

Sulfonated and modified PEEK as PEM

Polyether ether ketone or PEEK is a semi-crystalline thermoplastic polymer that belongs to the polyketone family of polymers (PEK, PEEK, PEEKK, PEKK, PEKEKK). Amongst them, PEEK is the most commonly used and produced in bulk production. The key properties of PEEK that make it widely used in various fields such as aerospace, automotive, electrical, and biomedical application are its good solvent resistance, dimensional stability, biocompatible, long life, and it exhibits exceptional mechanical properties [17, 18].

In order to improve the hydrophilicity and transportation of ions in PEEK material, sulfonation is carried out. Sulfonation is the process of either introducing sulfonic acid groups using sulfuric acid directly into the polymer chains as shown in Figure 4, by polymerizing functionalized sulfonated monomers or by grafting the sulfonic acid onto the aromatic backbone to produce random copolymers [9, 19]. However, the last method does not seem to be suggested as it leads to chemical degradation of the polymer chain [20].

The charged groups are important as they separate the protons from each other by water molecules and provide proton transport. Their addition depends on the substituents present in the ring [18]; substitution occurs on the aromatic ring between two ether (-O-) links. Many other polymers have also been sulfonated to enhance their properties in terms of wettability, water flux, perm selectivity, and solubility in solvents for processing. The solubility of PEEK enables it to be easily cast from organic solution and to eliminate complicated processes rather than when to fabricate perfluorosulfonic acid membranes. Other polymers, sulfonated polyarylene ether ketones (SPAEKs) with 60% of sulfonation degree, showed the best performance in terms of conductivity and methanol permeability [19].

At the same time, sulfonation also increased the proton conductivity of the polymer due to the improved hydrophilicity [21]. The proton conductivity is increased by increasing the degree of sulfonation. However, a higher sulfonation degree will increase the water uptake and raise another swelling issue. Swelling can make the membrane fragile, and changes of dimensions that lead to mechanical failures. Therefore, an optimum and moderate degree of sulfonation is crucial when undergoing the SPEEK sulfonation process. Based on the research by Li et al., it is advisable that for DMFC application, the degree of sulfonation for SPEEK is in the range of 30% to 60%. This is because too low a sulfonation degree will give poor conductivity. Otherwise, the polymers are highly swollen in methanol

water solution (1 M) when the degree of sulfonation is above 60% [22].

In the recent past, researchers have incorporated SPEEK with fillers to further enhance its properties, in addition to overcoming some limitations of having SPEEK alone as the membrane. This is due to the presence of significant numbers of dead-end channels in SPEEK limits, the conductivity thus affecting the overall performance [24]. Therefore, in order to not sacrifice the mechanical strength in the higher degree of sulfonation, fillers are added into an organic polymeric matrix.

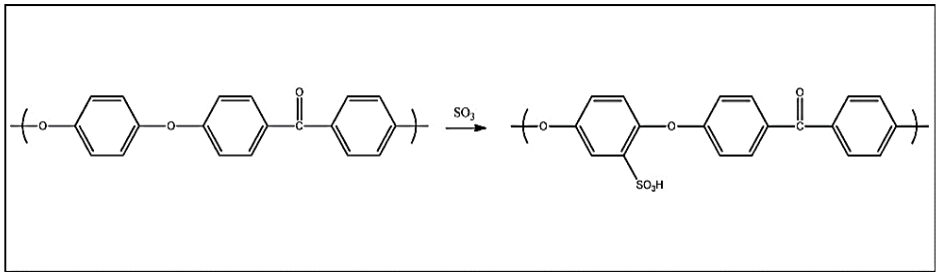

Figure 4. Process of PEEK sulfonation [23]

Preparation methods of composite PEM

As polymer SPEEK owns many of the dead channels, it limits the flow of effective ionic conductivity. These ionic conductive channels can be built by incorporating organic polymers with inorganic backbones. Different ways of incorporating them are illustrated in Figure 5. Organic-inorganic composite membrane can benefit in mechanical and thermal stability from inorganic backbone, while the organic polymer gives advantages in terms of chemical reactivity, ductility and flexibility of processing.

The composite of ionically conductive polymer and inorganic material can be varied, as shown in Figure 6. Usually, an inorganic precursor such as a monomer or oligomer is blended with a linear or network polymer matrix. The preparation methods of the nanocomposite materials include mixing or blending, *in-situ* polymerization or infiltration, and sol-gel.

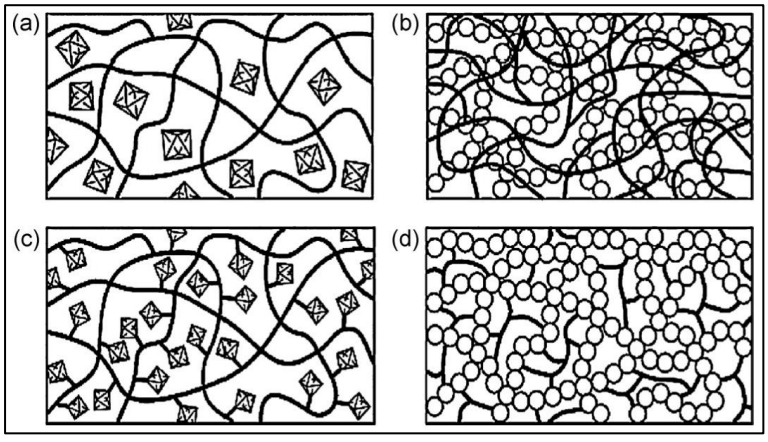

Figure 5. Different ways of incorporating the inorganic system in organic polymers: (a) inorganic moiety embedded into an organic polymer (b) interpenetrating networks with chemical bonds (c) inorganic groups incorporated by bonding to the backbone and (d) dual organic-inorganic hybrid polymer [25]

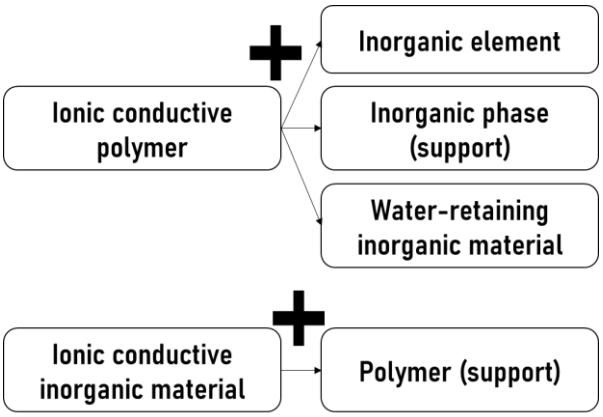

Figure 6. Different ways of organic-inorganic composite membranes arrangements [26]

Mixing or blending method.

The simplest method to prepare composite PEM is by direct mixing or blending of inorganic materials into the organic polymer matrix. There are two ways of blending the composite, which are melt blending and liquid-state blending. In both ways, it is important to ensure the desired composite components can be dispersed in a common solvent or melt at a high temperature.

Salarizadeh et al. [27] prepared blend nanocomposite SPEEK/perfluorosulfonic acid (PFSA)/barium strontium titanate (BST) membranes by dissolving SPEEK in N,N-dimethylacetamide (DMAC) followed by mixing with the BST dispersion and PFSA solution. The experimental procedure is shown in Figure 7.

Although melt blending is more common due to its efficiency and prevention from the dispersing of hazardous material into the environment, the filler agglomeration tends to occur when the inorganic nanoparticles are dispersed in polymer matrix. In order to overcome the limitation, the surface of the nanoparticles is being modified to produce nanostructural composites.

Composite of nanosilica and polymer is the common example of membrane that is prepared by solution blending due to its simplicity in preparation. This membrane is widely being researched for gas separation, pervaporation and PEM in fuel cell application [28].

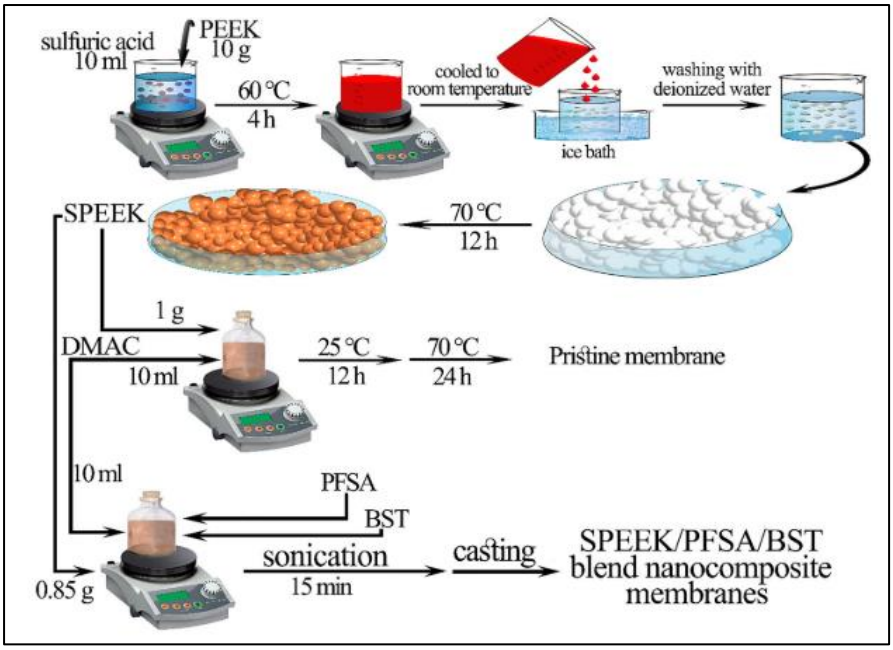

Figure 7. The steps involved in preparing the blend nanocomposite membrane SPEEK/PFSA/BST [29]

In-situ polymerization or infiltration method

In this method, inorganic nanoparticles are introduced in the polymer membrane to modify the transport properties. Firstly, the preformed membrane will be immersed in a solvent, allowing it to swell in order to increase the pore or void volume before the inorganic particle is doped or infiltrated. After the inorganic particle is infiltrated, the composite is cured by heat, radiation, or chemical grafting to gain covalent bonding inside the matrix. The drawback of this method is the leaching of inorganic materials from the membrane matrix [30].

Sol-gel method

This method is favorable as it is an environmentally friendly way and is conducted in low temperature. Briefly, sols are dispersions of colloidal particles in a liquid, while gels may be classified into four categories: (i) well-ordered lamellar structures of inorganics with organics (i.e., organopolysilsesquioxanes; (ii) covalent disordered polymeric networks; (iii) polymer networks formed through physical aggregation; (iv) disordered structures of inorganic and organic networks. There are two consecutive steps in sol–gel reactions, which are hydrolysis of metal alkoxides to produce hydroxyl groups and polycondensation of the hydroxyl groups to form a three-dimensional network. The process is started with solvents (low molecular weight) with alkoxide precursors $M(OR)_n$, (M is a network-forming element: Si, Ti, Zr, Al, B, etcetera, and R is an alkyl group (C_xH_{2x+1})) and water. Later, low molecular weight byproducts (alcohol or water) are produced during hydrolysis and condensation. They must be removed, resulting in shrinkage during the sol-gel process.

Modification of SPEEK membrane

Sulfonated PEEK is an organic thermoplastic polymer that possesses outstanding thermal and mechanical properties. As mentioned in the previous section, fillers are needed to overcome some of the drawbacks of SPEEK that can limit its potential to emerge as high-performance membrane. The introduction of nanostructures fillers can overcome the thermal and mechanical instability of SPEEK polymer. The inorganic materials as additives such as hygroscopic oxides (silicon oxide, zirconium oxide, titanium dioxide, iron-titanates, zeolites, and boron phosphate), solid acids and heteropolyacids (HPAs), clay, graphene oxide (GO), carbon nanotubes (CNTs), fullerene and perovskite oxides have shown improved performance for SPEEK membrane [31–33]. Besides overcoming the instability in thermal and mechanical properties, the modifications to SPEEK membrane through inorganic filler also improve methanol permeability in DMFC.

Zhang et al. [34] synthesized nanocomposite membrane by incorporating sulfonated hallyosite nanotubes (SHNTs) into the SPEEK matrix. The well-dispersed SHNTs in the SPEEK matrix bring advantages in terms of the thermal and mechanical stabilities of the membrane. Besides that, the water uptake, ionic exchange capacity, and proton conductivity have been improved tremendously due to the construction of ionic channels that are interconnected by the SHNTs in the SPEEK matrix. Figure 8 shows the improved proton pathways that will allow efficient proton transfer and lead to the enhancement of proton conductivity.

Bagheri et al. [35] prepared SPEEK, sulfonated poly (vinilidinfluoride-co-hexaflourpropylen) (SPVDF-co-HFP), and lanthanum chromite ($LaCrO_3$) as nanocomposite blend membrane using solvent casting method. The increasing in proton conductivity is observed at the nanoparticle content of 1.5 wt.%, and the addition of 1.5 wt.% $LaCrO_3$ nanoparticles managed to make this membrane as effective barrier against methanol permeation. Figure 9 shows the performance of the composite membrane with different content.

Later, Salarizadeh et al. [29] prepared another blend nanocomposite membrane of SPEEK with two different types of additives, namely perfluorosulfonic acid (PFSA) and $Ba_{0.9}Sr_{0.1}TiO_3$ (BST) doped-perovskite nanoparticles. The addition of both additives has indicated that proton conductivity is improved while methanol permeability is decreased compared to pristine SPEEK membrane. The increase in proton conductivity is contributed by the high specific surface area of perovskite nanoparticles

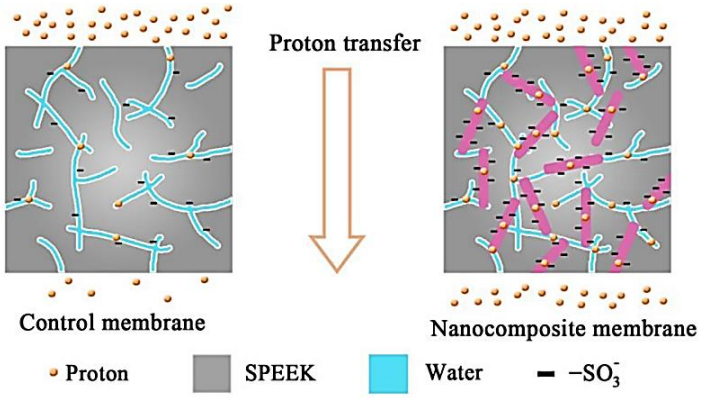

Figure 8. SHNTs interconnect the ionic channels within SPEEK matrix via -SO_3H groups [34]

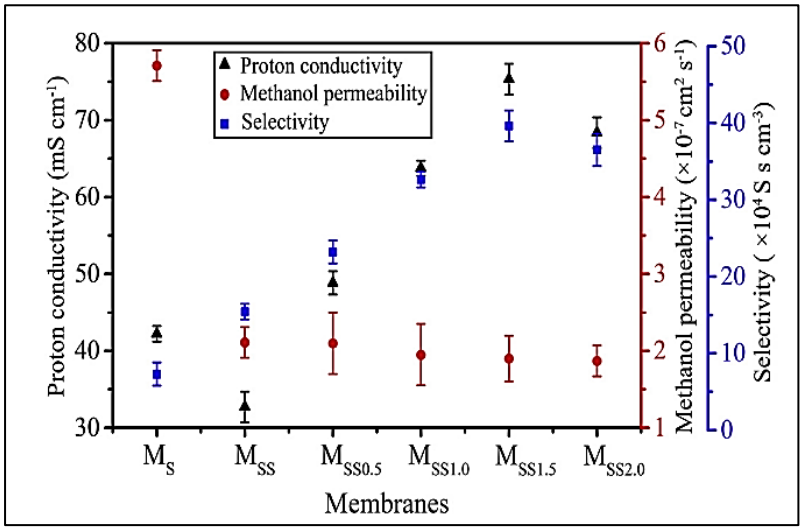

Figure 9. Comparison of different content with the performance of prepared membrane [35]

Table 3. Influence on membrane performances during the SPEEK modification

Composite	Improvement	Ref.
SPEEK/SnO_2/sBH	Water retention properties increase, which consequently enhance the ionic conductivity of the composite membrane. Methanol diffusion channels decrease and demonstrate the high power density as well as excellent durability	[36]
SPEEK/QDs/CS	Enhanced through-plane conductivity and decreased transfer anisotropy	[37]
sPEEK/sGNR-sGQD	Improved physico-chemical properties resulting in enhanced electrochemical selectivity. Significant enhancement in DMFC performance and better durability can be observed	[38]
SPEEK/CNFs	Improved mechanical strength and water uptake of the composite membranes and low methanol permeability	[39]
SPEEK/PVA/TEOS	The proton transport and fuel cells performance increased	[40]
SPEEK/PFSA/BST	Improved proton conductivity and methanol barrier. Enhanced mechanical stability	[29]

Properties of SPEEK composite membrane

Water uptake, swelling ratio, ion-exchange capacity, mechanical properties

The water uptake (WU) and membrane swelling (SW) are essential parameters in DMFC application as they directly affect the proton conductivity and mechanical stability of the membrane. Controlling the WU of the membrane is quite necessary for high WU can lead to mechanical and dimensional stability while low WU decreases the proton transferring rate within the membrane. They are calculated from the following equations:

$$WU\ (\%) = \frac{m_{wet} - m_{dry}}{m_{dry}} \times 100 \quad (7)$$

$$SW\ (\%) = \frac{L_{wet} - L_{dry}}{L_{dry}} \times 100 \quad (8)$$

To determine the water uptake (WU) and membrane swelling (SW), the membranes are dried and then their weights (M_{dry}) and the thickness (L_{dry}) are measured. After that, they are soaked in deionized water. Finally, the surface water of membranes is blotted with a clean paper, and immediately weights (M_{wet}) and thickness (L_{wet}) of membranes are measured.

The ion-exchange capacity (IEC) value is defined as the molar number of fixed sulfonate sites per gram polymer. It is decided by the concentration of exchangeable ions in membranes and determined by an acid-base titration method[41]. It is very closely related to water uptake as increasing the water uptake will increase the value of IEC. The value of IEC was calculated based on the following formula:

$$IEC = \frac{(N_{NaOH} \times V_{NaOH})}{mass_{dry}} \times 100\ \% \quad (9)$$

The dried membrane is soaked in a saturated NaCl solution for a certain time and later is titrated with a NaOH solution using phenolphthalein as an indicator. The N_{NaOH} is the concentration of NaOH solution, while V_{NaOH} is the volume of NaOH solution consumed. The mechanical properties of the membrane are investigated using a universal tensile testing machine. It is evaluated with tensile stress-strain tests. Typically, the value of Young's modulus is calculated from the slope of the initial linear part of the stress-strain curve. The maximum stress value of the entire curve was taken as the tensile strength [42].

Thermal and chemical stability

The thermal stability of the membrane is measured by its degradation of decomposition at a specific temperature. The membrane that has a good thermal stability should withstand a required temperature for a longer time before it degrades or decomposes [43]. It is usually investigated by a thermogravimetric analyzer (TGA) where the weight loss of the samples is determined.

The thermal stability study of the composite membrane SPEEK with inorganic additive, clay and electrospun fibers is carried out by Awang et al. [43]. The thermogravimetric analysis indicated that SPEEK with added inorganic filler (i.e., Cloisite) gives a higher degradation temperature compared to pristine SPEEK. It shows that the composite organic-inorganic membrane is thermally stable, especially when the amounts of Cloisite is increased as shown in Figure 10. The Cloisite acts as a mass transport barrier and insulator against the colatile compound when the heat is applied [44].

The chemical stability of the membrane is usually being tested by Fenton's reagent. The experiment subjects the membrane to a very large excess of hydroxyl radicals between 60 and 80 °C to assess chemical durability. The reagent is made when ferrous sulfate is dissolved in hydrogen peroxide (H_2O_2) aqueous solution. This is to mimic the real situation during DMFC operation where H_2O_2 is formed at the cathode side due to the partial reduction of O_2 and the iron ion (Fe^{2+}) that is formed from the corrosion of the iron back plate. The migration of Fe^{2+} to the cathode side will react with H_2O_2 and produces a free radical similar to the Fenton reagent. Then the prepared membrane is immersed in the reagent under stirring at a specific temperature. Carbon dioxide (CO_2) will be produced as a by-product when free radicals react with organic polymer. As CO_2 gas forms bubbles, the membrane structures tend to break if they cannot withstand the bubbles' pressure. Oxidative stability of the membrane is recorded by the time the membrane begins to break [35].

From the chemical stability test conducted by Salleh et al. [45] on composite membrane SPEEK/Cloisite/ triaminopyrimidine (SP/CL/TAP), it is proven that the presence of inorganic particles in nanocomposite membrane increased its resistance towards radical attack. The nanocomposite membrane can maintain its weight up to 48 hours. From the FESEM image, as shown in Figure 10, the surface deformation of SP/CL/TAP membrane started to occur after being exposed to Fenton reagent solution for 24h (Figure 11(h)).

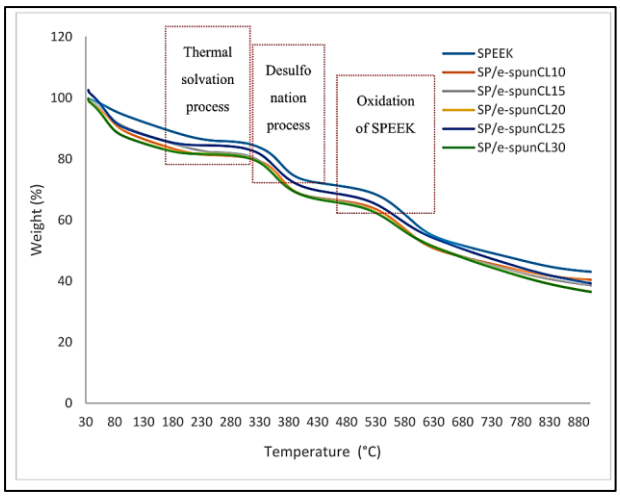

Figure 10. TGA of the SPEEK and composite SPEEK membrane with different amounts of Cloisite [43].

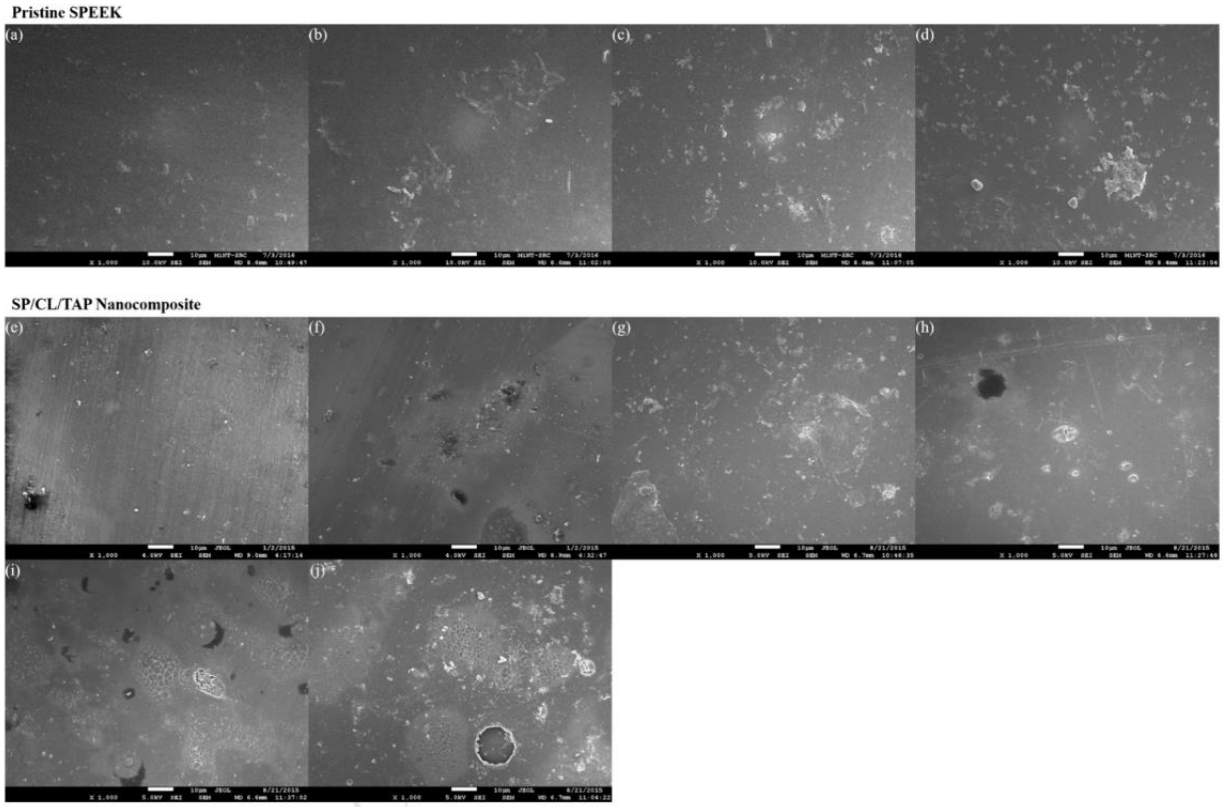

Figure 11. FESEM micrographs of pristine SPEEK and nanocomposite membrane SP/CL/TAP surface before (a,e) and after exposed to Fenton reagent solution for 6h (b,f), 12h (c,g) and 24h (d,h), 48h (i) and 96h (j) [45]

Methanol permeability

The methanol permeability (P, cm^2 s^{-1}) can be determined by different techniques such as potentiometry, gas chromatography technique (GC), and densimetry method. Each and every technique have its respective advantages and drawbacks, as summarized in Table 4. These three different experimental methods, however, provided very comparable results.

The cell was separated into two equal-sized compartments by a membrane. The compartment in the left side was filled with methanol solution while the compartment in the right was filled with deionized water and both part had equal volume. The prepared membranes with certain areas are located vertically between the two compartments after keeping them in deionized water. The schematic experimental set-up is illustrated in Figure 12 [46]. As there is a methanol concentration gradient between these two parts, methanol can diffuse from the left to the right compartment, and methanol permeability was measured as a function of time. It is calculated from the following equation:

$$C_R(t) = \frac{A\,P}{L\,V_R} C_L(t - t_0) \quad (10)$$

where, C_L and C_R are the concentration of methanol in methanol and water compartment (mol L^{-1}) respectively; L is the thickness of the membranes (cm), A is the diffusion area (cm^2), and V_R is the volume of deionized water in water compartment (mL). Methanol concentration in the water compartment was examined with time using a density meter.

Table 4. Summary of different techniques used to measure methanol permeability

Techniques	Advantages	Drawbacks
Potentiometry	• Simplest method • Cheapest	• Limited for certain parameters • Absolute values of concentration at a given time cannot be measured • Time-consuming
Gas chromatography technique	• Highly precise	• Very expensive
Densimetry	• Most efficient in terms of accuracy, simplicity, experimental time, and cost	-

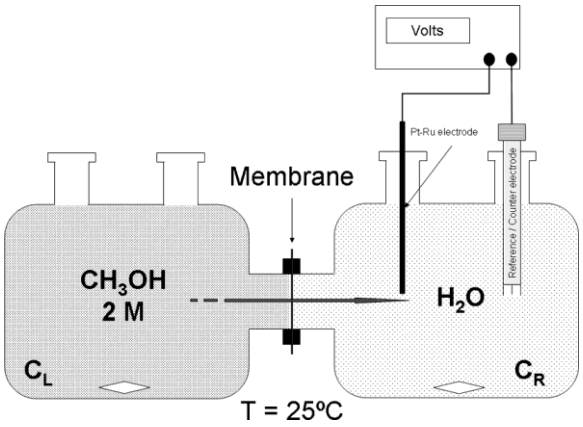

Figure 12. Schematic diagram of experimental set up to determine methanol permeability across the membrane [46]

Proton conductivity

The electrochemical performance of the composite membrane is often indicated by the value of proton conductivity. The proton conductivity heavily relied on the degree of sulfonation, water uptake, and methanol permeation. A summary of fundamental properties that contributed to proton conductivity of SPEEK based membrane is tabulated in Table 5. The proton conductivity is determined from the following equation:

$$\sigma = L/RA \quad (11)$$

where, σ is the proton conductivity of the membrane (S cm^{-1}), L is the thickness of the membrane (cm), R is the resistance of the membrane (Ω), and A is the surface area of the two electrodes (cm^2).

Gong et al. [42] illustrated proton conduction in composite membrane SPEEK/BPO_4@CNT in Figure 13. The composite membrane has higher proton conductivity compared to the pure SPEEK membrane. It could be primarily attributed to the dissociation of the absorbed water molecules on the BPO_4. The fundamental properties that contribute to the performance of composite SPEEK-based membranes that have been discussed in the earlier section are summarized in Table 5.

Table 5. Summary of fundamental properties of composite membrane SPEEK

Composite SPEEK-Based Membrane	Water Uptake (%)	Methanol Permeability ($\times 10^{-7}$ $cm^2 s^{-1}$)	Proton Conductivity @RT (Scm^{-1})	Ref

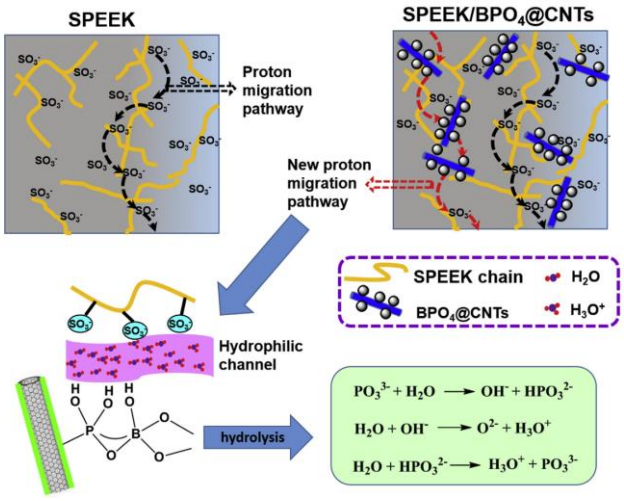

Figure 13. Schematic illustration of proton conduction in SPEEK and composite membrane SPEEK [42]

Future perspective and conclusions

The potential of composite SPEEK membrane as high-performance PEM is undeniable based on the past research. The properties such as water uptake and methanol permeation are closely linked to the performance of the membrane in terms of mechanical, thermal, chemical stability, and proton conductivity. With the results that have been obtained in literatures, the composite SPEEK membrane will be a strong competitor that has a big chance to replace the Nafion membrane. However, further investigations are needed i) to find optimum parameters and cost-effective methods in preparing the membrane , ii) to improve the distribution and proportion of inorganic particles in the polymer matrix , iii) to optimize the water uptake and methanol permeation in the membrane, iv) to produce a membrane that is suitable for higher temperature, humidity, and pressure.

In conclusion, the role of filler in improving the performance and properties of the SPEEK membrane is significant in comparison to the properties of either component in isolation.

Abstract

Solid oxide fuel cell (SOFC) is a technology used to generate electricity with less emission. Selection of a suitable, compatible cathode material that will be used with the ionic and protonic electrolyte is crucial in achieving an excellent performance of intermediate-low temperature SOFC. $LiCo_{0.6}Sr_{0.4}O_2$ (LCSO) is stoichiometrically prepared via glycine nitrate combustion followed by ball milling and triple roll mill (TRM) machine to produce a homogeneous LCSO cathode ink. The prepared sample powder of LCSO is initially characterised by X-ray diffraction (XRD) and scanning electron microscope (SEM) fitted with energy-dispersive X-ray spectroscopy. The XRD demonstrated that the prepared LCSO powder calcined at 800 °C shows a phase structure of rhombic lattice and space group of R-3m. The prepared ink is then layered on both sides of the samarium-doped-ceria (SDC) electrolyte to produce LCSO | SDC | LCSO symmetrical cell. The prepared ink has varied gap sizes on the TRM machine. The electrochemical performance of electrochemical impedance spectroscopy reports that the best gap size is at 40 µm with the lowest polarisation resistance (R_p), of 8.32 Ω. In conclusion, this work confirms the importance of a high-quality lithium-based cathode ink in SOFC applications.

Keywords: solid oxide fuel cell, cathode, ink, lithium, triple roll mill

Abstrak

Sel fuel oksida pepejal (SOFC) boleh dikategorikan sebagai teknologi pembebasan karbon rendah dalam menjana tenaga elektik. Pemilihan bahan katod yang sesuai dan serasi untuk digunakan bersama dengan elektrolit ionik dan protonik adalah penting dalam mencapai prestasi SOFC bersuhu sederhana-rendah (IT-LT SOFC) yang baik. $LiCo_{0.6}Sr_{0.4}O_2$ (LCSO) telah disediakan mengikut stoikiometri menggunakan pembakaran glisin nitrat diikuti dengan pengisaran bebola dan pengisaran tiga penggelek untuk menghasilkan dakwat katod LCSO yang homogen. Serbuk sampel LCSO yang disediakan pada mulanya dicirikan menggunakan pembelauan sinar-X (XRD) dan mikroskop elektron pengimbasan (SEM) yang dipasang dengan spektroskopi sinar-X penyebaran tenaga (EDX). Hasil dapatan XRD menunjukkan kalsin serbuk katod LCSO yang disediakan pada 800 °C menunjukkan struktur

fasa kekisi Rhombo dan kumpulan ruang R-3m Dakwat yang disediakan kemudiannya disapukan pada kedua-dua belah elektrolit samarium terdop seria (SDC) untuk menghasilkan sel simetri LCSO | SDC | LCSO. Dakwat yang disediakan dipelbagaikan saiz celah mesin gulung tiga. Daripada prestasi elektrokimia spektroskopi impedans elektrokimia (EIS) melaporkan bahawa saiz celah terbaik adalah pada 40 µm dengan rintangan polarisasi terendah, R_p 8.32 Ω Kesimpulannya, kajian ini mengesahkan kepentingan dakwat katod berasaskan litium berkualiti tinggi dalam aplikasi SOFC.

Kata kunci: sel fuel oksida pepejal, katod, dakwat, litium, pengisar tiga penggelek

Introduction

Fuel cells are currently receiving great attention worldwide due to their claim of being the safest and cleanest technology [1]. A fuel cell can also be considered an efficient power generator due to lesser emission and a higher rate of energy conversion efficiency compared with conventional internal combustion engines. Lina et al. stated that a fuel cell is a clean power generator with less noise pollution [2]. Fuel cells have several types, and this work explains solid oxide fuel cell (SOFC) in detail. Nowadays, SOFC is well-known in the technological and industrial fields. The only identification that distinguishes SOFC from other types of fuel cells is that they operate at a high temperature, ranging from 400 °C to 1000 °C [3–5]. SOFC is an energy conversion device that can convert chemical energy derived from the fuel into electrical and thermal energy [6,7].

SOFC consists of three main components: anode, cathode and electrolyte. The anode and the cathode are known as an electrode–electrolyte layer that is sandwiched between the anode and cathode electrodes [8]. The schematic of the SOFC is shown in Figure 1.

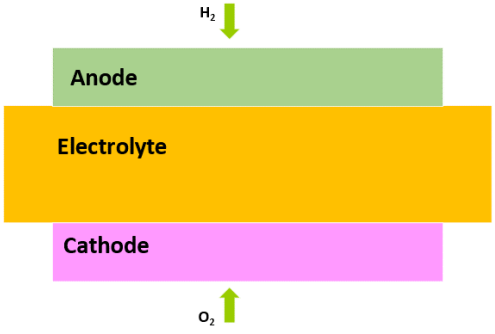

Figure 1. Schematic of SOFC

SOFC has a high energy efficiency when operating at a high temperature of 1000 °C [9, 10]. Studies show that SOFC can achieve an efficiency of 60%–65%. On the one hand, SOFC has been declared as the most promising power generation technology due to its variety of advantages. On the other hand, the high operating temperature which causes material degradation and an increase in manufacturing cost, also results in poor durability of SOFC and limits its application [11]. Accordingly, selection of an intermediate-low temperature is crucial to overcome these arising issues on high operating temperature. The temperature range of intermediate-low temperature is 400 °C–700 °C [12]. The operating cost of this device will be reduced by lowering its temperature, thereby enhancing its commercialisation. SOFC has two types of environments: oxide-conducting SOFC (O^{2-}-SOFC), which is the pioneer or conventional type, and proton-conducting SOFC (H^+-SOFC). Figure 2 (a) and (b) show the O^{2-}SOFC and H^+-SOFC, respectively.

Currently, the focus of SOFC development is on intermediate-low temperature SOFC (IT-LT SOFC). However, the high operating temperature of SOFC causes cell degradation issues. To overcome this problem, the operating temperature of SOFC should be reduced to 400-800 ℃. Existing materials that have been traditionally operated at elevated temperatures have poor electrochemical performance under this intermediate-low temperature environment. Accordingly, selection of a suitable and compatible cathode material is crucial for IT-LT SOFCs. Lithiated-based materials are one of the strong candidates for the cathode component of IT-LT SOFCs. The lithiated-based cathode has been widely used in many applications, such as batteries, electrochemical capacitors and O_2 metal batteries [13–22]. The lithiated-based material in SOFC provides a free moving lithium-

ion (Li^+) cation pathway [23]. The lithium-based cathode can be categorised as a triple ($H^+/O^{2-}/e^-$) conducting cathode material, indicating that it can allow those three conducting elements to pass through the cathode boundary or cathode active site [24]. Liu et al. stated that lithium cobaltite, $LiCoO_2$ is one of the promising lithiated-based materials to be used in SOFC applications with triple conducting mechanism capabilities [25,26]. Wan Yusof [27] reported that $LiCoO_2$ or lithium-based material shows a reasonable perspective in intermediate to low temperature for proton- and oxide-conducting SOFC applications [28]. Moreover, strontium (Sr) is widely used as a cathode dopant for most cathode materials to achieve high electrocatalytic activity, especially at the oxygen reduction reaction (ORR) that occurs only in the cathode [29]. Jamil et al. adopted a broad perspective, in which the existence of an Li compound may uplift oxygen concentration, especially at the grain boundary, resulting in high ionic conductivity [30]. Li^+ promotes proton transfer, which makes Li-based cathode materials viable for proton-conducting IT-LT SOFC. Improving the performance of this material requires an in-depth study of the powder and ink preparation aspects. Meanwhile, numerous studies have been conducted on the powder synthesis-related parameters. As previously discussed, a huge gap was observed on the ink production-related parameters. Hence, this study aims to produce a high-quality lithiated-based cathode ink ($LiCo_{0.6}Sr_{0.4}O_2$) by altering the gap size of roller in triple-roll mills and to characterize the physical properties and electrochemical performance of the cathode inks for IT-LT SOFC application. The high-quality cathode ink will be produced with a triple roll mill machine, which has been proven to be the optimum method for ink production.

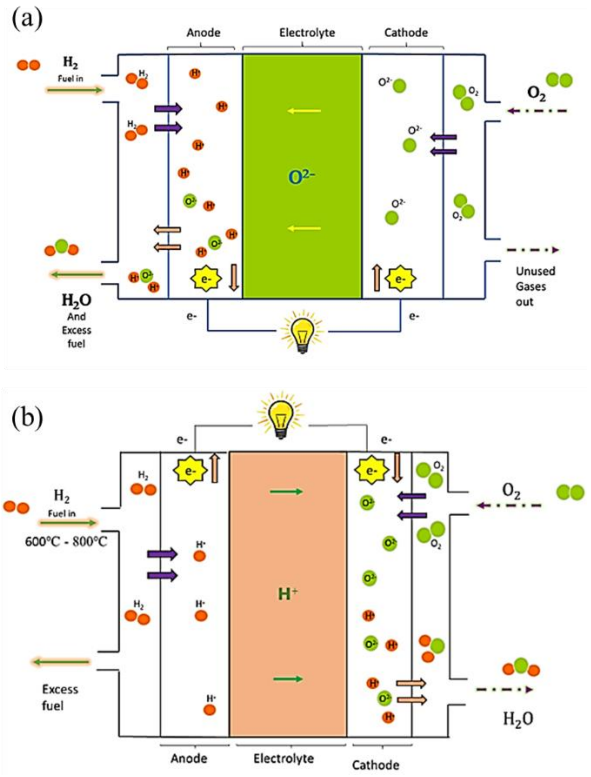

Figure 2. (a) O^{2-}SOFC and (b) H^+-SOFC

Materials and Methods

Preparation of cathode sample powder LiCoSrO

In this work, $LiCo_{0.6}Sr_{0.4}O_2$ precursor powders were produced through the glycine nitrate combustion method. The precursor materials were Lithium Nitrate ReagentPLus, $LiNO_3$ (Sigma Aldrich, Germany), Strontium Nitrate (ACS Reagent, >99%) $Sr(NO_3)_2$ (Sigma Aldrich, Germany) and Cobalt (II) Nitrate Hexahydrate Reagent Grade, 98%, $Co(NO_3)_2.6H_2O$ (Merck Chemicals, Germany). A stoichiometric amount of the precursor materials was dissolved in 100 mL deionised water and stirred for 40 min on a hotplate with a magnetic stirrer at room temperature. Afterwards, a calculated amount of glycine (Sigma–Aldrich, Germany) was added to the precursor material solution as fuel. The mixture was continuously stirred on the hotplate at room temperature for 18 h. Subsequently, the solution was continuously stirred whilst the temperature of the hotplate was slowly increased to between 250 °C to 300 °C to achieve the combustion of the materials and all the nitrates. Thereafter, the obtained black ash precursor powder was further dried at 120 °C for 12 h in

a drying oven. The raw powder was then ground using a mortar agate to obtain a fine, smooth powder. Finally, the dried fine precursor powder was calcined at 800 ℃ in a high-temperature furnace (Berkeley Scientific, USA) for 5 h holding time. The TGA graph of the previous study [27] on the same material shows that LCSO materials were decomposed at temperatures ranging from 700 – 1000 ℃. After the LCSO powder was calcined, it was subjected to X-ray diffraction (XRD) testing and scanning electron microscope (SEM) analysis for LCSO its characterisation.

Material characterisation

Wan Yusoff et al. [27] investigated the thermal decomposition behaviour of the LCSO powder in 2020, via thermogravimetric analysis/differential scanning calorimetry (TGA/DSC, SING Mettler Toledo, United States) to determine the optimal calcination temperature. The analysis was conducted on the LCSO precursor powder synthesised from room temperature to 1000 °C at a heating rate of 10 °C/min^{-1} under air with a flow rate of 50 mL/min^{-1}. Then, the precursor LCSO powder was further analysed via XRD (Bruker AXS D8 Advance, Germany) with a CuKα (λ = 0.15406 nm) radiation source to confirm its phase and structure. An X-ray diffractometer was operated at 40 kV and 40 mA, and fitted with a 1-D fast detector (Lynx-Eye). The XRD spectrum was recorded for 2θ ranging from 20° to 70° with a step size of 0.025°. The morphology of the LCSO particles was examined via SEM (Carl Zeiss EVO MA10, Germany). From the material characterisation, the optimal calcination temperature was selected to produce another batch of LCSO cathode powder, which was used to synthesise the LCSO cathode ink.

Ink preparation

The cathode ink was produced using several methods and techniques that have been utilized by other researchers. The common methods used for synthesizing the ink are triple roll mill (TRM) machine, ball milling and manual mixing (hands-on). The methods used by other researchers are summarised in Table 1.

Table 1. Summary of methods used to produce ink

Method	Element	Performance	Reference
Ball Milling	Iron and nitrogen dope carbide-derived carbon (SiCDC)	The grain size decreases from 1 μ to 200 nm.	Ratso et al. 2021[31]
	Multiwalled carbon nanotubes/epoxy suspensions	A better-quality texture of the material is produced.	Olowojoba et al. [32]
TRM Machine	Soda lime glass	Fast response and process can be broken down into phases. The particle size breakage yields a good result.	Böttcher et al. [33]
	$La_{0.6}Sr_{0.4}CoO_{3-\delta}$ (LSC)	High porosity and good electrochemical performance are achieved with a TRM machine.	Samat et al. [10]
Manual Mixing	$La_{0.6}Sr_{0.4}CoO_{3-\delta}$ (LSC)	The porosity is lower, and the value of ASR is higher compared with other methods.	Samat et al. [34]

Table 1 shows that using the TRM machine as the medium in synthesising the cathode is the best option because if the better quality and outstanding electrochemical performance. Several parameters in the ink production process are maintained variable during the research. Determining and varying the parameters is crucial to producing a high-quality cathode ink. Table 2 shows the parameters considered and previously studied. The parameters studied by the researchers include roller speed, frequency of rotation, roller gap size, ink thickness, feed rate and breakage behaviour.

Table 2. Parameter study related to the TRM machine

Parameter study related to the TRM	Reference
Roller gap size	Wan Yusoff et al. [27]
Roller speed and rotation frequency	Olowojoba et al. [32]
Roller speed, roller gap size, feed rate and breakage behaviour	Böttcher et al. [33]
Ink thickness	Samat et al. [34]
Roller speed and roller gap size	Somalu et al. [35]

TRM is essential in the production of homogenous screen-printing inks because it breaks down most particle agglomerates during milling. The difference in roller speeds produces shear stress between the rollers, which pull agglomerates apart when the material passes between the gaps. The working principle of the TRM machine is shown in Figure 3. The resulting shear rates between the gaps are provided in the following equation:

$$\text{Shear rate} = \frac{\Delta v}{x}, \quad (1)$$

Δv: speed difference, and x: gap between rollers.

The LCSO ink was prepared with EXAKT 50 I, Germany TRM machine in the SOFC Laboratory at Institute Fuel Cell UKM. The produced LCSO powder was ball-milled for 24 h with a 10-rpm rotating rate. The ink was prepared by using the right composition to produce a good-quality cathode ink. The ink composition is tabulated in Table 3. The postball milled LCSO powder was mixed with a vehicle buffer solution, dispersant and solvent. The premixed ink was manually ground before producing a smooth, fine ink with the TRM machine. Then, all the premixed ink was mixed well. The LCSO with various ink parameters were formed, and the parameters produced throughout this work are listed in Table 4.

Table 3. LCSO ink composition

Solid Content	Weigh (wt.%)
LCSO powder (ball milled)	67.33
Solvent (Terpineol)	29.98
Binder (Ethylcelulose N7 grade (0.25%–0.5 wt.%)	1.35
Dispersant (Hypermer KD15)	1.35

Table 4. LCSO ink parameter

Variable Parameter	Gap Size (μm)
1	g_1- 10
2	g_2- 20
3	g_3- 30
4	g_4- 40
5	g_5- 50

Fabrication of symmetrical cell LCSO|SDC|LCSO

The fabrication of symmetrical cell started with the production of an electrolyte pellet of $Sm_{0.2}Ce_{0.8}O_{1.9}$ (SDC). Then, the prepared LCSO cathode ink was layered on both sides of the electrolyte pellet. Prior to the half and symmetrical cell production for electrical conductivity and electrochemical impedance spectroscopy (EIS) analysis, the SDC powders (Sigma–Aldrich) were pressed into a coin-shaped structure to form an electrolyte substrate at 52 MPa. The SDC electrolyte was sintered at 1400 °C for 6 h. Then, the as-prepared cathode inks were screen printed two layers on one side (half-cell) and both sides (symmetrical cell) of the electrolyte surface with an active area, A, of 1 cm^2 prior to sintering at 800 °C for 2 h. The prepared symmetrical cell LCSO|SDC|LCSO is shown in Figure 3.

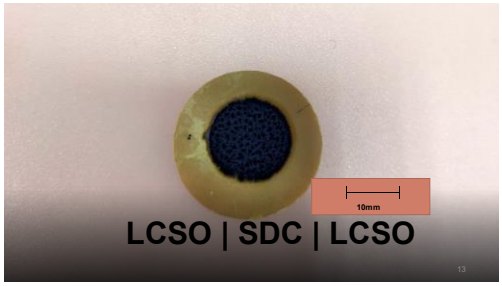

Figure 3. Prepared symmetrical cell LCSO|SDC|LCSO

Electrochemical analysis of the LCSO|SDC|LCSO symmetrical cell

The electrochemical performance was measured using EIS with a potentiostat (PGSTAT302 N, Metrohm Autolab, Netherlands) operating at 106–0.1 Hz with a sinusoidal voltage amplitude of 10 mV. Symmetrical cells were evaluated in the air at 500 °C–800 °C under typical IT-SOFC operating conditions, with a constant air flow rate of 0.2 $Lmin^{-1}$. EIS was performed on all symmetrical cells with a constant active area of 1 cm^2, and the data were processed with NOVA software (version 1.10) to determine the ASR values of the LCSO cathode.

Results and Discussion

Properties of prepared powder

The XRD spectrum of the as-synthesised powder cathode calcined at 800 °C and 900 °C for 5 h is shown in Figure 4. The data base cannot provide the full spectrum of LiCoSrO because this material is new. Accordingly, the XRD was compared with $LiCoO_2$ and $SrCO_3$. The calcined LCSO powders exhibited merely a single phase, as confirmed by the XRD measurement. The plotted results showed a peak almost similar to the reference $LiCoO_2$ with $SrCO_3$. All the prominent peaks in the XRD spectrum of the calcined powder were matched with the reference code PDF 00-050-0653 lithium cobalt oxide ($LiCoO_2$) of rhombic lattice structure and space group of R-3m and PDF 01-084-1778 strontium carbonate ($SrCO_3$) of orthorhombic lattice structure with space group of R-3m. Thus, the highest peaks were indexed to their Miller indices (hkl) of (111) and (104) for $LiCoO_2$ and $SrCO_3$, respectively.

The morphological analysis was conducted on the LCSO powders calcined at temperatures of 800 °C and 900 °C by SEM and EDX. The results for both microstructures are illustrated in Figures 5 and 6. The results show that the microgram has a random fragment structure, whereas EDX confirms that all the components of LCSO are in the cathode powders. The EDX graph in Figure 6 clearly shows that all the components of Li, cobalt (Co), strontium (Sr) and oxide (O_2) are present in the LCSO powder for both temperatures of calcined LCSO. However, the LCSO precursor powder calcined at a temperature of 800 °C shows less impurities than that calcined at 900 °C.

After analysing the calcined powder and producing a high-quality ink, the best composition was considered. Based on the LCSO ink composition in Table 3, the smooth, fine-texture ink was successfully produced using the in-house TRM machine. The produced LCSO cathode ink is shown in Figure 7.

Electrochemical performance analysis

Figure 8 shows the electrochemical impedance spectrum of the LCSO|SDC|LCSO symmetrical cells with different cathode ink parameters of the gap size of the TRM. The spectra are fitted via electrical circuit fitting composed of resistance (R) and constant phase element (CPE). Resistances and constant phase elements are illustrated by R_S, R_1, R_2, CPE_1 and CPE_2 for high- and low-frequency arcs. The impedance arc was analysed using an electric equivalent circuit, as shown in Figure 8(b). All the measured and calculated values of polarisation resistance and area specific resistance (ASR) at 800 °C of each symmetrical cell with different gap size are listed in Table 5. The impedance spectra in Figure 8(a) show that gap size of 40 µm is the lowest amongst the other gap sizes, and this is proven by the measured and calculated polarisation resistance, R_p, value in Table 5 that shows the gap sizes of 10, 20, 30, 40 and 50 µm of 32.35, 39.63, 17.07, 8.32 and 43.36 Ω, respectively. The LCSO cathode ink produced with the TRM shows that the best gap size is 40 µm with proven electrochemical performance of 8.32 Ω.

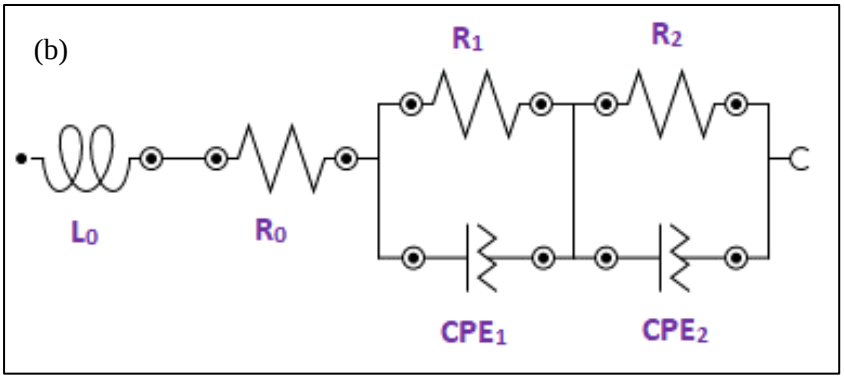

Figure 8. (a) Impedance spectra of the different gap sizes; (b) adopted an electrical equivalent circuit to analyse the impedance data

Table 5. Values of the polarisation resistance and ASR of LCSO|SDC|LCSO symmetrical cells of different gap sizes of the ink produced

Gap Size (μm)	Polarisation Resistance, Rp (Ω)	ASR at 800 °C (Ω cm^2)
10	32.35	16.175
20	39.63	19.815
30	17.07	8.535
40	8.32	4.160
50	43.36	21.680

Conclusion

The LCSO cathode ink is synthesised via glycine nitrate combustion. Subsequently, the cathode ink was produced using the TRM machine method, and the gap size of the TRM varied at 10, 20, 30, 40 and 50 μm. Amongst the different gap sizes, the best gap size is 40 μm with proven electrochemical performance of EIS with polarisation resistance, R_p value of 8.32 Ω and ASR of 4.160 Ωcm^2. This work benchmarks the attempt of a compatibility of an Li-based cathode ink in the application of IT-LT SOFCs. Moreover, this work is involved in and will compete in the production of a durable SOFC system to enhance its viability in actual applications. In the future, the production of the LCSO cathode ink under various IT-LT SOFC environments, such as proton conducting SOFC (H^+-SOFC) and oxide conducting SOFC (O^{2-}SOFC) will be conducted to find the optimal environment for LCSO cathode ink to work for.

Abstract

The electrocoagulation process is classified as green technology to treat landfill leachates. A 16 full factorial experimental design evaluated and optimized the electrocoagulation method and compromised efficiency and operational costs. This study assessed three factors: operation time, voltage, and electrode size, to determine the most influencing parameters and describe the interaction between chemical oxygen demand (COD) and turbidity removal. Statistical analysis results using a half-normal plot demonstrated that all main factors significantly affected the removal efficiency of COD and turbidity. The Pareto chart reveals that the order of significance for COD and turbidity removal efficiency was voltage > operation time > electrode size> interaction between voltage and electrode. The best regression coefficients (R^2) were obtained for COD and turbidity, which reached 0.9597 and 0.9908, respectively, confirming that the predicted values complied with the experimental values. This implied the appropriateness of the employed regression model. The optimization process results showed that for maximizing the removal efficiency of COD and turbidity, the optimal level of operation time was 30 min, voltage 30 V and electrode 10 cm2 by using a batch reactor.

Keywords: electrocoagulation, landfill leachate, chemical oxygen demand, turbidity

Abstrak

Proses elektrokoagulasi diklasifikasikan sebagai teknologi hijau untuk merawat tapak pelupusan larut lesap. Reka bentuk eksperimen 16 faktorial penuh telah digunakan untuk menilai dan mengoptimumkan kaedah elektrokoagulasi dan untuk mencapai kompromi antara kecekapan dan kos operasi. Kajian ini menilai tiga faktor: masa operasi, voltan dan saiz elektrod untuk menentukan parameter yang paling mempengaruhi dan menerangkan interaksi antara parameter untuk permintaan oksigen kimia (COD) dan penyingkiran kekeruhan. Keputusan analisis statistik menggunakan plot separa normal menunjukkan bahawa semua faktor utama mempunyai kesan yang ketara ke atas kecekapan penyingkiran COD dan kekeruhan. Carta Pareto mendedahkan, untuk COD dan kecekapan penyingkiran kekeruhan, urutan kepentingan ialah voltan > masa operasi > saiz elektrod > interaksi antara voltan dan saiz elektrod.. Pekali regresi terbaik (R^2) diperoleh untuk COD dan kekeruhan mencapai nilai masing-masing

0.9597 dan 0.9908 mengesahkan bahawa nilai yang diramalkan adalah mematuhi nilai eksperimen yang membayangkan kesesuaian model regresi yang digunakan. Hasil proses pengoptimuman menunjukkan bahawa untuk memaksimumkan kecekapan penyingkiran COD dan kekeruhan, tahap masa operasi yang optimum adalah 30 minit, voltan 30 V dan elektrod 10 cm^2 dengan menggunakan reaktor batch.

Introduction

Malaysia produces about 42,672 metric tons of solid waste every day, and the value may be increased every year due to urbanization, increase in population, and per capita waste generation [1]. Generally, organic wastes constitute 40 – 60 % of the overall weight in most developing countries. Despite several advantages of landfilling, the resulting heavily polluted leachate has caused an urgent concern because landfilling is a widely used method for solid waste disposal. Various factors influence leachate quality and quantity, such as landfilling technique, seasonal weather variation, waste type and composition, and landfill structure [2]. Therefore, environmental specialists are determined to develop effective treatments for vast quantities of heavily polluted leachates.

The EC process is a process to form floc with the help of oxidized metal in wastewater, whereby it needs to be cleaned by the electro-dissolution anode [3]. EG can also be defined as a process of removing the suspended solids from wastewater by using electricity to neutralize the harmful particles through hydroxide complexes formation in water to gather the suspended solid, help bridge, bind, and strengthen floc sedimentation due to gravity force. This process collects the suspended solids in water without coagulants, and then coagulation occurs when a direct current is applied, thus capable of removing small particles and setting them into motion. Several factors that influence the EC process's efficiency are electrode types, the gap between electrodes, electrode size, the configuration of metals, current density, charge loading, pH value of the sample, the addition of supporting electrolyte, and operation time. The electrodes that are usually used are iron, aluminum, and stainless steel. This metal sheet pair is anode and cathode [4].

Nowadays, most treatment methods widely used worldwide to treat wastewater are physical-chemical and biological processes, but the treatment of leachates by using these methods is complex due to low biodegradability and high toxicity. The biological process is a method that uses natural methods that depend on microorganisms, nematodes, and tiny creatures. At the same time, physical-chemical processes require added synthetic substances [5]. For example, Castillo-Suárez [6] used peroxicoaguation and solar peroxicoagulation in a batch electrolytic reactor in the presence of solar ultraviolet light and studied three main parameters to treat the leachates, which are pH value, current density, and treatment time. The use of these three parameters gives the optimal value of biochemical oxygen and COD removed at 55.5% and 62.3%, respectively. Jang et. al [7] studied the effect of adding lithium manganese oxide and activated carbon electrodes in the electrochemical sorption of the lithium-ion battery leachate. The authors found that increased capacity, selectivity, and purity depended on the reaction time and applied current. The same parameters; time, and current density, were also studied by Galvão [8] in the EC process treatment. Five responses were recorded: ultraviolet absorbance, biological oxygen demand, COD, turbidity, and color, while the percentage values of removal when applied with 128 Am^{-2} for 90 min were 40%, 90%, 40%, 82%, and 82%, respectively. The removal efficiency was increased to a maximum by increasing the electrolysis time, leading to a constant rate. The number of generated metal hydroxides increased with the electrolysis time.

In this regard, a group of researchers used the EC process to remove cefazolin and COD from hospital wastewater [9]. The tests were performed in three specific voltages (15V, 30 V, 50 V) and periods (10 min, 30 min, 50 min). The result showed that the maximum

efficiency of contamination removal in 50 min was more than 92%. Chairunnisak et al. [10] reported that the electrocoagulation method resulted in the optimum COD reduction of 94.53% from operating time of 39.28 min, 20 V, and without electrolyte concentration. A study conducted by Amarine et al. [11] showed that the removal efficiency depended on the electrodes' applied voltage and immersed surface. This removal efficiency was 94.41% after 150 min, the electrical voltage of 30 V, and the immersed surface of 33.75 cm^2. Another research by Bajpai et al. [12] found that an optimum condition (14 V and 47 min) at a pH value of 7.35, which provided experimental removal efficiency (75.6% COD, 78.7% total dissolved solids, 93.4% turbidity, and 63.2% chloride).

There is in situ generation of coagulants by the dissolution of sacrificial anodes due to direct current flow. Different studies have proven that the aluminum electrode was the most effective and successful. Therefore, aluminum was used as the electrode material in this study. The anode produces metal cations after its oxidation process by applying direct current; this cation involves further reactions and produces different polymeric hydroxides of metal, similar to salts used in conventional coagulation.

The reactions when using aluminum electrodes can be summarized as follows;

.

Anode reactions:

$$Al(s) \rightarrow Al^{3+}_{(aq)} + 3e \quad (1)$$

$$Al^{3+}_{(aq)} + 3OH^- \rightarrow Al(OH)_3 \quad (2)$$

Alkaline reactions:

$$Al^{3+}_{aq} + 3H_2O \rightarrow Al(OH)_3 + 3H^+ \quad (3)$$

Acidic pH range

Cathode reactions leads to mainly hydrogen evolution:

$$3H_2O + 3e \leftrightarrow {}^3/_2\, H_2 \uparrow + OH^- \quad (4)$$

As seen in the above reactions, EC combines oxidation, flocculation and flotation. The EC occurs in three steps. In the first step, a coagulant is formed due to oxidation of the anode. In the second step, pollutants get destabilized, while in the last step, the destabilized matters get united and removed.

EC is an exceptional strategy for water and wastewater treatment. While the EC has been applied to different modern gushing, for example, nourishment businesses, tannery, mechanical shops (dissolvable oil), polymerization production, and wastewater material industry. Naje & Abbas [13] limited studies were carried out on the effective voltage, operation time and electrode side in the electrocoagulation process time in the COD and turbidity removal. Simple, affordable, and efficient leachate treatment systems are urgently needed in developing countries because most conventional technologies in industrialized nations are too expensive and complex. Rusdianasari et al. [14]. EC is a simple method to treat wastewater efficiently, and it seems to be a promising treatment method due to its high effectiveness, lower maintenance cost, less need for labor, and rapid achievement of results. In this study, statistical analysis via factorial design was used to investigate factors that influence the reduction of two primary contaminants in leachate, which were COD and turbidity.

Materials and Methods

Sample collection

A close landfill that was shut down for over five years was selected to collect the leachate samples. Even though the landfill was shut down, the leachate was still being produced in the landfill. The amount of leachate produced was 200 m^3 per day, while the volume of leachate discharged was 190 m^3. The grab sampling technique was used for collecting the samples. Samples were kept at a temperature of 4 °C in an icebox to preserve the original circumstances of the sample. The main characteristics of the studied leachate samples are shown in Table 1.

Table 1. Characteristics of the leachate sample used in this study

Parameters	Units	Value
Chemical Oxygen Demand (COD)	mg/L	675
Turbidity	NTU	705

Experimental set-up

The batch experimental was set up as the electrochemical unit, which consisted of an electrocoagulation cell, a DC power supply, and aluminum electrodes. In this study, EC cell was made from aluminum anodes, and cathodes with 2 cm spacing were placed vertically on the cell floor. The electrodes had dimensions of 5.65 cm × 13.9 cm, with a functional area of 28.76 cm^2 (anode). The stirrer was set at 100 rpm to maintain the composition and avoid flocs in the solution. The electrodes were soaked in 0.4 M of HCl (hydrochloric acid) for 10 min and then rinsed with deionized or distilled water to remove any organic proteins from the surface of the electrodes. The procedure started with an electrocoagulation cell cleaned with distilled water and dried using a dryer. The experiments were carried out in batches. In each experiment, a 500 ml leachate sample was filled into the electrochemical cell with the Al electrodes dipped into the sample at room temperature. The electrodes (anode and cathode) were clamped at the electrode stand. The circuit was completed by connecting wires to the electrodes (anode and cathode) and the DC power supply.

Analysis

The removal efficiency of COD and turbidity was determined according to the following formulas:

$$\text{COD}\ (\%) = \frac{\text{COD}o - \text{COD}t}{\text{COD}o} \times 100 \quad (5)$$

where COD_O and CODt are the chemical oxygen demand (COD) at time = 0 (initial) and at t (reaction time, t), respectively.

$$\text{Turbidity}\ (\%) = \frac{Co - Ct}{Co} \times 100 \quad (6)$$

where C_0 and C_t are turbidity registered (in NTU) at time t=0 (initial) and at t (reaction time), respectively.

Full factorial design of experiments

The three independent factors used in the full factorial design were the voltage, operation time, and electrode size. In contrast, the responses used were the removal percentage of COD and turbidity to achieve the optimum conditions in the experimental design method approach. The input factor variables with their range and levels are shown in Table 2. In this work, 16 experiments were run wholly, including the combination of all levels of other factors, and performed randomly to reduce experimental errors. As the output of factorial screening tests, the critical interactions between all variables were given. The model's validity is verified by analyzing values in the analysis of variance (ANOVA) table. The interactive statistical data analysis tool software in the analysis design was used to construct the model for factorial screening design.

Table 2. Factors and levels used in this experimental design

Parameter	Low Level (-)	High Level (+)
Operation Time (min)	10	30
Voltage (v)	10	30
Size of electrode (m^2)	10	30

Results and Discussion

The effect of the voltages

The initial concentration is one of the remarkable factors in the electrocoagulation process. The influence of this factor on the COD and turbidity removal efficiency is depicted in Figures 1(a) and 1(b). As demonstrated in both figures, the COD and turbidity removal efficiency increased by increasing the voltages for the electrocoagulation process from 5V to 30V. However, more voltage increments caused a descending trend in the removal efficiency. The descending trend can be attributed to the fact that there is a threshold limit for the elimination. The decaying of COD and turbidity removal efficiencies due to the increase in electrical power reduced the lifespan of the electrodes.

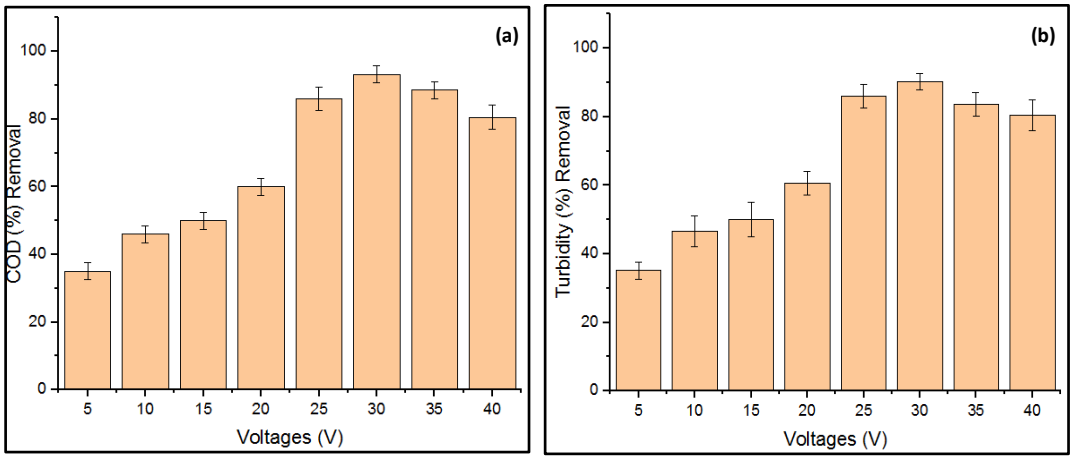

Figure 1. Removal percentages for (a) COD and (b) turbidity removal after 30 min of the mode of operation at different voltages

The effect of the operation time

Figure 2(a) and Figure 2(b) depict the effect of operating time on COD and turbidity removal efficiency. By changing the operating time from 5 min to 30 min, the removal percentages of COD and turbidity increased in the same trend of increment. In this process, EC involved two stages: destabilization and aggregation. The first stage is usually short, whereas the second stage is relatively long. Metal ions, as destabilization agents, are produced at the anode through electrochemical reactions. For 30 min, they indicated an increase in electrolysis duration and increased destabilization of colloidal particles. Both graphs demonstrated that the maximum efficiency of the EC process is obtained at a treatment time of 30 min, and a further increase in treatment time to 40 min did not result in any significant improvement in the removal efficiency of the studied parameters.

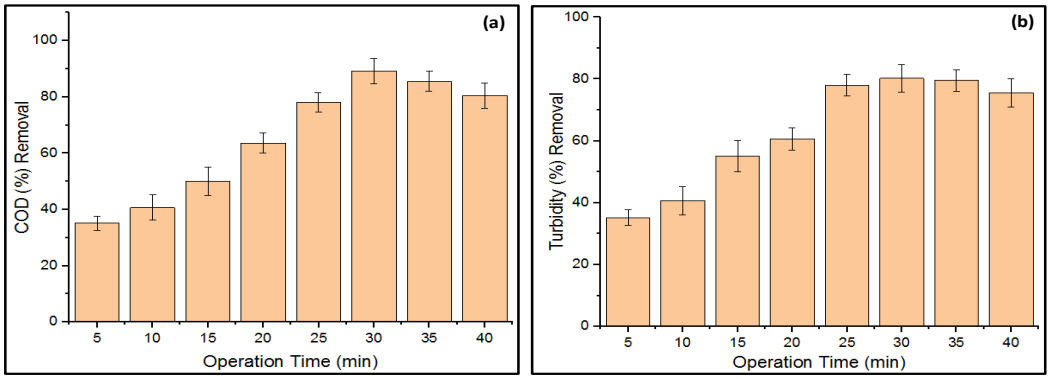

Figure 2. Removal percentages for (a) COD and (b) turbidity removal for 30 voltages for different operation time

The effect of the size of electrodes

Figures 3(a) and 3(b) shows that larger electrodes contribute to high COD and turbidity removal efficiencies. A larger surface area electrode has more area for this oxidation process. However, larger electrodes will incur higher costs and worsen portability. This study aims to preliminarily ascertain the effect of the electrode size on COD and turbidity removal and provide optimal electrode size for electrocoagulation

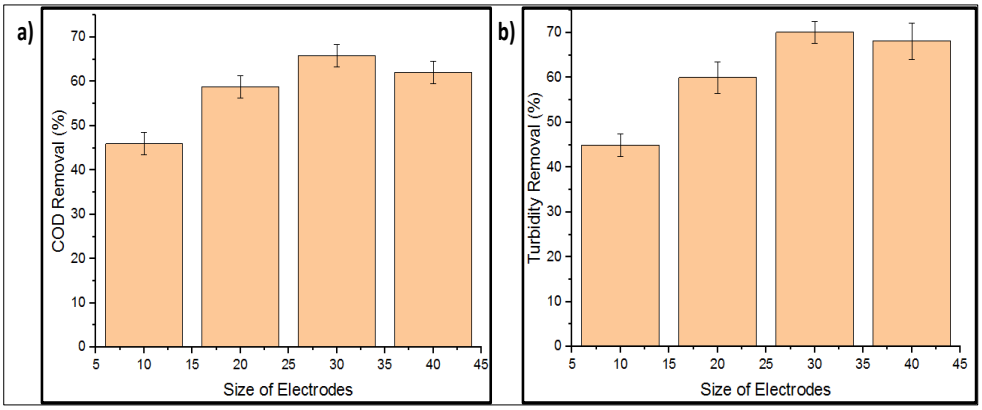

Figure 3. Removal percentages for (a) COD and (b) turbidity removal at the different sizes of electrodes for 30 min operation time and 40 volt

Statistical validity of the model

A matrix of full-factorial design from the two levels (24) is shown in Table 3. Each combination is experimentally carried out in a randomized sequence to meet the statistical requirement for independence of observations. As a result, two responses are examined in the leachate treatment: the COD and turbidity removal.

Table 3. The 3-factor full factorial design matrix and the response function

Exp	Factors			Removal Efficiencies	
	Operation Time	Voltage	Electrode Size	COD (mg/l)	Turbidity (NTU)

Analysis of variance (ANOVA)

Effect of variables on COD removal

The ANOVA for the correlative model development step is presented in Table 4 to describe the removal efficiency of COD as a function of the studied variables. It demonstrated that all the above factors are significant, and the (B) voltage is a highly remarkable variable. The ANOVA shows that the p-value for the model is less than 0.0001, and an F value of 27.22 is obtained for the model, demonstrating the significance of the developed correlation. Besides the main factors A, B, and C, which refer to the operation time, voltage, and electrode size, the model also suggested the interactions of AB, AC, BC, and ABC. Those interactions in the model are less than 0.05, except for the interactions of AB and AC. Nevertheless, these higher values of AB and AC did not affect the total p-value of the model.

Furthermore, the ANOVA table displays supplementary pieces of beneficial information. For instance, the quantity "R-squared" is defined as [15];

$$R^2 = \frac{\text{model sum of squares}}{\text{total sum of squares}} \quad (7)$$

The coefficient of determination (R^2), which shows proportional variation in the response explained by the independent variables in the linear regression model, is 0.9597, which means that the model could describe 95.97% of the variations in the response. The adjusted coefficient of determination (R^2adj) is 0.9244. The value of R^2, which is close to 1, revealed a significant linear relationship between the factors and response. There is a slight difference between R^2 and R^2adj values, which shows that some insignificant conditions (error) are included in the model. The final empirical models in terms of actual parameters are determined as follow

$$COD = +106.50 -15.75*A - 36.38 *B -14.25 *C +3.38 *AB +4.50 *AC + 11.88 *BC + 7.62*ABC \quad (8)$$

Table 4. ANOVA test for the removal of COD

Source	Sum of Squares	df	Mean Square	*F*-Value	*P*-Value	
Model	32081	7	4583	27.21901	<0.0001	significant

BC	2256.25	1	2256.25	13.40015	0.0064	
ABC	930.25	1	930.25	5.52487	0.0466	
Pure Error	1347	8	168.375			
Cor Total	33428	15				
Model Summary						
s	R-sq		R-sq(Adj)		R-sq(Pre)	
12.98	95.97%		92.44%		83.88%	

Figure 4 depicts the half-normal plot and Pareto chart, which shows that the primary factors and interaction factors might positively or negatively affect electrocoagulation process COD and turbidity removal efficiencies. A half-normal plot (Figure 4a) shows that the non-significant ones fell along with a straight line normal distribution and centered near 0. Meanwhile, the essential factors contributed to COD removal efficiencies away from the straight line. Therefore, in order of significance, B (voltage), A (operation time), and C (size of the electrode) have the effects of the most critical factors in COD removal efficiency. Other

significant factors included interaction between (BC) voltage and size of electrodes and (ABC) interaction between three factors, which are operation time, voltage, and size of electrodes (ABC). Factors with the tallest bars significantly affected the process in the Pareto chart. As depicted in Figure 4b, the Pareto chart had two lines: Bonferroni (3.584) and t value limit lines (2.306). The factors with t values above the Bonferroni line are essential. Also, the factors with t values between the Bonferroni and t value lines are significant. However, those with t values below the t value-line are not remarkable.

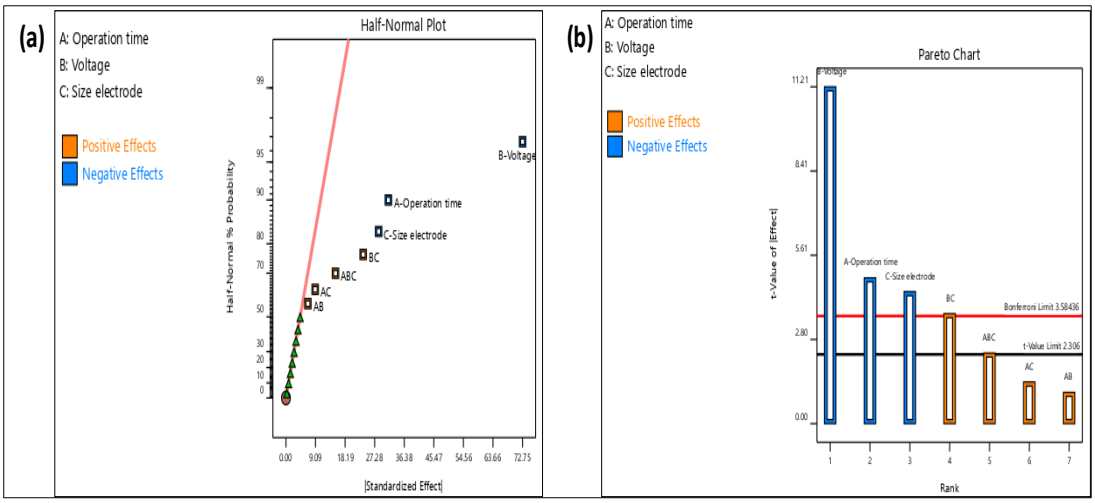

Figure 4. (a) Half-normal probability plot of the effects for the removal of COD and (b) standardized Pareto chart for COD

Effect of variables on turbidity removal

Table 5 shows the ANOVA test for the removal of turbidity. The models or variables with a *p*-value < 0.05 are considered significant with a 95% confidence level. Therefore, the result of ANOVA in Table 4 showed that all variables A, B, and C and the interactions of AB, AC, and BC are significant model terms in terms of turbidity, except for the ABC interaction. The model obtained a *p*-value of 0.0001, implying that the model is significant. The ANOVA result shows that the coefficient of determination, R^2, for the model was 0.9908, which means that the quality of the model is 99.08%. The adjusted R^2 for the model is 0.9522, which shows a good agreement between the results predicted by the regression design and experimental data. A reasonable agreement between the adjusted R^2 and predicted R^2 indicated an adequate model, as shown in Table 5. The final empirical models in terms of actual parameters are determined as follows,

$$\text{Turbidity} = +109.56 - 17.69 *A - 37.69 *B - 15.56*C + 5.06 *AB + 6.19 *AC + 12.69*BC + 4.94*ABC \quad (9)$$

12.42	96.65%		93.72%		86.60%	

The factorial design plot, including the half-normal plot and Pareto chart of effects, are shown in Figure 5. The half-normal probability plot of the effects in Figure 5a shows the absolute values of the estimated effects from the largest effect to the smallest effect. From this analysis, it could be observed that the largest effect on turbidity removal efficiencies that is well displaced in the plot was the AB interaction (operation time and voltage), followed by B (voltage), AC interaction (operation time and size of electrode), BC interaction (voltage and size of electrode), A (operation time) and (C) size of the electrode. The sequence of the significant main effects with respect to decreasing influence on turbidity removal is found to be AB > B > AC > BC > A > C > ABC. The half-normal plot of the effects indicated that the single factor has a negative effect. By increasing the level, there is a significant reduction in turbidity in landfill leachates - another quick way to screen the significant factors is by analyzing the Pareto chart of the estimated effects. The Pareto chart is generated and tabulated, as shown in Figure 5b, to validate the results obtained from the half-normal probability plot of effects in Figure 5a. Pareto chart analyses revealed that all factors and interaction factors are statistically significant, and none of them was below the limit of Benferroni (3.46).

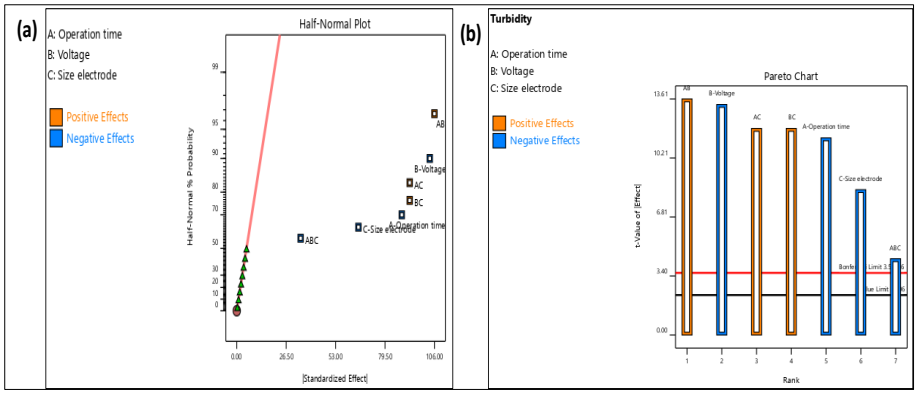

Figure 5. (a) Half-normal probability plot of the effects for the removal of turbidity and (b) standardized Pareto chart for turbidity

Model validation and multiple response optimization
An additional experiment is performed for each set of experiments to validate the models further. Optimized conditions and corresponding maximum COD removal are depicted using the ramp graph shown in Figure 6. Under the optimum conditions, three replicate experiments are conducted. The conditions with predicted and measured results are listed in Table 6. The table shows that the three responses are close to those estimated using factorial design. The model's validity is confirmed as the variation coefficients were around 5% for COD and turbidity removals. This method provided savings in terms of the time and size of electrodes.

Electrolysis time also significantly affects the efficiency of electrochemical coagulation methods in removing pollutants. It determines how much coagulant is produced and how much the cycle costs [16]. Increasing electrolysis time up to the optimum level increases pollutant removal efficiency but does not increase it beyond the optimum level. The fact is that the formation of coagulants at constant current voltage increases with an increase in electrolysis time, resulting in increased efficiency for removal [17]. The voltage applied to the electrodes is one of the most critical parameters that affect the efficiency and economy of the electrocoagulation cycle [18]. Figure 7 shows a sample of leachate landfill before and after the electrocoagulation process. A clear solution is obtained after using the electrocoagulation process by using parameters in this experime

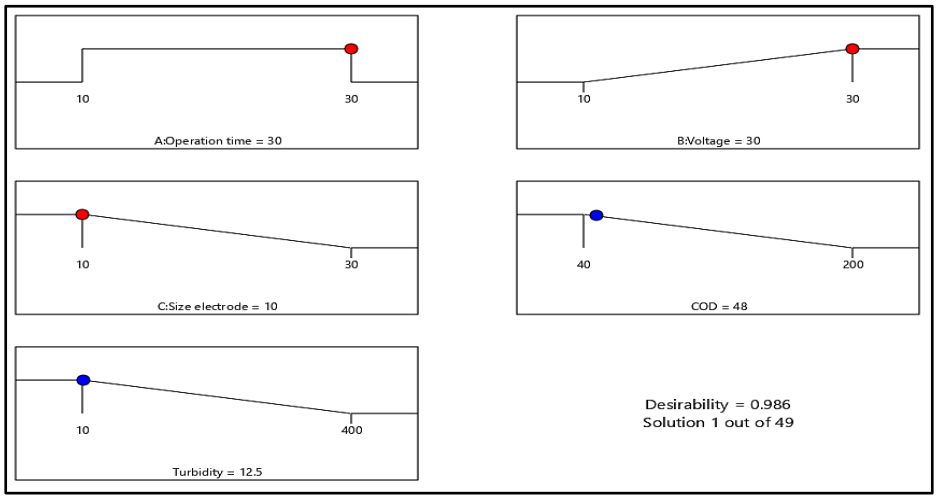

Figure 6. Suggestion value for optimization model

Table 6. Validation of the model

Removal Efficiencies	Factors			Predicted	Average Experimental Results
	Operation Time (min)	Voltage (V)	Electrode Size (m^2)		
COD (mg/l)	30	30	10	48.00	45.72
Turbidity (NTU)	30	30	10	12.5	11.87

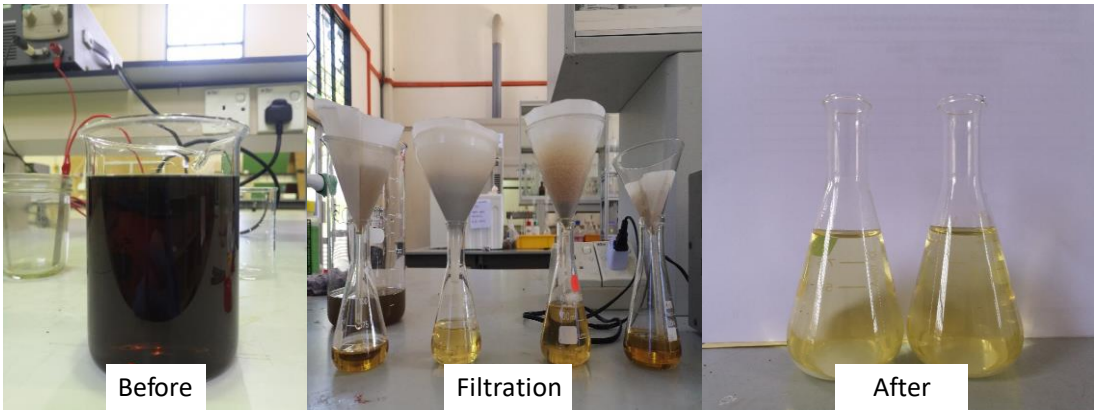

Figure 7. Sample leachate landfill before and after electrocoagulation

Conclusion

In this study, the FFD design of the experiment was used to observe the impact of voltage, operation time, and size of electrodes for the removal of COD and turbidity from landfill leachates by the electrocoagulation process. The screening experiment for the EC process was obtained by running 16 combinations of experiments provided by FFD design in the design of experiment software. The optimum condition was achieved by keeping the goal of operating time maximum, voltage maximum, size of electrode minimum, COD, and turbidity pollutant removal efficiencies in the "maximized" condition. The statistical analysis showed that the relevant p-value of each model was less than 0.001 (p-value < 0.001), indicating the corresponding significance of the model for all responses. The predicted values of COD and turbidity were 48 mg/l and 12.5 NTU, respectively. The maximum COD and turbidity removal experimental values were 45.72 mg/l and 11.87 NTU, respectively, at 30V, 30 min, and 10 cm electrode sizes. Therefore, this indicated that the electrocoagulation process gave good response for the treatment of leachate samples and agreed with the predicted values with less than 5% deviation.

Abstract

Nowadays, research efforts are focused on developing low-Pt and non-Pt catalysts for ORR. The addition of Pt-group metal (PGM) in pure Pt to form Pt-PGM catalysts exhibits better ORR performance than pure PGM catalysts and Pt/C. More than 20 wt.% of Pt loading is required in Pt-PGM alloys for improving catalytic activity. Studies have also shown that the addition of transition metal (TM), which has a smaller atomic size, into PGM reduced the bond distance between two metallic atoms and geometric parameters, thus remarkably improving the catalytic stability and ORR activity. However, TM based catalysts should be supported on nitrogen-doped carbon with high surface area to attain high ORR activity. A large surface area and high electronic conductivity of carbon support also facilitate the ORR activity. Performances of alloy catalysts are directly related to their synthesis temperature and structural properties. Designing the core-shell combinations and controlling the shell thickness is one of the structural strategies in enhancing mass activity and durability. Lately, irradiation techniques are used to modify the physicochemical properties. Nevertheless, TM-based catalysts are usually stable in alkaline solutions but not in acidic solutions. This review focuses on the strategies to develop cost-effective catalysts from low-platinum and non-platinum catalysts with enhanced ORR activity.

Keywords: oxygen reduction reaction, platinum group metal alloys, transition metal catalysts, synthesis techniques

Abstrak

Pada masa kini, usaha penyelidikan tertumpu kepada pembangunan mangkin platinum (Pt) bermuatan rendah dan bebas platinum untuk tindak balas penurunan oksigen (ORR). Penambahan logam kumpulan Pt (PGM) dalam Pt tulen untuk membentuk Pt-PGM menunjukkan prestasi ORR yang lebih baik daripada prestasi mangkin PGM tulen dan Pt/C. Sebanyak lebih daripada 20 wt.% muatan Pt adalah diperlukan dalam aloi Pt-PGM untuk meningkatkan aktiviti pemangkinan. Kajian telah menunjukkan penambahan logam peralihan (TM) yang mempunyai saiz atom yang lebih kecil ke dalam PGM mengurangkan jarak antara dua atom logam dan parameter geometri sekali gus meningkatkan kestabilan pemangkinan dan aktiviti ORR. Namun demikian,

mangkin berasakan TM perlu disokong dengan karbon terdop nitrogen yang berpermukaan yang luas untuk mencapai aktiviti ORR yang tinggi. Penyokong karbon yang berpemukaan luas dan mempunyai kekonduksian elektronik yang tinggi juga memudahkan aktiviti ORR. Prestasi mangkin aloi adalah berkait langsung dengan suhu sintensi dan sifat strukturnya. Mereka bentuk gabungan teras-cangkerang dan mengawal ketebalan cangkerang adalah salah satu strategik penstrukturan dalam meningkatkan aktiviti jisim dan ketahanan. Akhir-akhir ini, teknik-teknik penyinaran digunakan ubah mengubahsuai sifat fizikokimia. Namun demikian, mangkin berasaskan TM biasanya stabil dalam larutan alkali tetapi tidak dalam larutan asid. Ulasan ini berfokus pada strategik untuk membangunkan magkin berkos efektif daripada mangkin Pt bermuatan rendah dan bebas platinum dengan aktitiviti ORR yang dipertingkatkan.

Kata kunci: tindak balas penurunan oksigen, logam aloi kumpulan platinum, mangkin logam peralihan, kaedah sintesis

Introduction

A fuel cell is an energy conversion device that converts chemical energy into electric energy through an oxidation reaction at the anode and a reduction reaction at the cathode. The cathode reaction, known as oxygen reduction reaction (ORR), is a fundamental reaction to various disciplines, such as energy conversion, material dissolution, or biology. The performance of fuel cells depends on the rate of ORR [1, 2]. Difficulties in O_2 adsorption, O-O bond cleavage and oxide removal are the main reasons for the sluggish reaction kinetics of ORR [3]. The state-of-the-art Pt/C (platinum/carbon black) catalyst and Pt-based alloy catalysts are used for the cathode reaction in aqueous electrolytes, and these catalysts are considered the best for ORR. All Pt or Pt-based catalysts still suffer from CO and S poisoning on Pt, loss of active surface area, corrosion of carbon support, low durability and limited supply, high cost, and use of a high amount of Pt [4–6]. So, non-Pt based catalysts with improved catalytic activity are required to overcome these limitations of Pt [7]. The main characteristic of an effective fuel cell catalyst is its capability to facilitate the rate of ORR [8]. Transition metal (TM) alloys, chalcogenides, carbides, nitrides, and metal-N4 macrocyclic compounds instead of Pt/C and PGM catalysts, are potential electrocatalysts for ORR [9]. Composition, particle size, crystallographic orientation, etc contribute to the enhancement in catalytic activity and d-band vacancy is considered as an important factor for enhancing catalytic behavior towards ORR. For developing a cost effective catalyst with improving ORR activity, the current research follows four different trends: 1) to reduce the wt% of Pt in alloy catalysts, 2) to develop the PGM free catalyst named M-N-C, where M for transition metal, nitrogen, and carbon, 3) to utilize the carbon with large surface area as catalyst support and 4) synthesis technique for designing cost-effective ORR cathode catalysts[10–13]. In the following section, we describe the general mechanism of ORR cathode in acidic and alkaline solutions, which gives a clear idea of the reaction paths.

General mechanism of ORR cathode

In general, anode and cathode reactions occur on a metal surface. The reaction that occurs at the cathode site is known as the ORR reaction. Usually, the ORR reaction is the limiting reaction step of the overall reaction because of its sluggish kinetic, hence it is essential to understand the ORR mechanisms to design an effective catalyst.

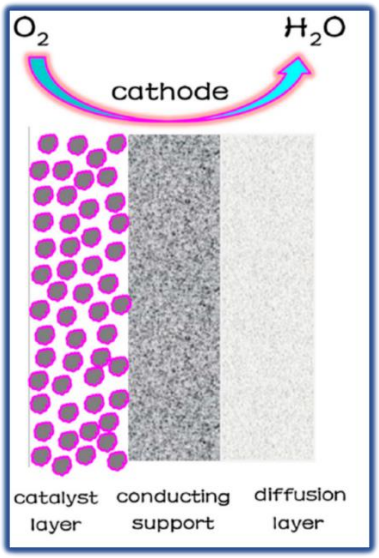

Figure 1. The structure of PEMFC cathode with catalyst layer [14]

The ORR mechanism involves a direct four-electron (4e-) or a series of two-electron (2e-) pathways. A one-step 4e- transfer mechanism is more efficient than a 2e-transfer mechanism. Thus, catalysts that facilitate the 4e- pathway reaction are more favorable. In the $4e^-$ transfer pathway, O_2 is converted into either H_2O (acidic medium) or OH^- (alkaline medium) on a single catalytic site. This process depends completely on the electrolytes [14–17].

In an acidic electrolyte, the $4e^-$ transfer pathway can be written as in Eq. (1):

$$O_2\,(g) + 4H^+\,(aq) + 4e^- \rightarrow 2H_2O(l) \quad (1)$$

and $2e^-$ transfer pathway can be expressed as Eqs. (2, 3, and 4):

$$O_2\,(g) + 2H^+\,(aq) + 2e^- \rightarrow H_2O_2\,(l) \quad (2)$$

H_2O_2 is produced in the intermediate step of the Eq.(2) pathway. H_2O_2 is finally reduced to water:

$$H_2O_2\,(aq) + 2H^+\,(aq) + 2e^- \rightarrow 2H_2O\,(l) \quad (3)$$

or is decomposed as follows:

$$H_2O_2(aq) + 2H(aq) + 2e^- \rightarrow 2H_2O(l) + O_2(g) \quad (4)$$

On the other hand, O_2 is converted into OH^- by $4e^-$ pathway, which is written as Eq. (5), and forms HO_2^- via $2e^-$ pathway in an alkaline medium,

$$O_2\,(g) + 2H_2O\,(aq) + 4e^- \rightarrow 4OH^-\,(l) \quad (5)$$

Eqs. (6,7 and 8) express the step of the $2e^-$ transfer pathway alkaline solutions.

$$O_2\,(g) + H_2O\,(aq) + 2e^- \rightarrow HO_2^-\,(l) + HO^- \quad (6)$$

Peroxide is also unstable

$$HO_2^-\,(aq) + H_2O\,(l) + 2e^- \rightarrow 3OH^-\,(aq) \quad (7)$$

and decomposes into the following:

$$2HO_2^-\,(aq) \rightarrow 2HO^-\,(aq) + O_2(g) \quad (8)$$

Pt-group alloy catalysts

Pt is the best monometallic catalyst for ORR in acidic and alkaline solutions. The fuel cell stack needs almost 80%–90% Pt, which increases the cost of the entire stack. Moreover, Pt has some drawbacks, such as CO poisoning, short life span, low durability, etc. So, the current research trend emphasizes reducing Pt use and the development of bimetallic and trimetallic alloy catalysts to overcome the stumbling block of Pt [18–20]. Some researchers used several noble metals like Pd, Ir, Rh, Ag, and Ru as cathode catalysts. All single noble metal catalysts followed the $4e^-$ pathway but exhibited lower catalytic activity than Pt. Improvement of catalytic activity depends on the optimization of particle size and shape, surface structure, support metal, and synthesis process [21]. It also revealed that combinations of two Pt-group metals can tune the ability of oxygen adsorption due to constructing a hetero-metal-metal bond by altering the electronic configurations. Coupled metals also generate a new active site. The mutual effect of changing electronic and geometric structure encourages a $4e^-$ reaction pathway towards ORR [17]. The d band vacancies which consider as important parameters increase due to the existence of Pt atom, d band vacancies boosted 2π electron donation from O_2 to the catalyst surface. Finally, O_2 reacted with donated electrons and protons to yield desirable H_2O molecules [22].

Due to the similar crystal structure of Pt, palladium-based catalysts have stimulated extensive concern among researchers [23]. Zhou et al. reported that Pt-Pd/C exhibited higher durability than commercial Pt/C as a cathode catalyst. They also concluded that particle size and electrochemical surface area (ECSA) loss are associated with durability, and larger particles are more stable in alkaline solution [24]. Wang et al. established the relationship between weight ratio and particle size. They reported that ORR activity was controlled by the size of Pt nanoparticles, and 30% of Pt-Pd/C exhibited remarkable performances, whereas the weight ratio of Pt: Pd was 1:1. The mass activity (MA) and the ECSA value of this Pt-Pd/C catalyst (MA= 0.488 mA μg^{-1} and ECSA=107.7 $m^2\,g^{-1}$) are four times and 1.69 times higher than those of commercial 10% Pt/C (MA=0.123 mA μg^{-1} and ECSA=63.6 $m^2\,g^{-1}$) in acidic solution[25, 26]. The ratio of Pt-Pd has a great impact on surface morphology and catalytic activity. In the presence of Pd, Pt-Pd/C exhibits larger ECSA, higher mass activity, and larger particle size.

The impact of Pt-Pd/C with different atomic ratios on the particle size, mass activity (MA), and ECSA values

are depicted in Figure 2. From the graph, it is clear that smaller particle size is expected for better ORR activities. A relationship is observed between ECSA and the particle size and ratio. Particle size shows an increasing trend with an increasing Pt: Pd in compositions, and ECSA shows a decreasing trend with the increasing Pt: Pd. A higher amount of Pd, i.e. above 1:2 (Pt: Pd), causes a lower dispersion rate, which is the key reason for the decrease in catalytic activity and mass activity [27]. Pd increases overall ORR performance, especially stability in both acidic and alkaline-aqueous electrolytes. A low particle dispersion rate still occurs if the ratio of Pt: Pd is more significant than 1:2. So, it is a major question of which ratio will be taken into consideration.

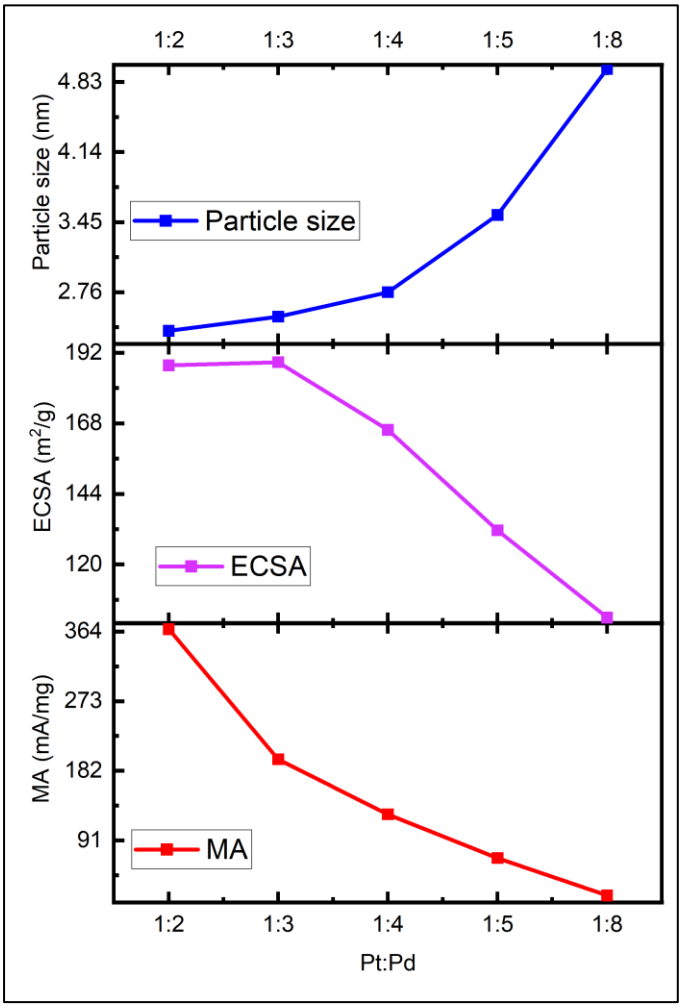

Figure 2. The Impact of Pt: Pd on particle size MA, and ECSA [27]

Ru is another alternative metal for reducing the use of Pt and improving catalytic activity. Small particles show better CO tolerance than large particles for Pt-Ru alloys. The Pt: Ru ratio of 1:1 exhibits an enhanced ORR activity, and the morphological change induces several active sites for CO oxidation, but the oxidation state of Ru is gradually decreased by increasing particle size [28]. In both types of electrolytes. Pt-Ru alloy exhibited better mass activity and stability than state of art Pt/C. Ru surface facilitates the break of O-O bond and

supports the proton transport at the same time. As a result, Pt nanoparticles exhibited enhanced ORR catalytic activity [29, 30]. The ECSA, mass activity, and Pt-Ru particle size vary with Pt atom in alloys[31]. According to the literature, the degree of alloying Pt-Ru strongly depends on the nature of the electrolyte. The particle size of the Pt-Ru catalyst decrease with increasing pH of solution[32]. The main drawback of Pt-Ru alloy is that it needs more Pt than Pt-Pd, and as a single metal catalyst, Ru/C exhibits lower catalytic activity compared with Pd/C, Ir/C, and Rh/C in acidic media [33].

In acidic solution, Pt-Pd/C and Pt-Ir/C both catalysts exhibited almost the same ECSA and both catalysts performed better than Pt/C. In terms of stability, Pt-Ir/C was better than Pt-Pd/C and Pt/C. Pt and Ir's nucleation helps to improve the durability and catalytic activity. Crystallite size could be able to tune the performance of Pt-Ir [34, 35]. The mass ratio is the most important factor for the Pt-Ir catalyst. The Pt-Ir/C (16:84) presents a larger ECSA value, which is 28.7 $m^2 g^{-1}$, and its mass activity is 373.3 mA mg_{pt}^{-1}, which is greater than Pt/C (ECSA=18.3 m^2 g^{-1} and MA=142.9 mA mg_{pt}^{-1}). However, Pt-Ir/C (4:96) and Pt/C possess the same ECSA value, but Pt-Ir/C (4:96) exhibits lower catalytic activity than Pt/C [36]. Like other Pt group metal alloys, Pt-Ir follows the 4e- pathway and exhibits improved ORR activity. Catalytic performances of this catalyst are strongly influenced by the synthesis technique, treatment temperature, catalyst support, and the presence of Pt [37].

Pt-Rh alloy also exhibits better durability than a single Pt catalyst. Rh itself does not participate in the activity of the catalyst, but the existence of Rh plays a crucial role[38]. Rh covers only 15%–20% of the surface because Pt suppresses it. Both metals possess a similar crystal structure and similar-sized cells. So, it is difficult to determine the active phase that belongs to Rh. A small amount of Rh is needed to make a Pt-Rh alloy and acts as a bimetallic catalyst[39]. Narayanamoorthy et al[40] reported that supportless Pt-Rh alloy is better than Pt-Rh catalyst with Vulcan carbon (VC) and Pt/C (CB). Supportless Pt-Rh (154.4 m^2g^{-1}) possesses a higher ECSA value than Pt-Rh/C (103.5 $m^2 g^{-1}$) and is 2.5 times higher than Pt-Rh/VC (61.76 m^2 g^{-1}). The cluster morphology depends on the availability of Pt surface[40]. Several studies concluded that smaller particle sizes presented larger ECSA, which exhibit higher mass activity and stability. All PGM alloys follow the $4e^-$ pathway and exhibit comparable catalytic activity in both electrolytes.

Making alloys with low-cost materials is a good strategy for reducing Pt use. TMs are the most acceptable metals for changing the electronic configuration in the cluster [41]. The addition of PGM increases the particle size, whereas Ag reduces the particle size due to its small diameter (<5 nm), facilitating ECSA and ORR activity. Many investigations have been performed on Ag to overcome the limitation of Pt/C [42]. The catalytic activity of Pt-Ag/rGO is slightly higher than that of Pt/C in acidic solution with a Pt: Ag ratio of 1:3.This catalyst exhibits a larger ECSA value (67.8 $m^2 g^{-1}$) than Pt/C (39.2 $m^2 g^{-1}$) [43]. Pt-M/C (M=Fe, Co, Ni) presents a larger particle size compared with Pt/C. The particle size of Pt-M/C is calculated to be 2.5 nm to 2.8 nm, whereas that of Pt/C is 2.1 nm when the ratio of Pt: M is 50:50. Pt-Fe/C (100 $m^2 g^{-1}$) exhibits the highest ECSA value among Pt-M/C, which is lower than 50 wt% of Pt/C (119 m^2 g^{-1}). All Pt-M/C show improved mass activity compared with Pt/C. The variable electron state of TM atoms induces a strong interaction between TM-O, which encourages the slower loss rate of ECSA than PGM [44, 45].

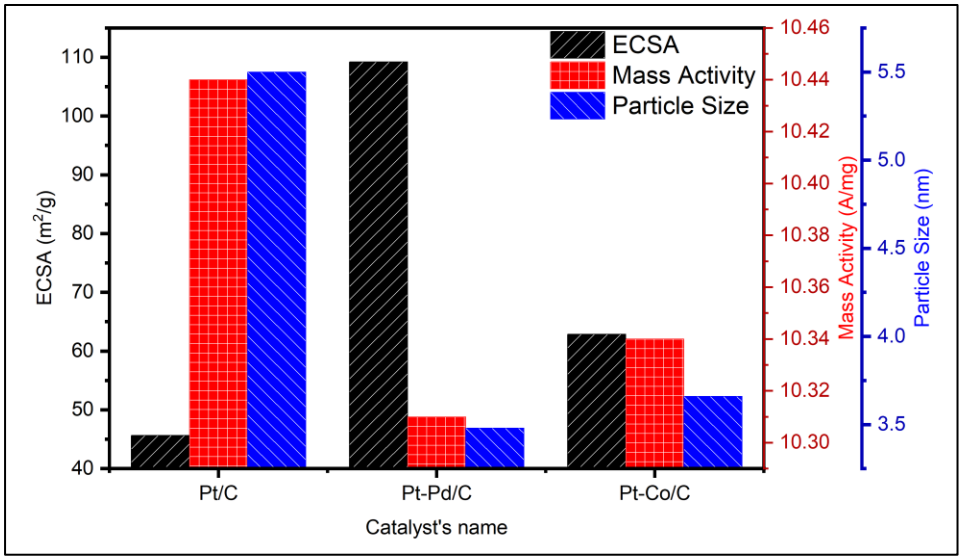

Figure 3. Effect of making alloy with platinum group metal (PGM) and transition metal (TM) [46]

From Figure 3, it has been seen that Pt-Pd/C increases the ECSA and decreases the particle size. On the other hand, Pt-Co/C reduces the ECSA, and particle size was a little larger than Pt-Pd/C. In the case of MA, TM exhibited better performance than PGM. Catalytic activity increased due to lattice compression, resulting from the downward shift of the d-band center of Pt and Pd. ORR activity showed a decreasing trend with an increasing amount of Co. Compare with Pt-Pd/C and Pt/C, Pt-Co/C showed better stability in acidic solution. However, it has been suffering from low stability while using in Toyota Mirai Fuel Cell Vehicles [46–49]. To overcome the stability problem, Pt-Fe/C is a good substitute for Pt/C. Fe can tune the electronic structure of Pt that enhanced the durability of Pt-Fe/C in an acid medium [50, 51]. PGM sites' surface activity has been influenced by the small atomic size of TM and the reduction in the PGM-TM bond, which serves better catalytic activities of PGM-TM alloys. The study revealed that the enhancement of ORR performance depends on the density of PGM [52].

According to literature, the observed improvement in catalytic activity reveals several issues that should be considered in future studies to develop a better catalyst, as follows: (i) increase in the resistance to particle sintering; (ii) surface roughening due to the removal of some alloying metal that increases the electrochemical surface area; and (iii) preferential crystal orientation [52–55]. High durability and catalyst activity are the keys to solving the current problem of Pt. PGM and PGM-TM alloy catalysts exhibit excellent activity and stability compared with traditional Pt/C catalysts. All types of mixed metal alloys are suitable substitutes for commercial Pt/C in alkaline electrolytes. In acidic electrolytes, these catalysts show poor performances without Pt in their composition. PGM-TM bond helps increase durability and stability, but a large amount of PGM is needed to exhibit better catalytic activity.

TM alloy catalysts for ORR

Many experimental studies proved that nitrogen-doped carbon support increases the concentrations of ORR active sites and stability by associating two adjacent carbon crystallites of TM catalyst; the configuration of TM active sites changes completely according to C-N species [56–58]. Here, we discuss some promising TM catalysts that exhibit improved ORR activity in the presence of N.

Fe-N-C has drawn much attention due to its catalytic performances. N coordinated Fe atom has been a highly active center for ORR [59]. Fe-N-C nanoparticles show outstanding stability in both acidic and alkaline

solutions. Only 0.5 wt% of the Fe-contained Fe-N-C catalyst possesses a high surface area (1501 m^2g^{-1}) and exhibits superior durability to Pt/C. Half wave potential ($E_{1/2}$) of Fe-N-C and commercial Pt/C is presented in Figure 4.

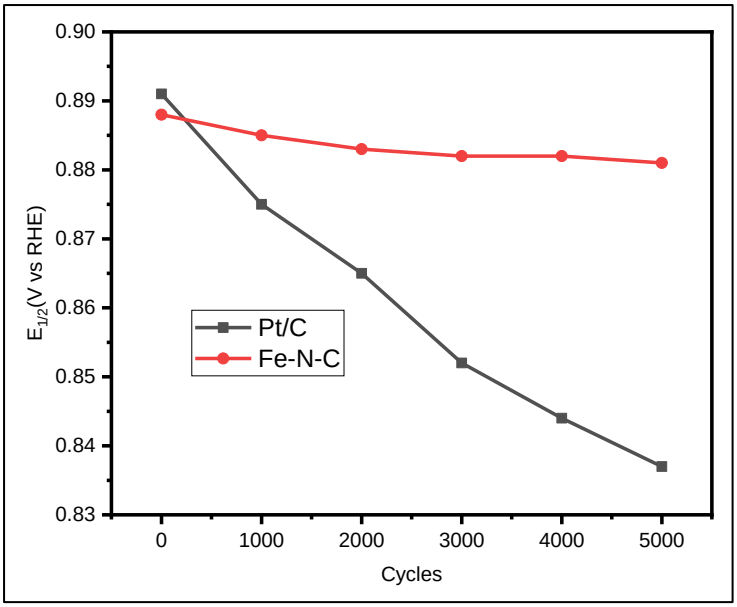

Figure 4. $E_{1/2}$ of Fe-N-C and Pt/C at every 1000 cycles in the durability test [60]

From Figure 4, it is clearly observed that after 5000 potential cycles, Fe-N-C remains unchanged whereas Pt/C gradually decreases under the same condition [60, 61]. The formation of Fe-N is powerfully demonstrated by carbon chemistry. Fe-N active sites are also an essential issue for ORR activity. The Fe-N/C/rGO (10% to 20% of Fe) exhibits improved ECSA and ORR activity, which are comparable with those of Pt/C and are higher in comparison with those of Fe-N/C/rGO (5%–10% of Fe), Fe-N/C, and Fe-N/rGO [62, 63]. Fe-N-based catalyst follows the $4e^-$ reaction pathway in both types of electrolytes. The weight percentage of Fe plays an important role in the composition. This percentage depends on the presence of inducing elements, such as N, P, and S [64]. The gap between the valence and conduction bands of Fe atom (-0.82 eV) enhances catalytic stability and a small amount of metal doping can increase conductivity, and durability [65]. Jiang et al reported that the binding energy of O_2 that presents in the Fe-N_x site helps the adsorption of O_2 on Fe-N_x sites, which promotes ORR activity of Fe-N-C. 20wt% to 35wt% ionomer concentration increases the ionic conductivity of the cathode site. Above 35 wt.% concentration, active sites gradually decrease. However, unsaturated Fe can change the charge density of N-doped carbon support and the central Fe atom in Fe-N_x. Some researchers replaced Fe with Co or Ni [66–68].

Co is the most widely used substitute and partial substitute metal in compositions due to its low price, high durability, and $4e^-$ reaction selectivity [69]. The Co-based catalyst exhibited superior stability to that of Fe. Like Fe, the bimetallic atom-doped Co catalyst shows better ORR performance by forming dual sites than a single metal Co catalyst. Double active sites facilitate electron transfer [70]. Partially substituted Co-Te/C (1:1.93) and Co-Se/C (1:1.25) are catalysts that follow the $4e^-$ reaction pathway in acidic solution, but the catalytic activity is not comparable with that of Pt/C [71]. Support metal has an impact on Co-based catalytic activity. Co_2P/NRC nanorods enhance durability and catalytic action to a level comparable to Pt/C in alkaline media [72]. The performance of the Co-N-C-based catalyst depends on the active site of Co-N_x and

nitrogen-containing functional groups and the effect of mutual interaction between Co-O-C and Co-N-C bond formations. Co-N/C catalyst follows the $4e^-$ reaction pathway and exhibits high durability and current density. High amounts of Co^{2+} oxidation states are associated with increasing ORR activity [41, 57, 73]. Co-Fe alloy is among the prominent non-PGM catalysts for ORR. It has been reported that charge redistribution between Fe-Co alloy and N-supported graphitic carbon-nanotube enhances the catalysts' behavior. The corrosion resistance and electronic conductivity increase with the amount of Co increase in alloy [74, 75].

Ni-based catalyst is another good alternative to most active Pt-group metal catalysts. Ni or Ni alloys are not easily oxidizable, and the Ni structure facilitates the transportation of ions and the charge conductivity[76]. N-doped Ni-Co and Fe-Ni catalysts showed comparable ORR performance with Pt/C and exhibited superior stability [77, 78]. The enhancement of catalytic activity completely depends on the mutual effect of Ni and the N-carbon metal's electronic structures. The edge N atom and the geometric effect of support metal regulate the electronic configuration of Ni [79, 80]. Ni-Mo catalyst showed the highest mass activity among Pt free catalysts used in the present time due to the high dispersion of Ni particles, and Mo facilitates mass activity[81]. In an alkaline aqueous solution, the N-C structure works as a support of the Ni nanoparticles and enhances the catalytic activity towards ORR [79].

As a 3d transition metal, Cu shows high electro-catalytic activity towards ORR due to its valence electron configuration, which is closest to Pt. It has a very strong complex ability to generate Cu-N bonds and exhibits the highest stability in an aqueous solution among 3d transition metals [82]. Cu metal works as an active component for ORR, and this metal is used for constituting active sites. Cu enlarges the surface area of the catalyst. Cu^{2+} ions have a great affinity to form a stable complex with N-based ligands. Cu-N interaction speeds up the peroxide reduction and oxygen activation [83, 84]. The CuFe/C (1.5wt.% Fe and 1.7 wt.% Cu) alloy catalyst and Pt/C (30%) exhibit the same catalytic activity. Fe^{3+}-N works as an active site for ORR, and Cu^{2+}/Cu^{+} plays the role of a redox mediator that shuttles the electron from the electrode to $FeN\text{-}O_2$ [85]. During ORR, the Fe atom in Cu alloy facilitates the desorption of oxygenated intermediates, which increases the rate of ORR kinetics. The electronic structure of catalyst metals has been changed by the interaction between the metal catalyst and the support metal. N particularly helps donate electrons to the O-O bond, thereby increasing stability [86]. Cu ascribes to high redox potentials, and the current densities of the d-orbital of Cu lead to a weaker O-O bond [87].

Among the transition metals, manganese oxides became the focus of research due to their variable oxidation states and high stability in alkaline media. Mn^{3+} species modifies the crystallinity, surface area, and pore size of catalysts [88]. Liu and co-workers identified the two types of Mn coordination, octahedral Mn^{4+} (i.e. partial d-orbital filling Mn) and pyramidal Mn^{3+} and Mn^{3+} coordination is essential for ORR activity [89]. The N-C structure helps reduce electron cloud densities on a carbon atom by inducing N. The active site of the Mn-N-C catalyst is the combined structure of N-C and Mn-N [90]. The covalency of the Mn-O bond is responsible for specific ORR activity and works as an electron transfer mediator to O. The existence of Mn^{3+} on the active site facilitates the ORR activity, whereas Mn^{4+} encourages the $4e^-$ reaction pathway [91].

However, TM based catalysts exhibit higher levels of ORR activity in alkaline media that indicate the exchange of electrons and the change of oxidation state during ORR, the exact role of TM is not clear[57]. Transition metals (TM) have been recognized as alternatives due to their high corrosion resistance and stabilities, electrical conductivities, and mechanical strengths. N-doped carbon-supported TM catalyst exhibits better ORR activity in alkaline solution. Formation of C-N increases the concentration of active sites.

Benefits of the carbon support

Carbon support helps increase the electronic behavior of catalysts and enhances ORR performance. ECSA, durability, reaction pathway, and electrical conductivity have been influenced by support materials [92]. Corrosion of metal is an important factor in fuel cell

operations. Carbon support metal helps overcome corrosion problems by making a strong bond between nanoparticles and support materials [93]. Carbon nanomaterials are considered good catalyst support due to their excellent properties, which ensure the following parameters: 1) high electrical conductivity; 2) large surface area; 3) strong interaction between support and catalyst; 4) high electrical stability under the fuel cell condition, and 5) low cost [94–96]. Large surface areas of support suppress the particle size. This criterion helps make a highly concentrated catalyst particle that increases the efficiency of the electrode by reducing embedded sites and shortening the reactant pathway [97, 98]. C(Carbon black) is widely used for commercial Pt catalysts. Poor durability and low catalyst metal utilization are the main weaknesses of C. GO (graphene oxide), rGO (reduced graphene oxide, MWCNT(multiwall carbon nanotube), and so on are considered a better substitute for C. [99, 100]. Nowadays, GO and rGO are widely used because of the partial transition from sp^2 to sp^3carbon atoms. Both GO and rGO derivatives of graphene are easy to produce on a large scale using graphene sheets, catalyst metal is located between pores, thereby reducing the aggregation of catalyst metals, and this behavior helps enhance catalyst efficiency [101, 102]. Studies revealed that in rGO, oxygen groups participate in the transfer of electrons, which causes the reduction of catalytic activity. Electric contact efficiency plays an important role between two catalyst particles. rGO has higher thermal stability than GO due to lower defect density [103, 104].

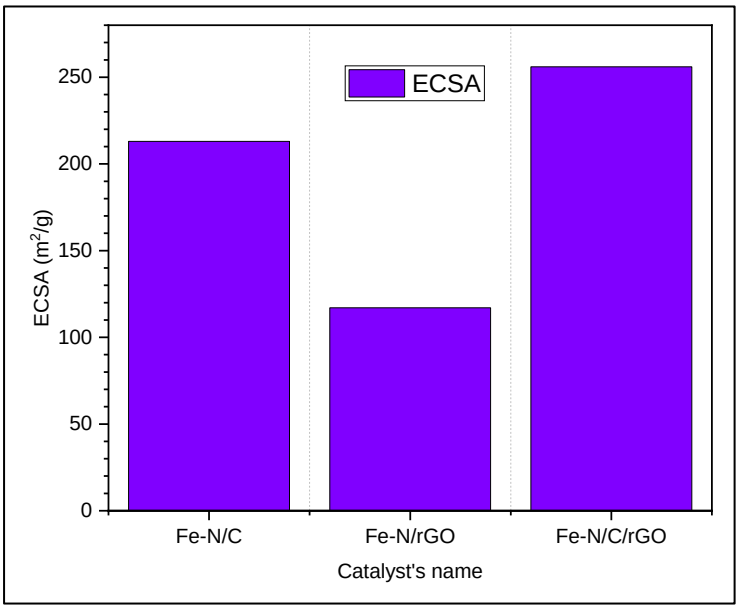

Figure 5. Effect of carbon support on ECSA [63]
