It has been seen from Figure 5, ECSA of catalysts changes with the change of support metal, carbon black (C) supported Fe catalyst exhibited larger ECSA than reduced graphene oxide (rGO). Fe catalyst presented the largest ECSA while C and rGO were used together [63] Surface modification of the graphene sheet is conducted by inducing the heteroatom to boost the interaction with a metal catalyst; graphene aggregation is avoided by changing the interfacial properties [105]. The electrochemical activity of the non-PGM catalyst depends on the doped element (N, S, and P) that supports carbon. The edge plane sites contribute to the improvement of catalytic performances, and spin densities on adjoining carbon atoms induce different ORR sites [64, 106–109]. Based on the above discussion, we summarise the properties of different carbon forms in Table 1, that influence the ORR activity.

Table 1. Represents the ECSA, conductivity, advantages, and disadvantages of widely used carbon forms as support

Carbon Materials	**ECSA ($m^2 g^{-1}$)**	**Conductivity ($S\ cm^{-1}$)**	**Advantages**	**Disadvantages**	**Ref.**
Vulcan XC-72	250	2.77	The catalytic activity can be increased by surface modification and pre-heat treatment.	Low utilization of metal catalysts and poor durability.	[110, 111]
CNT	50-1000	200-900	Excellent electrochemical stability and high hydrophilicity produce better ORR reactions.	Highly sensitive to different gas and synthesis methods.	[52, 112, 113]
GO	2630	$\sim 10^4$	Easy to synthesis on an industrial scale and functionalized as well.	Catalytic properties change with changing synthesis tech.	[114–116]
Ordered porous carbon(OPC)	600-2800	3.28×10^{-4} - 2.2×10^{-3}	Stability increases with increasing annealing temperature	Electrochemical activities strongly depend on pore size and the diameter less than 10nm.	[117–120]
Graphene nanosheets (GNS)	56	10^3-10^4	Highly stable than MWCNT, SWCNT, CB, and GO	Highly sensitive to the synthesis process. During preparation, it losses many properties due to aggregate.	[98, 121, 122]

Promising synthesis technique for ORR catalysts

The synthesis condition influences the catalyst compositions and structure of active sites. Several strategies are used to establish a catalyst that is comparable to Pt/C in both acid and base solutions. Among the improvement techniques, pyrolysis and core-shell techniques are widely used for developing alloy catalysts. Most recently, the irradiation method utilizes for obtaining a higher degree of alloying.

Pyrolysis

Different types of metal alloys help reduce PGM use and help modify the surface structure and reactivity within alloying elements through the change of electronic and geometric structure [11, 111]. Alloying PGM with transition metals declines the OH adsorption due to the existence of PGM-TM bond distance in lattice contraction, which promotes higher ORR activity than pure PGM. The durability of PGM-TM alloys depends

on the degree of alloy homogeneity [52, 123]. Performances of alloy catalysts are directly related to pyrolysis treatment. The effect of pyrolysis temperature has been illustrated in Figure 6(a-f).

From the TEM image of FeCN/GN(graphene nanosheets), it is clear that below 700^{o} C, only a few FeCN particles have been observed, marked by the white circle in Figure 6(a) and 6(b) which were pyrolyzed at 500^{o} C and 600^{o} C respectively. Figure 6(d-f) represents FeCN samples that pyrolyzed at 800 ^{o}C, 900 ^{o}C, and 1000 ^{o}C respectively. FeCN particles were uniformly distributed on GN(graphene nanosheets) above 700 ^{o}C. Figure 6(c) represents the sample pyrolyzed at 700 ^{o}C. At 700 ^{o}C, FeCN/GN exhibited the highest electron transfer (3.94) and ORR activity in acidic solutions. In general, a pyrolysis temperature below 700 °C is not enough to induce stable and active ORR sites [112, 124, 125]. The formation of Fe-N_x active sites strongly depends on pyrolysis, which contributes to ORR activity. N atoms have been successfully united into a carbon matrix, and the proportion of N touches the maximum level at 900 ^{o}C [53,119]. The pyrolysis treatment approach helps increase the concentration of ORR sites by modifying the M-N_x/C structure. Heat treatment also controls metal-N bonding [76,120].

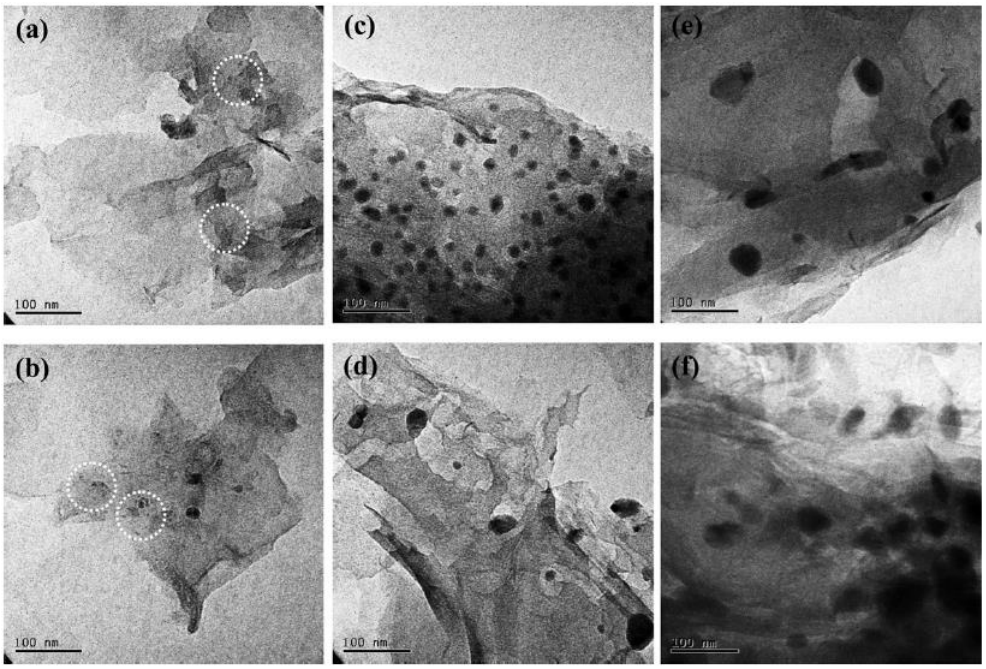

Figure 6. TEM image of FeCN/GN at 500 ^{o}C (a), 600 ^{o}C (b), 700 ^{o}C (c),800 ^{o}C (d), 900 ^{o}C (e), and 1000 ^{o}C (f) [124]

Core-shell structure

Mutual interaction of core metal and shell facilitates the mass activity and durability of ORR in both acidic and alkaline electrolytes. Generally, a core-shell-structured catalyst is designed by capturing the catalyst metal in carbon materials. This structure provides an exclusive electronic interaction between confined nanomaterials and carbon shells, thereby playing the main role in the enhancement of catalytic activity. Both single metal particles and metal alloy materials can serve as shells or core [105, 108]. This approach leads to a change in the d-band positions, which help provide higher activation energies. Ligand performances enhance catalytic activity and improve charge transfer [100]. Core materials and shell thickness are important factors for stability and ORR performance. Shell thickness helps with long term stability. The thickness of the shell screens the core interactivity, which improves catalytic stability [31, 115]. Gautam et al. reported that a shell material graphene nanosheets appears on behalf of electron collectors and tricks the core ion to form the existing active sites by providing high stability [116]. [116]

Irradiation technique

The irradiation process helps improve structural properties and chemical properties. γ-Irradiation helps reduce the oxygen functional group from the GO sheet and increases C=C bands. It also modifies the sp^2 character of C. Some work has been done using gamma irradiation. In the case of few-layered graphene materials, the O/C ratio exhibits a decreasing trend when γ-irradiation dose increases for GO and GONR (nanorod) [117]. A remarkable characteristic has been observed in preparing graphene aerogel (GA) from the GO sheet. GA shows more stability and has a honeycomb structure with a high C/O ratio after irradiation. No significant weight loss can be observed due to γ-irradiation.[118]. However, dose rate, total dose, type of solvent are important parameters for gamma irradiation induced synthesis technique. These parameters can be able to alter the size, chemical, and physical properties of the final product. Sharin and co-workers reported the reduction of GO has occurred when the cumulative dose was 35kGy. They utilized different amounts of irradiation dose,0, 5, 15, 20, and 35kGy on GO powders [119, 126, 127] In an aqueous solution (water/alcohol), Irradiation decompose the water molecules to hydroxyl radical, OH^-, hydrogen radical, and hydrated electron, H^* and e^- species. Alcohol removes the oxidative OH and converts it into reductive radicals.[121]. In the case of a heterogeneous catalyst, gamma irradiation changes the concentration of the active site of a catalyst surface, whereas electron beam irradiation induces a new active center by switching the chemical bond and creating defects on a catalyst surface [128]. Kakitani et al. reported that Pt-C bond formed during ion-beam irradiation (Ar^+). This bond changes the chemical state of Pt nanoparticles and carbon support that suppresses Pt oxidation and improves overall catalytic activity towards ORR [129]. After Ar^+ irradiation, carbon nanofiber-supported PtRu exhibits a lower crystal size (19.5 nm) due to the change in the valence state of support metal, whereas non-irradiated carbon nanofiber-supported PtRu shows a larger crystal size (20.1 nm) [130]. Proton irradiation leads to a break M (metal)-O bond by producing highly active radicals on the metal surface. During irradiation, the 2p orbital of O and the 3d orbital of metal merge, thereby reducing the bang gap, which increases the electronic conductivity and overall performance of the metal catalyst [131]. Ohkubo and co-workers suggested that the electron beam irradiation reduction method can synthesize both alloy and metal oxide on the carbon support simultaneously[132].

Conclusion

From the discussions, it is clear that all PGM alloys are comparable catalysts for ORR cathode in both acid and alkaline mediums, though 20%wt of Pt is needed for promising performance. Mixing PGM and transition metal is a good strategy for reducing the use of Pt. PGM-TM alloy catalysts also improve ORR activity and follow the $4e^-$ pathway in both types of solutions. However, 50wt% of PGM is required in the PGM-TM cluster for enhancing ORR activity. Most of the TM-based catalysts have been developed with the N supported carbon. N atom produces C-N sites that provide higher active site densities and mass transport. In the absence of the N atom, the TM-based catalysts are not comparable with commercial Pt/C and other PGM catalysts. N supported Fe, and Fe doped Co catalysts

work in acidic solutions, but it is not comparable with commercial Pt/C. All M-N-C (M= transition metal) exhibited better catalytic activity than Pt/C in alkaline solution. Choosing ideal carbon support can improve the catalytic activity of TM alloy in an acidic medium. The amount of nitrogen and carbon defects and metallic particles' existence are common factors for improving performance.

Alloy and pyrolysis are closely related to each other. Homogeneity of alloy catalysts depends on pyrolysis temperature. Core-shell is a popular technique for alloy catalysts. In this process, catalyst behaviour is associated with the mutual interaction between the core metal and the shell metal. Shell thickness also plays a hidden role to facilitates ORR. Nowadays, different types of irradiations have been taken a superior position in research.

Abstract

A new dual mixed moieties of acetylide (C≡C) and chalcone (-CO-CH=CH) system namely 3-(naphthalen-1-yl)-1-(4-(phenylethynyl)phenyl)-2-propen-1-one (**3NPP**) was successfully designed and synthesized via Claisen Schmidt condensation reaction. Spectroscopic characterization and thermal analysis were conducted via Infrared Spectroscopy (FTIR), ^{1}H and ^{13}C Nuclear Magnetic Resonance (NMR) and Thermogravimetric (TGA) analysis. Density functional theory (DFT) assessment with basis set of B3LYP/6-31G (d,p) was computed to investigate the energy level of HOMO and LUMO, charge transfer within the molecule by global chemical reactivity descriptors (GCRD), molecular electrostatic potentials (MEP) and hyperpolarizability analyses. The simulated calculation reveals that the HOMO-LUMO energy gap of **3NPP** exhibited at 3.51 eV and has demonstrated good agreement with experimental optical band gap (E_g^{opt}). Additionally, **3NPP** possesses high NLO response with total first hyperpolarizability (β_{tot}) of 420.51× 10^{-30} esu. The presence of π-conjugated acetylide groups has improved nonlinear optical property and potential for application in optoelectronic.

Introduction

Recently, organic nonlinear optical (NLO) materials attracted enormous interest due to their promising applications in optical power limiting applications [1, 2], second harmonic generation (SHG) photonics and electro optic (EO) processes [3, 4]. The development of this material becomes a promising alternative approach due to their large nonlinear response, extremely fast switching time and convenient optimization routes through molecular engineering compared to the currently studied inorganic materials [5]. Among various NLO materials reported, chalcone derivatives exhibit excellent nonlinear optical (NLO) properties by having the combination of electron donor and acceptor group substituents on phenyl rings are used due to the delocalization of electron of the electron in π-conjugated system [5, 6, 7, 8]. Besides that, the process of delocalization of electron of the electron in π-conjugated leads to high electron density mobility which makes them the ideal candidates for NLO materials [9]. According to Arshad et al., Donor-π-Acceptor (D-π-A) systems are widely been used in information storage, optoelectronic, and also NLO applications. π-conjugated framework will act as the centre which gets appended by electron acceptor at one side and an electron donor group at the other side [10]. In previous study, many researchers had synthesized chalcone derivatives based on aromatic system with tuning the electron donating group (EDG) and electron withdrawing group (EWG) such as (E)-1-(4-ethylphenyl)-3-(4-(heptyloxy) phenyl) prop-2-en-1-one [11],(E)-N-(2-(3-(4-ethoxyphenyl)-1-(2-(phenyl sulfonylamine)phenyl)prop-2-en-1-one, (E)-3-(4-chlorophenyl)-1-(2-(phenylsulfonylamine)phenyl) prop-2-en-1-one and (E)-3-(4-bromophenyl)-1-(2-(phenylsulfonylamine)phenyl)prop-2-en-1-one [9]. These system were reported as the ideal candidates to be developed as NLO materials.

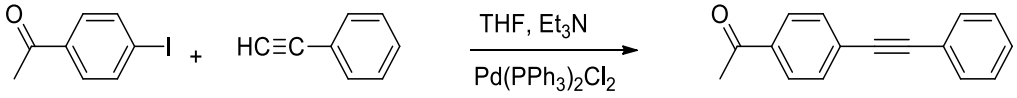
Within this interest, herein we present a work by introducing new chalcone-based system, 3-(naphthalen-1-yl)-1-(4-(phenylethynyl)phenyl)-2-propen-1-one (**3NPP**) with the combination of active extended conjugated acetylide system (C≡C) featuring D-π-A system. The focal point molecular candidates in this work are the extended conjugated system of acetylene (C≡C) and the chalcone system, which are made up of two distinct moieties that are used as active electronic components. Due to the extension of conjugation within the molecules aided by active donor and acceptor groups located at each terminal of the molecules, it is expected that the combination of these two systems in a single molecular framework will allow electrons to easily move through the conjugated framework from electron donor to electron acceptor group. It was designed and synthesized due to its structural simplicity and high reactivity, acetylene represents a versatile building block for organic synthesis, and its chemistry has evolved rapidly [12]. This molecule consists of π-electron which can facilitate the electron in the compound. The presence of π-conjugated polymer possessing electron-donating and electron-withdrawing groups exhibit low-lying charges transfer excited states and large second-order optical nonlinearities [13]. Besides, π-bridges and spacers, are important when tweaking NLO characteristics. The essential characteristics for a material to qualify as a good NLO material are red shifted absorption maxima, greater dipole moments, and thermal stabilities. Alkyne analogues have demonstrated blue shifted absorption maxima and worse thermal stabilities [14, 15]. In addition, the calculations were performed by using density functional theory (DFT) method to investigate

the physico-chemical properties of the designed molecule and can support experimental values. Furthermore, DFT calculation can be carried out to obtain the molecular orbitals, orbitals and electrostatic surface map [16]. In addition, DFT was used due to its great accuracy in reproducing the experimental values of molecular geometry, vibrational frequencies, atomic charges, dipole moment [17]. From the DFT calculation, NLO properties of **3NPP** can be described and compared to experimental values.

Materials and Methods

All chemicals, solvents, and reagents that were used in this work were 4-iodoacetophenone, phenylacetylene, 1-pyrenecarboxaldehyde, palladium(II) chloride, triphenylphosphine, sodium hydroxide, acetonitrile, triethylamine, tetrahydrofuran, hexane, dichloromethane, and ethanol were purchased from Acros Organics, Fisher Scientific, Merck, and Sigma Aldrich. They were used as received without further purification tasks carried out.

Characterization and Instrument

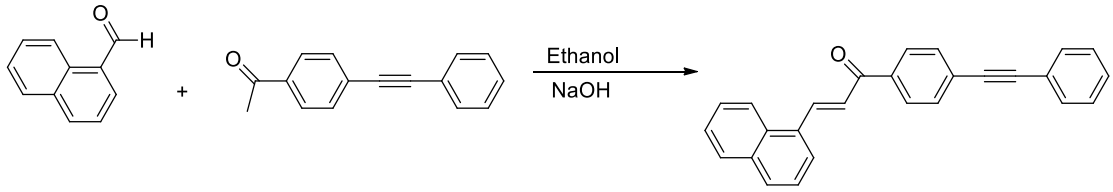


Fourier Transform-Infrared Spectrometer (ATR-FTIR) spectra were recorded using Perkin Elmer 100 spectrophotometer in the range of 4000-450 cm^{-1} spectral. The ^{1}H-NMR and ^{13}C-NMR spectroscopy analyses were conducted by using Bruker Avance III 400 MHz Spectrometer by using deuterated $CDCl_3$ as solvent. Next, the UV-Vis spectra were obtained using Spectrophotometer Shimadzu UV-1601PC in 1 cm^3 cuvette. Besides, Thermogravimetric analysis (TGA) was performed using Perkin-Elmer TGA analyzer from 30 ℃ to 900 ℃ at a heating rate of 10 ℃/min in the presence of a constant nitrogen flow.

Computational method

Frontier molecular orbitals (FMOs), global chemical reactivity descriptors (GCRD), and the NLO properties such as dipole moment, polarizability, and hyperpolarizability were carried out by density functional theory (DFT) using Gaussian 16 program package. All the images and graphs are visualized by Gauss view 6.0. The B3LYP functional was used with the 6-31G(d,p) basis set for the optimization of the structure. The basis set was chosen due to the calculated values by using B3LYP/6-31G(d,p) basis are considerably better agreement with the experimental which also includes the consideration of the polarization function supplied provided a lower error, more precise bond lengths [18].

Synthesis of precursor: 1-(4-(phenylethynyl)phenyl) ethanone (PPE)



The experimental details regard to Sonogashira precursor, **PPE** has been reported before in previous literature [19]. Hence, in this study, some modification have been carried out in for the interest of this work. 4-iodoacetophenone (0.5 g, 2.03 mmol), phenylacetylene (0.23 mL, 2.03 mmol), $Pd(PPh_3)_2Cl_2$ (40 mg, 0.057 mmol), and triethylamine (7 mL) were dissolved in tetrahydrofuran (40 mL) in the two-necked 250 mL round bottom flask. The reaction was refluxed for approximately 14 hours. The progress of the reaction was monitored by using Thin Layer Chromatography (TLC) (hexane: ethyl acetate, 4:1). After the reaction was adjudged completion, the reaction was cooled to room temperature prior filtration. Then, the mixture was dried *in-vacuo* prior purification via column chromatography to afford off-white solid as a precursor (**PPE**). Yield; 50%. The synthetic pathway of precursor is shown in Scheme 1.

Scheme 1. Synthetic pathway for precursor, 1-(4-(phenylethynyl)phenyl)ethanone (**PPE**)

Synthesis of 3-(naphthalen-1-yl)-1-(4-(phenyl ethynyl)phenyl)-2-propen-1-one (3NPP)

The synthetic approach for the preparation of title compound (**3NPP**) is summarized in Scheme 2. 1-(4-(phenylethynyl)phenyl)ethanone (0.2 g, 0.908 mmol) was dissolved in ethanol (20 mL) in 250 mL two-necked round bottom flask. Then, 1-naphtaldehyde (0.12 mL, 0.908 mmol) was charged into the reaction while being stirred. Then, the mixture was left unattended for a few minutes in order to become homogeneous. Next, 20% sodium hydroxide solution (15 mL) was added into the mixture dropwise and the reaction was left with constant stirring for approximately 7 hours. The progress of the reaction was monitored by using thin-layer chromatography (TLC) (hexane: dichloromethane, 3:2). After the reaction has completed, the mixture was poured into the beaker containing several ice cubes. The mixture was left overnight for the precipitate formation. After that, it was filtered and dried at ambient environment. The crude product obtained was recrystallized from acetonitrile to obtain yellow solid as the title product (yield: 75%).

Results and Discussion

Vibrational analysis

The FT-IR spectrum of **3NPP** is presented in Figure 1 within the range of 4000-450 cm^{-1}. Form the experimental data, there are five absorption bands of interest which represent the ν(CH) aromatic, ν(C≡C), ν(C=O), ν(C=C) aromatic and ν(C=C) ranging from weak to medium intensities. The absorption band for experimental stretching aromatic CH was observed at 3048 cm^{-1} and 2997 cm^{-1}. Meanwhile, the absorption band for C≡C was observed at 2361 cm^{-1} and 2342 cm^{-1} as the medium intensity peak. This peak appeared as a diminished absorption intensity of ν(C≡C) was observed due to the effect of the inter-stacking interaction and dipole moment of the molecule [13]. The medium and sharp band for carbonyl (C=O) appeared at 1655 cm^{-1} which is supported by Mobaraki and Hemmateenejad, 2011 which stated the peak of carbonyl (C=O) stretching can be found at the range of 1750-1600 cm^{-1} [20]. In **3NPP**, the presence of intermolecular hydrogen bonds and the conjugation of the carbonyl bond with the C=C bonds greatly decrease the carbonyl group's double bond nature, lowering the stretching frequency of C=O [21]. The absorption band of C=C stretching was observed at 1589 cm^{-1} which confirms the formation of chalcone compound [22] and C=C aromatic was found at 1570 cm^{-1}.

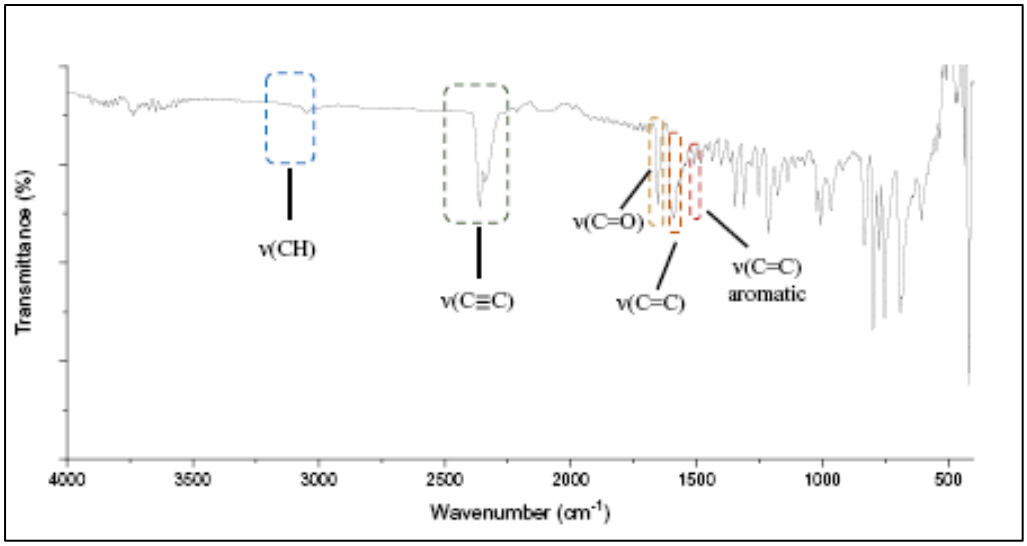

Figure 1. IR spectrum of **3NPP**

Optical properties

Electronic absorption spectrum of **3NPP** was recorded in the range of 200-600 nm in dichloromethane (DCM) solvent (c= 1×10^{-5} M). In the solution state, absorption maxima were recorded at 266 and 335 nm, which indicate π-π* and n-π* transitions. The value of maximum wavelength (λ_{max}) of absorption of **3NPP** was observed at 266 nm shows π-π* transition which assigned to arise from overlapping of phenyl ring and carbonyl (C=O) chromophore. Next, n-π* transition at the wavelength (λ_{max}) 335 nm shows the presence of carbonyl (C=O) moieties. Eq. 1 was used to calculate the optical energy band gap (E_g^{opt}), which was given in eV. According to the formula of $E_{gap} = hc/\lambda_{edge}$, the E_g value of **3NPP** is exhibited 2.92 eV.

$$E_g^{opt}(eV) = 1240 / \lambda_{edge} \quad (1)$$

The computed electronic absorption using time dependent-DFT approach employing B3LYP functional and 6-31G (d,p) basis set in solvent effect (dichloromethane) through Integral Equation Formalism Polarizable Continuum Model (IEF-PCM). The spectrum are shown in Figure 2. The electronic transition of the computed UV-Visible at 398 nm which attributed to HOMO to LUMO transition orbitals. This region shows n-π* and π-π* transition which attributed the to the excitation in the aromatic ring and the presence of carbonyl (C=O) moieties [23].

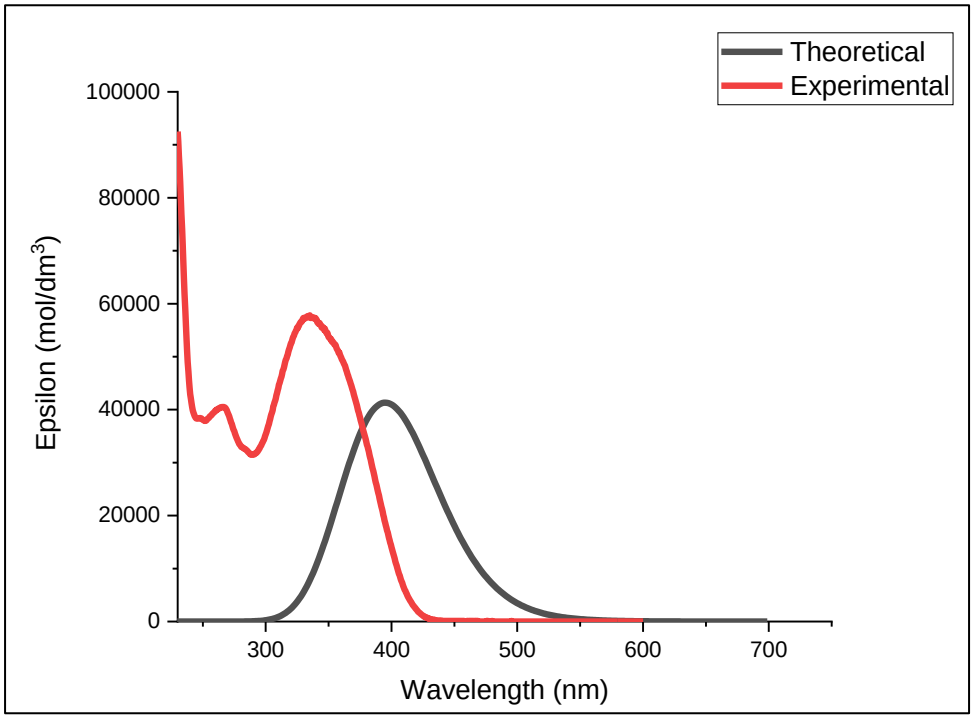

Figure 2. The UV-Visible spectrum of **3NPP**

NMR analysis

The title derivative of ethynylated-chalcone (**3NPP)** was identified by using nuclear magnetic resonance (NMR). The spectra of ^{1}H and ^{13}C NMR were recorded by using Bruker Advance III 400 spectrometer, deuterated chloroform ($CDCl_3$) is used as solvent, and trimethylsilane (TMS) was used as an internal standard. Moreover, the frequency that is used for both ^{1}H and ^{13}C NMR were 400.11 MHz and 100.61 MHz respectively. The spectra of ^{1}H and ^{13}C for **3NPP** are shown in Figure 3 and Figure 4. In ^{1}H spectrum, alkene moieties can be observed at δ_H 7.46-7.55 ppm (*J*-coupling=12 Hz) and δ_H 8.190 ppm (*J*-coupling=10 Hz) as doublet resonance multiplet due to the overlapping between the aromatic proton and doublet resonance which indicates the *E*-configuration of the synthesized compound. The strong coupling constants mostly represent the trans coupling of nearby protons, confirming the trans conformation with regard to the double bond [24]. Then, aromatic phenyls proton which can be observed at the range of δ_H 6.900 -8.650 ppm as multiplet and pseudo-doublet resonances which are supported by previous reported studies [6].

For the ^{13}C NMR, there are two signals appeared within the range of δ_C 87.79-91.72 ppm which represent the alkyne moieties where the splitting of these peaks were due to the influence of their non-symmetrical structure [20]. The aromatic phenyls carbons can be observed at δ_C 121.54-140.71 ppm. The peak resonated at δ_C 188.25 ppm corresponded to carbonyl (C=O) carbon atom. This is due to the formation of intramolecular hydrogen bonding and electronegativity effect of oxygen atom which pulled a certain number of electrons and deshielded the resonance to higher chemical shift [20].

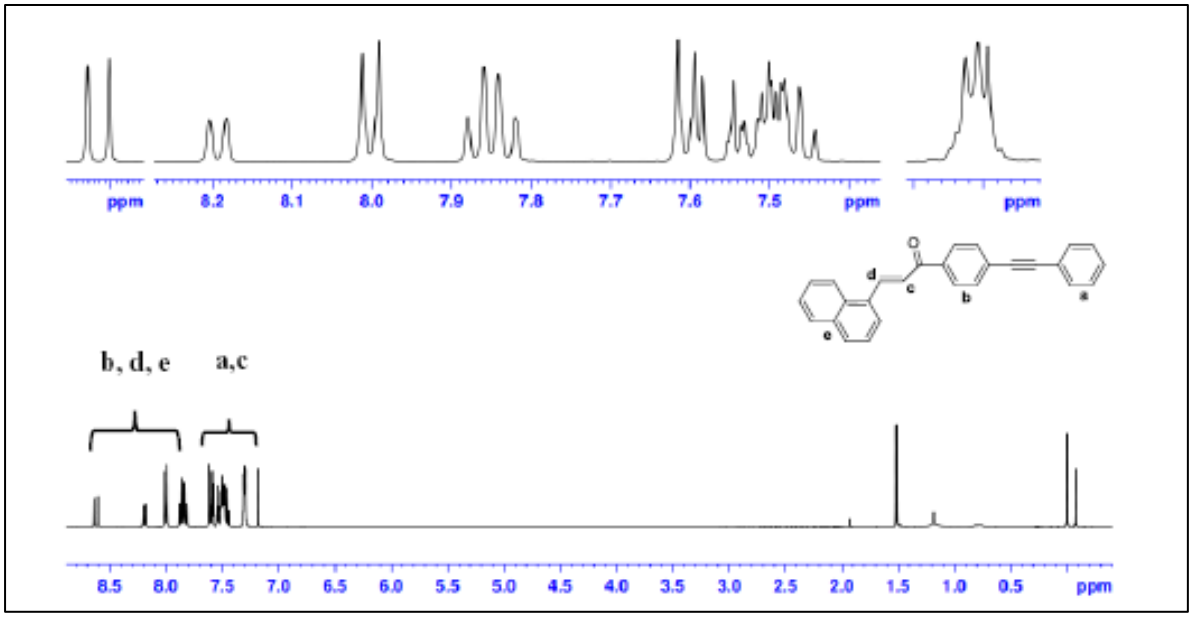

Figure 3. [1]H NMR spectrum of **3NPP**

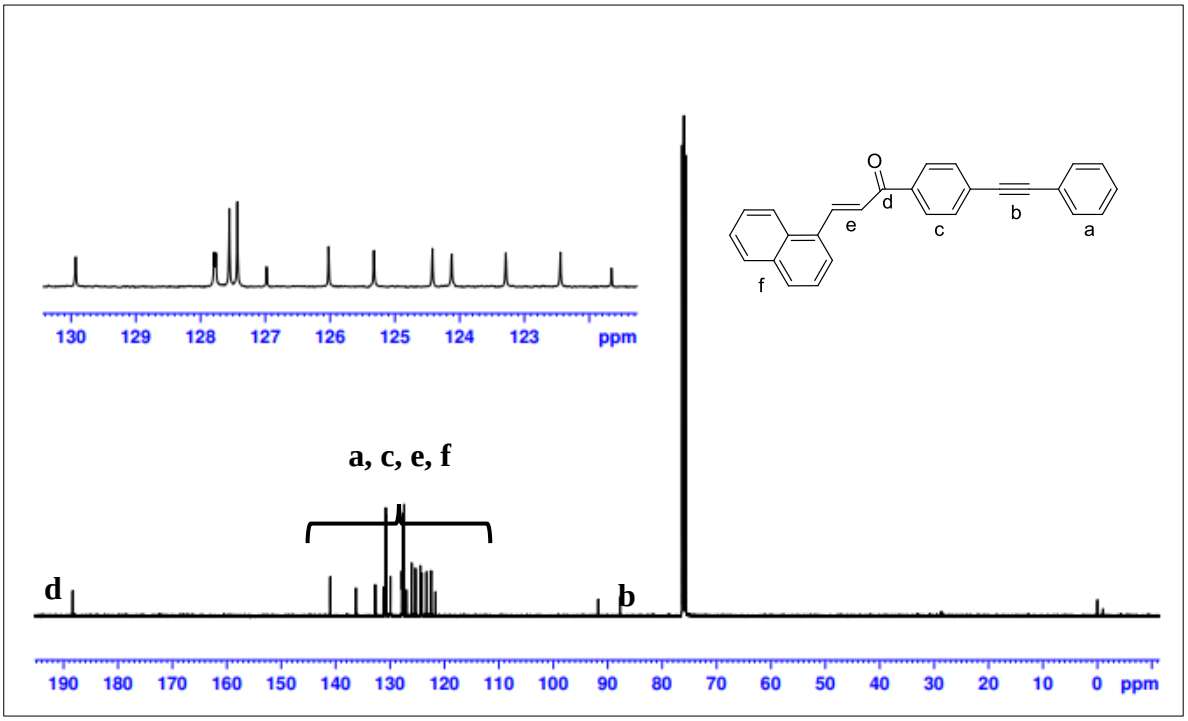

Figure 4. [13]C NMR spectrum of **3NPP**

Thermal analysis

The TGA and DTG thermogram of **3NPP** are shown in Figure 5. The TGA/DTG curve shows that the title compound started to degrade in two steps. For the first step, the degradation occurred at 273.81 ℃ which the onset temperature (T_{onset}) and ended at 539.93 ℃ which the offset temperature (T_{offset}) with an initial weight loss of 18.27%. Meanwhile, for the second step, the degradation occurred at 539.93 ℃ which the onset temperature (T_{onset}) and stop at 735.53 ℃ which was the offset temperature (T_{offset}) with the weight loss of 72.75%. The weight loss is due to the decomposition of compound to a gaseous state. The high thermal stability of the compound is suitable for NLO application [25].

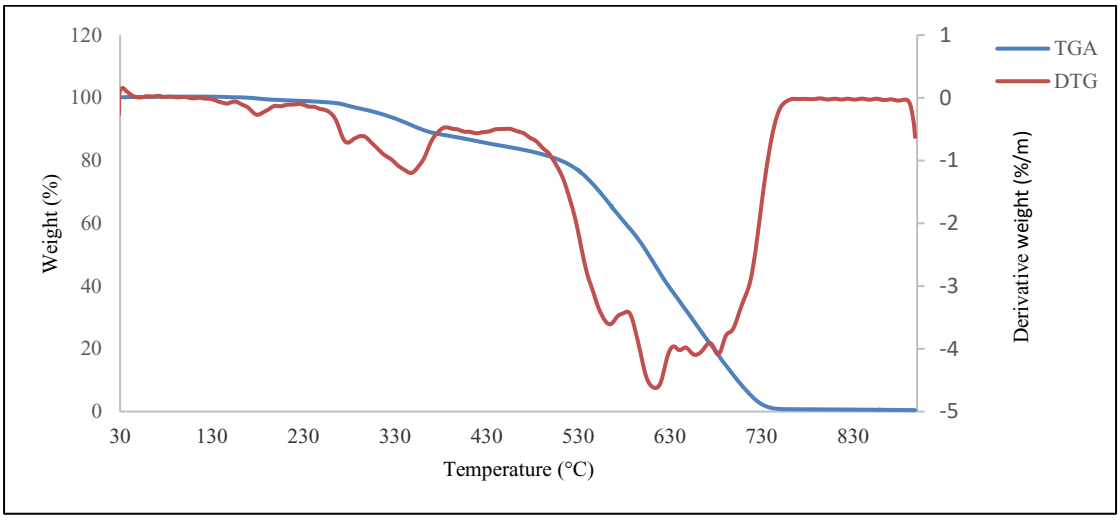

Figure 5. The TGA and DTG thermogram of **3NPP**

Frontier molecular orbitals

Frontier molecular orbitals (FMOs) are an important key role to understand the chemical stability of a molecule. The FMOs of **3NPP** was computed via TD-DFT with B3LYP/6-31G (d,p) as shown in Figure 6. The HOMO is the outermost orbital containing donor electron, while LUMO is the innermost orbital containing free places to accept electrons [16]. The HOMO is mainly concentrated on the chalcone structure and naphthalene substituent, which acts as electron donor groups. This is due to the existence of a greater electron density in the chalcone structure's naphthalene substituent. The LUMO is produced by the molecule's conjugated double bond, implying that the naphthalene substituent plays a role. Aromatic electrophile substitution reactions on chalcone structures and aromatic nucleophile substitution reactions on alkyne groups is facilitated by the naphtalene group. Furthermore, the inclusion of an alkyne group increases the title compound's intermolecular charge transfer (ICT). The energy gap for HOMO-LUMO of the synthesized molecules is relatively small which is 3.51 eV. The differences between theoretical and experimental results can be attributed to the fact that the experimental results were obtained in the solution phase, wherein various inter and intra molecule interactions can be observed within the solvent and solution. It could be attributed to a solvent phase of an isolated single molecule in theoretical calculations (using the stated software) [26]. It is found that the energy band gap relatively small than the previous chalcone compound [11]. This molecule is soft and the values of the energy bandgap is in the range of semiconducting materials which can exhibit good polarizability and non-linear optical (NLO) properties [11]. There are two electronic excitation energies were involved which are the electron transition from the ground state (S_0) to the excited state (S_n) and others information are depicted in Table 1.

Moreover, the global chemical reactivity descriptors (GCRD) are the technique to understand the chemical properties such as chemical hardness (η), chemical softness (S), chemical potential (μ), electronegativity (χ) and electrophilic index (u) = [$\mu^2/2\eta$]. The formula is derived from HOMO-LUMO energies, taking the HOMO energy as ionization potential (I) and LUMO as electron affinity (A) [27], and the data are tabulated in Table 2.

Chemical hardness (η) = [($E_{LUMO} - E_{HOMO}$)/2] (2)
Chemical softness (S) = [$1/2\eta$] (3)
Chemical potential (μ) = [($E_{HOMO} + E_{LUMO}$)/2] (4)
Electronegativity (χ) = [(I + A)/2] (5)
Electrophilic index (u) = [$\mu^2/2\eta$] (6)

From the calculation, it was found that **3NPP** is kinetically stable with the hardness value of 1.76 eV, chemical potential of -4.05 eV, chemical softness of 0.28 $e^{-1}V^{-1}$, electronegativity of 4.05 eV and electrophilic index of 4.66 eV suggesting that the title compound gives excellent chemical strength and stability properties.

Table 1. Excitation energy, oscillator strength and major contribution of electronic transition

Molecule	Wavelength, λ (nm)	Excitation Energy (eV)	Oscillator Strength (f_o)	Assignments, Major Contributors (%)
3NPP	403	0.07	0.67	$S_0 \rightarrow S_n$ (62.45 %)

Table 2. Molecular orbitals energies of HOMO and LUMO (eV) and the global chemical reactivity descriptors (GCRD)

Molecule	E_{HOMO}	E_{LUMO}	ΔE (eV)	η (eV)	μ (eV)	S ($e^{-1}V^{-1}$)	χ (eV)	u (eV)
3NPP	-5.80	-2.29	3.51	1.76	-4.05	0.28	4.05	4.66

Molecular electrostatic potential analysis

The molecular electrostatic potential (MEP) analysis is computed by using DFT B3YLP/6-31G (d,p) level of theory. MEP as in Figure 7 gives important information regarding the reactive site of the molecule [28, 29], visualizing the size and shape of the molecule [30]. The reactivity of **3NPP** can be determined by predicting the nucleophile and electrophile site of the molecule. MEP surface gives the information of the charge distribution region of the molecule. In this 3D plot, the blue and brown regions indicate the positive and negative charge of **3NPP**. The blue region is spread over the hydrogen atom comprising the electrophilic sites meanwhile the red region is the nucleophilic site which contains oxygen atom [10]. For **3NPP**, the negative charges are more concentrated on the oxygen atom of the carbonyl (C=O) group in the range between -5.239×10^{-2} a.u (red) towards 5.239×10^{-2} a.u (blue) in the map because it represents a potential nucleophilic attack site. This indicates that the (C=O) oxygen atom is the most reactive spot for interacting with the nucleophile via an intermolecular hydrogen bond [6].

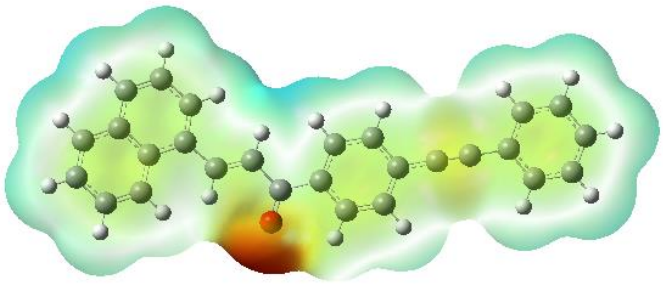

Figure 7. MEP surface for **3NPP**

Non-linear optical properties: DFT calculation

In the computational NLO studies, dynamic linear polarizabilities (α) and first hyperpolarizabilities (β) were calculated in order to examine the nonlinear optical (NLO) properties by using DFT method in the Gaussian 16 program. In addition, the isotropic polarizability ($<\alpha>$), anisotropic polarizability ($\Delta\alpha$), total beta (β_{tot}) of the first hyperpolarizability were calculated via DFT B3LYP/6-31G (d,p) and were calculated using the following equations [27, 31]. The Gaussian output file had ten hyperpolarizability tensors (β_{xxx}, β_{xyy}, β_{xzz}, β_{yyy}, β_{xxy}, β_{yzz}, β_{zzz}, β_{xxz}, β_{yyz}, β_{xyz}) and six linear polarizability tensors (α_{xx}, α_{yy}, α_{zz}, α_{xy}, α_{xz}, α_{yz})

correspondingly, in the x, y, and z directions [32]. The related parameters of **3NPP** are tabulated in Table 3.

The total dipole moment (μ_{tot}) was recorded at 2.93 which is higher than the previous chalcone compound [11]. The higher dipole moment will indicate the higher electron density which will lead to a greater charge transfer [33]. The higher the dipole moment, the higher the first polarizability will indicate the higher NLO properties [31]. Moreover, the isotropy polarizability ($<\alpha>$) of **3NPP** was found at 57.52×10^{-24} esu, while the anisotropy of polarizability ($\Delta\alpha$) was recorded at 86.81×10^{-24} esu. Furthermore, the 1st polarizability β_{tot} of **3NPP** was 420.51×10^{-30} esu. The higher value first polarizability due to the small HOMO-LUMO gap [25].

$$\mu_{tot} = (\mu_x^2 + \mu_y^2 + \mu_z^2)^{1/2} \quad (7)$$

$$<\alpha> = \frac{1}{3}(\alpha_{xx} + \alpha_{yy} + \alpha_{zz}) \quad (8)$$

$$\Delta\alpha = \frac{1}{\sqrt{2}}[(\alpha_{xx} - \alpha_{yy})^2 + (\alpha_{yy} - \alpha_{zz})^2 + (\alpha_{zz} - \alpha_{xx})^2 + 6(\alpha_{xy}^2 + \alpha_{xz}^2 + \alpha_{yz}^2)]^{1/2} \quad (9)$$

$$\beta_{tot} = (\beta_x^2 + \beta_y^2 + \beta_z^2)^{1/2} \quad (10)$$

$$\beta_{tot} = [(\beta_{xxx} + \beta_{xyy} + \beta_{xzz})^2 + (\beta_{yyy} + \beta_{yzz} + \beta_{yxx})^2 + (\beta_{zzz} + \beta_{zxx} + \beta_{zyy})^2]^{1/2} \quad (11)$$

Table 3. Dipole moment, polarizability, and the value of 1st order hyperpolarizability

Dipole moment (Debye)	**3NPP**
μ_{tot}	2.93
Polarizability, α ($\times 10^{-24}$ esu)	
α_{xx}	110.17
α_{yy}	18.40
α_{zz}	44.00
α_{xy}	-8.81
α_{xz}	11.67
α_{yz}	7.45
$< \alpha >$ ($\times 10^{-24}$) in esu	57.52
$\Delta\alpha$ ($\times 10^{-24}$) in esu	86.81
1st Hyperpolarizability, β ($\times 10^{-30}$ esu)	
β_{xxx}	-102.36
β_{xyy}	2.53
β_{xzz}	-9.28
β_x	-342.06
β_{yyy}	0.40
β_{xxy}	14.75
β_{yzz}	1.48
β_y	53.09
β_{zzz}	-1.18
β_{xxz}	-72.76
β_{yyz}	-9.46
β_z	238.75
β_{xyz}	8.90
β_{tot}	420.51

Conclusion

The new conjugated ethynylated based chalcone (**3NPP**) featuring D-π-A concept was designed and successfully synthesised as active non-linear optical (NLO) response. From the findings, the title compound of **3NPP** is thermally stable up to 320.60 ℃ with the weight loss of 91.02 % in two steps of degradation process. The introduction of acetylide moiety reveals the enhancement of stability of this system. The energy band gap of **3NPP** is 3.51 eV which is compatible to further this system for optoelectronics applications. According to the findings, this compound also could be used as a good NLO active material. The development of suitable electron transport materials for organic electronic devices can be aided by precise design, synthesis, and theoretical investigation of these compounds. Furthermore, the molecular electrostatic potential (MEP) also shows the reactive sites in this reaction. **3NPP** also has excellent NLO properties by DFT calculation with the value of β_{tot} =420.51× 10^{-30} esu and reveals good polarizability. From the preliminary outcome, further investigation on the similar molecular system can be applied as ideal and promising NLO material for the development of any optical application.

Abstract

Clinacanthus nutans Lindau (*C. nutans*) or locally known in Malaysia as the Sabah Snake Grass (SSG) contains phytochemicals such as flavonoids and phenolic acids. The leaves of the plant exhibit antioxidant, anti-inflammatory, and antiviral properties, thus, it was traditionally used to treat venomous injuries, rheumatism, and sprains throughout Asia. Previous studies of the antioxidative activity in *C. nutans* extracts have been carried out under different conditions or using different extraction methods, which may have resulted in a varied yield of antioxidative constituents. Thus, this study aimed to compare the total phenolic content (TPC), total flavonoid content (TFC), and antioxidative activity of *C. nutans* methanol, water, and hexane extracts using the traditional solvent extraction method. Results showed that the water extract contains the highest TPC value (3.66 ± 0.11 mg GAE/g) followed by methanol (2.84 ± 0.36 mg GAE/g) and hexane (0.13 ± 0.03 mg GAE/g). The TPC values of methanol and water extracts were significantly higher than hexane ($p < 0.05$). For TFC value, the methanol extract was the highest (1.91 ± 0.05 mg QE/g), followed by water extract (1.50 ± 0.01 mg QE/g) and hexane was not detected. The radical scavenging activity (RSA) decreased in the order of methanol > water > hexane extract. In conclusion, the study suggests that high phenolic and flavonoid contents in *C. nutans* extracts may be the key factor for it to act as an excellent source of natural antioxidants.

Keywords: Sabah snake grass, total phenolic content, total flavonoid content, radical scavenging activity

Abstrak

Clinacanthus nutans Lindau (C. nutans) atau lebih dikenali oleh penduduk tempatan di Malaysia sebagai belalai gajah mengandungi fitokimia seperti flavonoid dan asid fenolik. Dedaun tumbuhan berikut mempamerkan sifat-sifat seperti antioksida, anti radang, dan antivirus. Oleh itu, ia secara tradisionalnya digunakan di seluruh asia untuk merawat kecederaan berbisa, sakit sendi, dan seliuh. Kajian terdahulu mengenai aktiviti antioksida dalam ekstrak *C. nutans* menggunakan kaedah ekstrak yang berbeza atau dalam keadaan yang berbeza. Justeru, ini boleh menjana hasil kandungan antioksidan yang berbeza. Kajian ini betujuan membuat penilaian jumlah kandungan fenolik (TPC), flavonoid (TFC), dan aktiviti antioksida bagi ekstrak metanol, air, dan heksana daripada *C. nutans* dengan kaedah pengekstrakan pelarut tradisional. Keputusan menunjukkan bahawa ekstrak air

mengandungi kandungi TPC tertinggi (3.66 ± 0.11 mg GAE/g) diikuti metanol (2.84 ± 0.36 mg GAE/g) and heksana (0.13 ± 0.03 mg GAE/g). Bagi nilai TFC, ekstrak methanol adalah tertinggi (1.91 ± 0.05 mg QE/g), mingikuti ekstrak air (1.50 ± 0.01 mg QE/g) dan heksana (tidak dikesan). Nilai TPC ekstrak metanol dan air adalah jauh lebih tinggi daripada heksana ($p < 0.05$). Perencatan radikal bebas (RSA) bagi ekstrak dalam tertib menurun adalah seperti berikut; metanol > heksana > air. Konklusinya, kajian ini mencadangkan bahawa kandungan fenolik dan flavonoid yang tinggi dalam ekstrak *C. nutans* mungkin menjadi faktor utama untuk ia bertindak sebagai sumber antioksida semula jadi yang hebat.

Kata kunci: belalai gajah, jumlah kandungan flavonoid, jumlah kandungan fenolik, perencatan radikal bebas

Introduction

C. nutans, or commonly known as *Belalai Gajah* in Malaysia, is a small plant native to tropical Asian countries [1]. The leaves of the plant can be described as flat, opposite, and narrowly elliptic-oblong in shape and the mature part of the plant exhibits lower levels of phytochemicals, chlorophyll, ascorbic acid, and phenolic content in comparison to its younger counterparts [2]. The slightly curved stem that supports the leaves resembles the curvature of an elephant's trunk where the name *Belalai Gajah* was derived [3].

C. nutans is used in Thailand as a traditional antivenom therapy for venomous creatures like snakes, jellyfish, and scorpions [4], while native Singaporeans utilise the plant for detoxification purposes [5]. The plants' anti-inflammatory characteristics allow locals in China to utilise it as a treatment for rheumatism and sprains from injuries [6]. The extract of *C. nutans* has demonstrated antioxidant activity and protection against free radical-induced haemolysis [7], which allows the plant to be further developed as a natural antioxidant for human consumption [8]. The leaf of the plant also exhibits antiviral properties against the herpes simplex virus type-2 (HSV-2) [9]. Yet, more studies are needed to establish and comprehend the bioactive components and therapeutic characteristics of this plant due to its multiple and beneficial attributes [10].

An antioxidant is an agent that has the ability to greatly delay or prevent the oxidation of an oxidisable substance when it is introduced at low concentrations compared to the substance [11]. The antioxidant effect mainly results from phenolic compounds such phenolic acid, flavonoids, and phenolic diterpenes. These compounds have the capability to undergo redox reaction, which absorbs and neutralises free radicals through the suppression of singlet and triplet oxygen [12]. Studies have isolated various bioactive compounds in *C. nutans* which exhibit antioxidant activity such as polyphenols [13], ferulic acid, caffeic acid, protocatechuic acid, chlorogenic acid [14], phthalic acid [15] and gendarucin A [16]. Studies have reported that the ethanolic extract of the leaf exhibited higher antioxidative activity than the stem extract [16], yet the extract exhibited remarkably lower antioxidative activity than green tea extract [13]. A study demonstrated that crude chloroform extract possessed the highest antioxidant activity compared to crude methanol and aqueous extracts [15]. However, other have reported that the crude 80% aqueous methanol extract had the highest antioxidant activity compared to fractionation extracts [17]. In addition, the activity of a younger plant extract was found to be higher than the older plant, and the buds extract showed significant higher activity than the leaf extract [18].

Most of the previous literatures had employed the basic liquid extraction method to study the antioxidative properties of methanolic extract in *C. nutans* [19-22]. Nevertheless, the investigation of antioxidative properties for other extracts, such as water and hexane extracts, had either used liquid extraction at higher temperatures (70°C) [21] or fractionation extraction from the crude methanolic extract [20]. Antioxidants are heat sensitive and are prone to degradation after prolonged heating [23], which results in a lower yield of its constituents. In addition, different extraction methods may result in varied yields of antioxidative constituents [24]. Previous studies have no comparable data on the antioxidative activity of *C. nutans* crude extract using methanol, water, and hexane. This study was thus conducted to compare the TPC, TFC and antioxidant

activity of *C. nutans* using the basic liquid extraction method under room temperature.

Materials and Methods

Plant material

1 kg of *C. nutans* leaf was purchased from a herbal shop in Cheras, Kuala Lumpur. The authentication of the plant was confirmed by the Forest Research Institute Malaysia.

Extraction of *C. nutans*

The dried leaf of *C. nutans* was grinded into a fine powder with a blender. 100 g of fine plant powder was agitated in three different solvents (hexane, methanol, and distilled water) for 48 hours at room temperature. Each sample was filtered and concentrated by evaporation using a rotary evaporator at 60°C. The dried extracts were weighted and dissolved in methanol with the concentration of 0.1 g/mL and were stored at -20°C for further analysis.

Determination of TPC of *C. nutans* extracts

The Folin-Ciocalteu colorimetric method was used to quantify TPC. Gallic acid (GA) was used as the standard. The GA stock solution (50 µg/mL) was prepared in water and further dilution was made to achieve the calibration curve in the range of 1-40 µg/mL. 0.1 mL of each extract were placed into a volumetric flask and mixed with 0.2 mL of Folin-Ciocalteu phenol reagent and 1.5 mL of 6% Na_2CO_3 solution. The volume of the mixture was adjusted to 10 mL before incubation for 30 min in the dark. The absorbance of the mixture was then monitored and quantified against blank at 725 nm using a UV-visible spectrometer (Beckman Coulter DU730). The concentration of phenolic compounds was represented in microgram GA equivalent per gram of extract (mg GAE/g) [25], with the equation shown below:

$$\text{TPC} = \frac{[\text{Concentration of GA from calibration curve (µg/mL) x Volume of extract (mL)}]}{\text{Mass of plant extract (g)}} \quad (1)$$

Determination of TFC of *C. nutans* extracts

The aluminium colorimetric method was used to analyse the TFC [25]. Quercetin was used as the standard. The quercetin stock solution (50 µg/mL) was prepared in ethanol and further dilution was made to achieve the calibration curve in the range of 6.25-40 µg/mL. 50 µL of each three extracts were placed into a volumetric flask and mixed with 5 mL water, 0.6 mL $NaNO_3$, 0.5 mL $AlCl_3$, and 4 mL NaOH. The mixture was then incubated for 20 min in the dark. The absorbance of the mixture was then quantified at 415 nm using a UV-visible spectrometer. The concentration of flavonoid was represented in microgram quercetin equivalent per gram of extract (mg QE/g) [25], with the equation shown below:

$$\text{TFC} = \frac{[\text{Concentration of quercetin from calibration curve (µg/mL) x Volume of extract}]}{\text{Mass of plant extract (g)}} \quad (2)$$

Radical scavenging activity of *C. nutans* extracts: 2,2-diphenyl-1-picrylhydrazyl (DPPH) assay

An amount 60 µg/mL DPPH (Alfa Aesar, Lancashire, UK) stock was freshly prepared with ethanol. 10 µL of plant extracts were individually mixed with 3 mL of DPPH and incubated for 30 min. The absorbance values were recorded using a UV-vis spectrometer at 517 nm [25].

2,2'-azino-bis-(3-ethyl)benzothiazoline)-6-sulfonic acid diammonium salt (ABTS) radical cation scavenging assay

The ABTS assay was carried out as described by Rakholiya et al. [26]. 10 µL of plant extracts were individually mixed with 3 mL of ABTS radical cation solution and incubated for 40 min. The absorbance values were recorded using a UV-vis spectrometer at 734 nm.

The %RSA of DPPH and ABTS cation radical were quantified according to the equation shown below:

$$\%RSA = \frac{(\text{Absorbance of blank} - \text{Absorbance of sample}) \times 100\%}{\text{Absorbance of blank}} \quad (3)$$

Statistical analysis

The two-tailed t-test was used to analyse the differences between methanol, hexane, and water extracts of *C. nutans*, where $p < 0.05$ is considered statistically significant. Statistical calculation was performed using Microsoft Excel (Microsoft Office Professional Plus 2019, Washington, United States).

Results and Discussion

Extraction of *C. nutans*

The percentage yield for methanolic, hexane, and water extracts were obtained from 100 g of dried plant powder as shown in Table 1. Water extract had the highest percentage yield (8.09%) when compared to the methanolic extract (4.92%) and hexane extract (4.80%), which had the lowest percentage yield. The high yield in methanol was most likely due to the solubility of important components of SSG in methanol, such as the phenolic groups [27]. The polarity of the solvents used for extraction impacted the phenolic solubility [28]. Furthermore, water can enhance extraction efficiency [29] and this may result in the high recovery of phenolic compounds due to the high polarity in water.

Table 1. The net weight and percentage yield of *C. nutans* for methanol, hexane, and water extract

Solvent for Plant Extraction	Net Weight (g)	Yield (%)
Methanol	2.191	4.92
Hexane	2.400	4.80
Water	4.050	8.09

Total phenolic content

Phenolic acids, flavonoids, and tannins are considered the most important dietary phenolic components among several types of phenolic compounds [30]. Phenolic compounds especially phenols act as antioxidants, immunological boosters, anti-clotting agents, and hormone modulators by modifying the prostaglandin pathways which prevent platelets from clumping and have the capacity to inhibit particular enzymes that induce inflammation [31]. The Folin–Ciocalteu test is the current standardised technique to determine TPC in food or biological samples, which is based on the interaction of phenolic compounds with a colorimetric reagent that permits detection in a visible spectrum [32-33]. Gallic acid (GA) was used as the positive control in the quantification of TPC. The TPC of three extracts (methanol, water, and hexane) were yielded from the calibration curve [$y = 0.0389x - 0.0079$); $R^2 = 0.9901$] obtained from the GA concentrations in µg GAE/g expression (Figure 1), where y is sample absorbance at 750 nm while x is the concentration of TPC.

Figure 2 shows that the methanolic extract has the highest content of TPC (3.66 ± 0.11 mg GAE/g), followed by methanol extract (2.84 ± 0.04 mg GAE/g), while hexane extract had the lowest content of TPC (0.13 ± 0.03 mg GAE/g). The two-tailed t-test showed significant differences between the TPCs among the three extracts ($p < 0.05$). All TPC values obtained were lower than reported in literature. Fadhlin Baharuddin et al. [34] reported that the TPC of methanolic extract was 11.05-13.87 mg GAE/g when the temperature ranged from 30-55°C. Ismail et al. [17] reported that the TPC of aqueous and hexane extracts fractionated from the crude methanolic extract possessed 415.76 and 50.24 mg GAE/g, respectively. These inconsistent findings resulted from differences in method of extraction, parts

of plant, maturity of plant and storage of plant [35]. Nevertheless, our results agreed with previous study which showed that the water extract had the highest TPC and hexane extract had the lowest TPC [17].

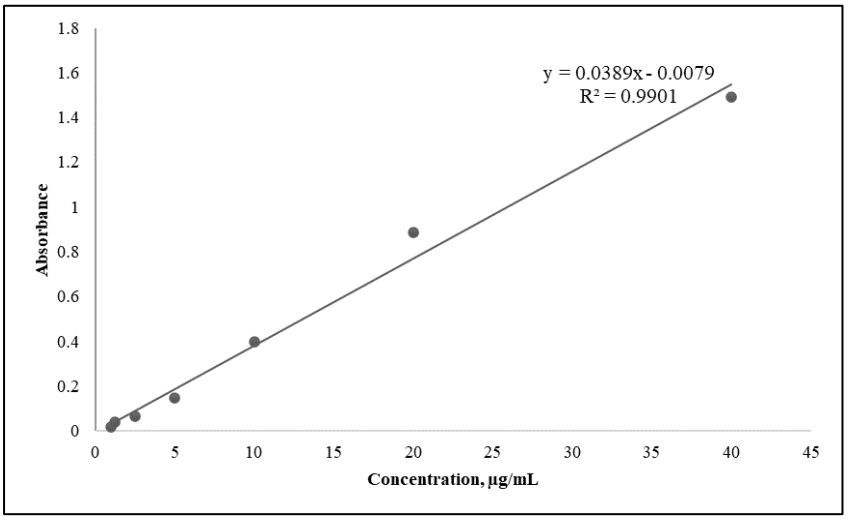

Figure 1. The calibration curve of the gallic acid standard solutions

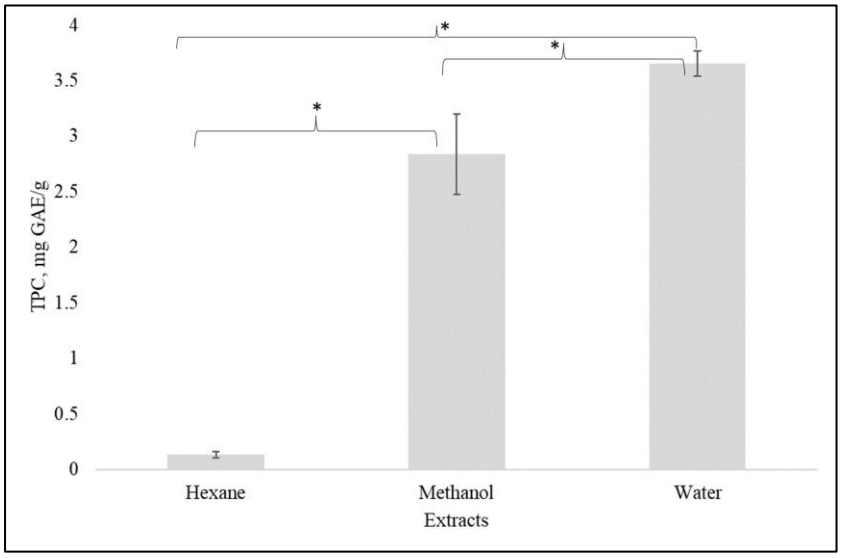

Figure 2. Mean total phenolic content for *C. nutans* hexane, methanol, and water extracts which were expressed as gallic acid equivalent (GAE). All experiments were performed in triplicates. Asterisk (*) indicates statistically significant at the level of $p < 0.05$ between the extracts

Total flavonoid content

Flavonoids are classified into different subclasses based on their composition, including flavanones, flavones, flavanols, and flavonols, with myricetin, kaempferol, and quercetin being the most common [36]. It is a water-soluble phytochemical compound which is obtained from essential plant phenolic with beneficial antimicrobial, anti-inflammatory, and antioxidant properties as well as the ability to inhibit oxidative cell damage and carcinogenesis [30]. Quercetin was used as the positive control in determining TFC. The TFC of three different extracts were yielded from the calibration curve [$y = 0.0824x - 0.2444$; $R^2 = 0.957$] obtained from the quercetin concentrations in µg QE/g as shown in Figure 3, where y is sample absorbance at 415 nm and x is the concentration of TFC. Figure 4 shows that the methanolic extract has the highest content of TFC (1.91 ± 0.05 mg QE/g), followed by the water extract (1.50 ± 0.01 mg QE/g); meanwhile, the hexane extract cannot be determined as the absorbance is below the limit of detection from the calibration curve. The two-tailed t-test showed significant differences in TFCs between the water and methanol extract ($p < 0.05$). Previous literature reported that the TFC of 80% methanolic extract of *C. nutans* was 4.31-7.32 mg QE/g, where the phenolics content of the plant was higher as the plant grew [19]. The variation in results may be due to many factors such as plant age [19] or different geographical distribution of the plant which affects the plant's metabolism [35]. Our findings showed that the TPC in methanolic and aqueous extract was remarkably higher than hexane extract, and this trend is also observed in previous literature where the water extract has the highest TPC and hexane extract has the lowest TFC [17].

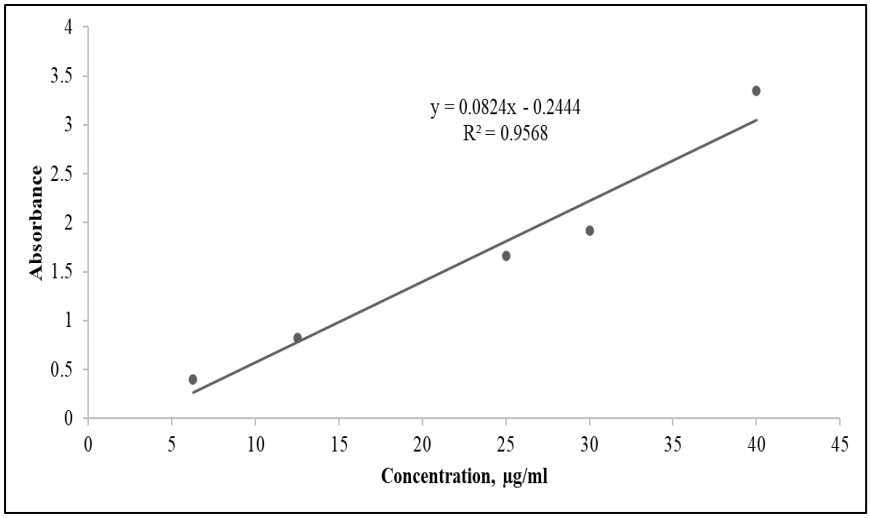

Figure 3. The calibration curve of the quercetin standard solution

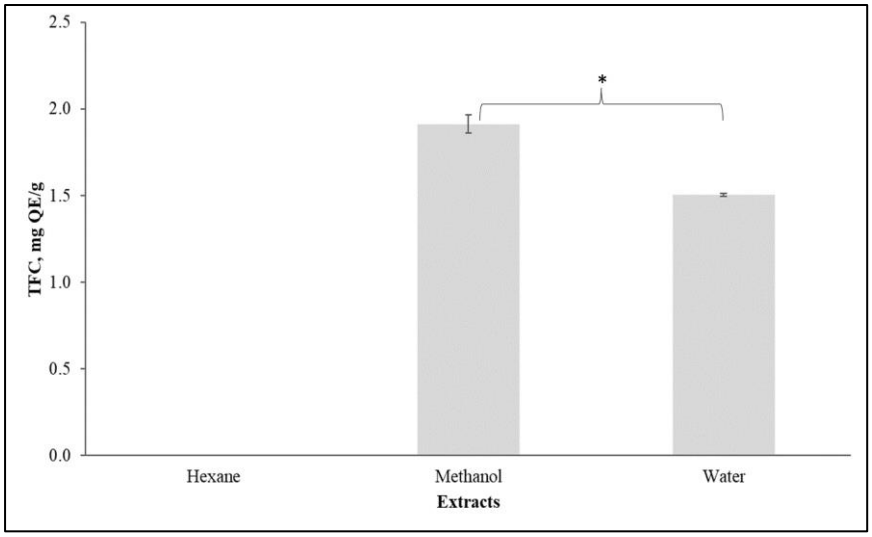

Figure 4. Mean total flavonoid content for *C. nutans* hexane, methanol and water extracts which were expressed as quercetin equivalent (QE). All experiments were performed in triplicates. Asterisk (*) indicates statistically significant at the level of $p < 0.05$ between the extracts

Radical scavenging activity - DPPH and ABTS assay

DPPH and ABTS assays are prominent surrogate markers to detect antioxidant capacity and evaluate potential substances behaving as free radical scavengers [37]. Table 2 shows that the DPPH and ABTS scavenging activity have the same trend, where the %RSA decreases in the order of methanolic > water > hexane extract. Our findings agree well with Ismail *et al*. [34] who reported that the methanolic crude extract exhibited the highest antioxidative activity and hexane fraction extract exhibited the lowest antioxidative activity.

Table 2. The %RSA of DPPH and ABTS cation radical for hexane, methanol and water extracts of *C. Nutans*

Plant Extract	%RSA	
	DPPH	ABTS
Hexane	16.04 ± 1.46	3.64 ± 0.48
Methanol	59.27 ± 0.86	99.94 ± 0.22
Water	53.40 ± 3.72	74.94 ± 2.04

Conclusion

C. Nutans was extracted using liquid extraction method under room temperature. The three types of solvents used for extraction are hexane, methanol and water. The TPC, TFC, and antioxidative activity were quantified using Folin-Ciocalteu assay, aluminium colorimetric method, DPPH, or ABTS assay, respectively. The value of TPC decreased in the following order: water > methanol > hexane, where the water extract (3.66 ± 0.11 mg GAE/g) was 1.3- and 28-folds higher than the methanol (2.84 ± 0.04 mg GAE/g) and hexane (0.13 ± 0.03 mg GAE/g) extracts, respectively. Meanwhile, the TFC value of methanol extract (1.91 ± 0.05 mg QE/g) was 1.3-fold higher than water extract (1.50 ± 0.01 mg

QE/g), however, the hexane extract was too low to be detected. Lastly, the DPPH and ABTS radical scavenging capability of the three extracts decreased in the following order: methanol > water > hexane. Methanol and water extracts displayed supreme antioxidative scavenging activity compared to hexane extract and this might be due to the high phenolic and flavonoid content. These results suggest that *C. nutans* extracts are a good source of natural antioxidants.

Abstract

Fine quality coating materials for a variety of surfaces using environmentally friendly substrates are continuously in demand. A large proportion of acrylate derivatives, which are toxic and hazardous, were found in most of the coating formulations. Many efforts have been done to replace acrylate derivatives with other materials derived from renewable resources. In this work, several formulations of wood coating containing different composition of epoxy acrylate and enzymatically synthesized epoxide from soybean oil or wax esters mixture of dioleyl adipate and 1,5-pentanediol diricinoleate were prepared. The formulations were subjected to performance evaluations including gel content, pendulum hardness, and surface test. Formulation 1 containing 85% epoxy acrylate and 15% epoxidation from soybean oil exhibited the highest gel content (79.5%), pendulum hardness (61.02%) and surface resistance to different types of liquid. Increase in surface resistance was observed using a formulation containing 85% epoxy acrylate and a mixture of 1,5-pentanediol diricinoleate and dioleyl adipate (1:1, w/w; 15%). Therefore, these reduced acrylate formulations showed good potential in the development of high-quality UV-curable wood coating.

Keywords: coating, acrylate, epoxide, ester, ricinoleate

Abstrak

Bahan salutan yang berkualiti untuk pelbagai permukaan menggunakan substrat mesra alam sentiasa mendapat permintaan. Sebilangan besar derivatif akrilat, yang beracun dan berbahaya, ditemui dalam kebanyakan rumusan salutan. Pelbagai usaha telah dilakukan untuk menggantikan derivatif akrilat dengan bahan lain yang diperoleh daripada sumber yang boleh diperbaharui. Dalam kajian ini, beberapa formulasi salutan kayu yang mengandungi komposisi epoksi akrilat dan epoksida yang disintesis secara

enzimatik daripada minyak kacang soya atau campuran ester lilin dioleil adipate dan 1,5-pentanediol dirisinoleate yang berbeza telah disediakan. Formulasi ini tertakluk kepada penilaian prestasi termasuk kandungan gel, kekerasan pendulum, dan ujian permukaan. Formulasi 1 yang mengandungi 85% epoksi akrilik dan 15% epoksida dari minyak kacang soya menunjukan kandungan gel (79.5%), kekerasan pendulum (61.02%) dan rintangan permukaan terhadap pelbagai jenis cecair yang tertinggi. Selain itu, peningkatan terhadap rintangan permukaan diperhatikan menggunakan formulasi yang mengandungi 85% epoksi akrilik dan campuran dioleil adipate dan 1,5-pentanediol dirisinoleate (1:1, w/w; 15%). Oleh itu, formulasi akrilat yang dikurangkan ini menunjukan potensi yang baik dalam pembangunan salutan kayu awetan-UV yang berkualiti tinggi.

Kata kunci: salutan, akrilat, epoksida, ester, risinoleate

Introduction

A protective coating is an essential layer of material that is applied to the surface of another material, especially wood-based products, to protect it against degradation and disintegration over time [1–3]. The coating must be stabilized from yellowing, cracking, blistering, and delaminating. The commonly used conventional solvent-based curing coatings are always susceptible to environmental pollution. High amounts of volatile organic compounds (VOCs) or hazardous air pollutants (HAPs) are emitted into the atmosphere during the curing process [4]. In recent years, advances in environmental awareness, economic view, energy preservation, and products performance have prompted a change from conventional to UV radiation curing method. A high number of tightly crosslinked polymer networks can be easily formed using the method, which improves coating properties including high gel content, hardness, and surface resistance [5–7].

In UV curable coatings formulation, the use of acrylate derivatives in the coating formulations is unavoidable as it is essential for polymerization during the curing process [3, 8, 9]. However, many health issues have been reported due to its toxicity [10, 11]. Epoxides derived from vegetable oils have been prospected to lead the changes in UV-curable coatings due to their biodegradability, high abundance, low toxicity, and triglyceride structures suitable for the preparation of major constituents of UV-curable coatings [12, 13]. Demengeot et al. has discovered that the crosslinking of epoxidized linseed and rapeseed oils without reactive diluents resulted in viscous formulations that were difficult to dry. The addition of reactive diluents, on the other hand, had greatly increased the film's hardness [14]. Besides, epoxidation of soybean oil (ESBO) with hydroxyethyl methacrylated maleate precursor had significantly improved in the coating properties when compared with the commercial product [13].

Liquid wax esters are also gaining industrial interest since they are non-hazardous, biodegradable, and have excellent tribological properties [15], thus being attractive in lubricants and coating applications. They consist of long-chain fatty acids and fatty alcohols with a chain length of 12 carbons or more. Liquid wax adipate esters such as dioleyl adipate can be enzymatically synthesized in a solvent-free system which offers a green benign process and great product selectivity [16]. Dioleyl adipate, which contains two double bonds, may have a significant effect on the radiation curing because the free radical would attack the bonds for polymerization to occur. It was reported that a coated thin film of formulation containing dioleyl adipate made from renewable raw materials can produce 90% polymerization and surface resistant performance of up to 4.5 N [17].

Hence, this study aimed to evaluate and validate the usage of epoxide (ESBO) or a mixture of esters (dioleyl adipate and 1,5-pentanediol diricinoleate) produced via enzymatic reaction in replacing acrylate derivatives for wood coating formulations. The products were then undergone ultraviolet (UV) radiation curing and their hardness and chemical resistance were tested to estimate their suitability as wood coatings.

Materials and Methods

Materials

Craynor 104D80 (mixture of EB600 and glyceryl propoxylated triacrylates, 60:40) used in this study was a gift from Akzo Nobel Industrial Coatings (Malmo, Sweden) while, Darocur 1173 was a gift from Malaysia Nuclear Agency (Selangor, Malaysia). Epoxidized Soybean Oil (ESBO) was a gift from Prof. Rajni Hatti-Kaul (Lund University, Sweden). Novozyme® 435 (immobilized *Candida antarctica* lipase B on macroporous acrylic resin, 10,000 propyl laurate units/g) was purchased from Novozymes A/S (Bagvaerd, Denmark). All chemicals and solvents used in this study were analytical grade and used without any further treatments unless otherwise stated.

Enzymatic Production of Esters

Dioleyl adipate was synthesized using an optimized method from a previous study [16]. Briefly, the synthesis was prepared in a 500 ml stirred tank reactor with a working volume of 350 ml. The reactor was equipped with a flat-blade disk turbine agitator, with a temperature control system (Julabo MB-13, Germany) and sampling ports. The enzymatic synthesis of dioleyl adipate was prepared by mixing oleyl alcohol and adipic acid in the reactor at a molar ratio of 5.3:1 and catalyzed by Novozym® 435. Meanwhile, 1,5-pentanediol diricinoleate was produced by reacting ricinoleic acid and 1,5-pentanediol with a molar ratio of 3:1 in a 1 L three-neck flask for a large-scale reaction. An amount of 3% Novozyme® was used in toluene solvent. The reaction was started at 65 °C with 200 rpm under 100 mmHg vacuum pressure for 9 hours. The percentage of fatty acid conversion during the esterification was then quantitated using Equation (1). The ester formed was expressed as equivalent to the conversion of the fatty acid. In addition, both products were confirmed by Fourier transform infrared (FTIR) analysis (Perkin-Elmer, Model 1650, United States).

$$\text{Percentage of conversion (\%)} = \frac{V_{\text{control}} - V_{\text{sample}}}{V_{\text{control}}} \times 100\% \quad (1)$$

where, $V_{control}$ is a volume of 0.1 M KOH needed to titrate the control, and V_{sample} is a volume of 0.1 M KOH needed to titrate the sample.

Formulation of wood coating

Oligomer (epoxy acrylate) and reactive diluents (ESBO and esters) were mixed in different proportions with continuous stirring to obtain a homogenous mixture for reduced acrylate wood coating formulations as summarized in Table 1. Formulations 1-8 were mixed with a 6% photoinitiator (Daracour1173) and applied onto paper plates of desired sizes using a bar coater with 150 μm thickness. The coated samples were irradiated using a UV curing conveyor system which is available at Akzo Nobel Surface Coatings, Malmö, Sweden. Even though formulations were aimed as wood surface coating, paper plates have been used as a standard to undergo further analysis after radiation. The formulation mixture was applied on a paper to determine the maximum curing rate by passing through a UV oven equipped with a 120 W/cm^2 mercury lamp. Performances of Formulations 1-8 on pendulum hardness, surface test and physical observation were evaluated according to the standard requirements.

Table 1. Epoxide and esters composition in reduced acrylate wood coating formulations

Formulation	Composition (%, w/w)			
	Epoxy Acrylate	Epoxidation Soybean Oil	1,5-Pentanediol Diricinoleate	Dioleyl Adipate
1	85	15	-	-
2	85	-	7.5	7.5
3	75	25	-	-
4	75	-	12.5	12.5
5	65	35	-	-
6	65	-	17.5	17.5
7	55	45	-	-
8	55	-	22.5	22.5

Gel content

Gel content was determined by measuring the weight loss of the sample after extraction using acetone for 10 hours at 60 °C [17]. Cured films for different UV radiation exposure were peeled off from the glass tile and weighed to obtain the initial weight. Then, the films were extracted using a Soxhlet extractor to remove unreacted materials inside the coating film. Finally, all cured films were dried in a vacuum and weighed to estimate the gel content. Higher gel content means more crosslinking took place. The amount of gel content was calculated using Equation (2).

Pendulum hardness

Two pendulum hardness methods including Köenig and Persoz can be used to measure the hardness of a coating. A Köenig pendulum hardness tester (Byk, Switzerland) was employed to monitor the surface hardness of the cured film during UV curing, where oscillation was counted between 6° and 3°[18]. After UV exposure, the pendulum hardness of the UV cured film surface was measured with respect to the pendulum oscillation time. The result is expressed as percentage hardness and calculated using Equation (3).

Surface resistance

Assessment of the surface resistance including mar and chemical resistance was evaluated according to EN 12720 (European Standard EN 12720: 1997 Furniture-Assessment of surface resistance to cold liquid) and was performed using Akzo Nobel Industrial Coatings, Malmö, Sweden. The high-speed mar tester was utilized to simulate the effect of fingernail mar at a computed velocity range from 0.3 m/s to 3.4 m/s in a consistent manner by controlling the speed and normal impact force across a coating surface as described by Anderson et al. [19]. The chemical resistance test was then conducted by exposing the cured film to different types of liquids including alcohol (1 hour), coffee (1 hour), water (24 hours), and grease (24 hours). Briefly, a filter paper was immersed in a liquid and was placed on the test surface and later was covered by an inverted glass basin. After a specified period, the paper was removed, and the surface was washed and dried. The surface was then examined for possible damages such as discoloration, changes in gloss or color, and blistering [4].

$$\text{Gel Content (\%)} = \frac{\text{Weight after extraction}}{\text{Initial Weight}} \times 100\% \quad (2)$$

$$\text{Pendulum Hardness (\%)} = \frac{\text{No. of oscillation for sample}}{\text{No. of oscillation for standard glass}} \times 100\% \quad (3)$$

Results and Discussion

Enzymatic production of esters

Direct enzymatic esterification of oleyl alcohol and adipic acid using the previously optimized method [16] was found to produce 95% conversion of dioleyl adipate in the reactor. The presence of ester was confirmed by the FTIR analysis. The FTIR analysis of dioleyl adipate was found to be similar as reported by Chaibakhsh et al. [16], where the absorption bands of C=O and C-O were observed in the region 1690-1794 cm^{-1} and 1162-1263 cm^{-1}, respectively. In addition, ricinoleic ester had also been enzymatically prepared using lipase to evade the problems of discoloration, odor, and high energy costs which usually occurred in high-temperature chemical processes [13,14]. Approximately 87% conversion of 1,5-pentanediol diricinoleate was successfully achieved after 9 hours of reaction. Figure 1 shows that ricinoleate ester had a higher absorption band at wavenumber 1733 cm^{-1} as compared to ricinoleic acid due to the transmittance percentage of C=O (carboxyl and ester group). A similar finding was reported by Ghoshray et al. on the enzymatic synthesis of ricinoleate ester with long-chain fatty alcohol by Lipozyme TM [22].

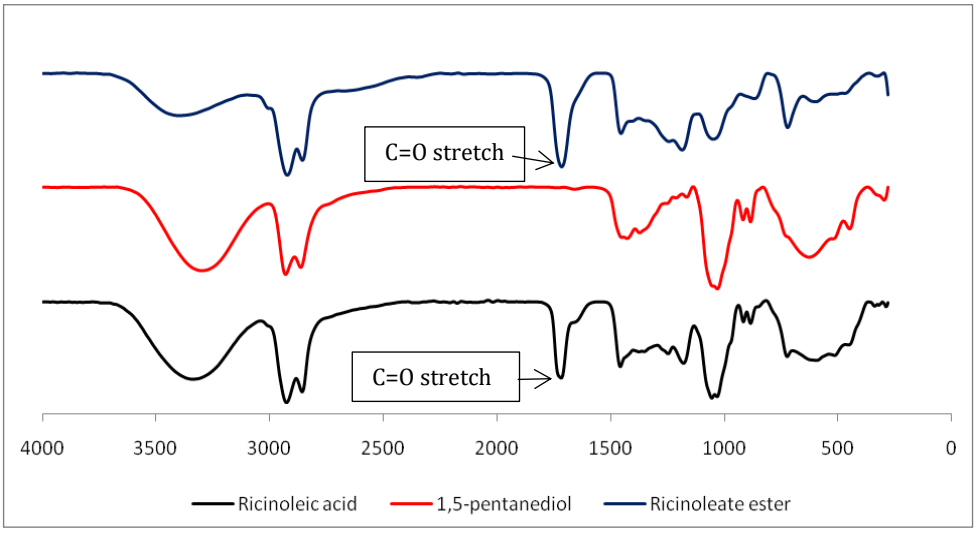

Figure 1. Infrared spectrum for ricinoleic acid, 1,5-pentanediol, and ricinoleate ester after enzymatic reaction using Novozyme® in toluene at 65 °C and 200 rpm stirring rate under 100 mmHg vacuum pressures for 9 hours.

Formulation of Wood Coating

Many researchers have reported on the development of UV-curable coating formulations. However, only a few studies on the production of high-quality UV-curable wood coatings with reduced epoxy acrylate using liquid wax esters as reactive diluents have been done. In this study, different percentages (15-45%) of epoxide (ESBO) or ester (mixture of dioleyl adipate and pentanediol ricinoleate) were used in the formulation. As shown in Table 2, the physical appearance of Formulation 1 and Formulation 2 showed a clear and transparent coating, which was similar to the commercial product containing high epoxy concentration. However, further reducing the epoxy concentration will lead to a transparent and opaque appearance on the glass plate.

Table 2. The physical appearance of coating formulations cured by UV light

Formulation	Amount of Epoxy Acrylate (%)	Physical Appearance After Radiation
Epoxidation of soybean oil		
1	85	Cured, transparent
3	75	Cured, translucent
5	65	Not cured
7	55	Not cured
Mixture of 1,5-pentanediol diricinoleate and dioleyl adipate (1:1, w/w)		
2	85	Cured, transparent
4	75	Cured, opaque
6	65	Cured, opaque
8	55	Cured, opaque

Gel content

Gel content estimation is an important property of any coating as it directly measures the degree of crosslinking, which decides the final properties of the coating [23]. Since the first pass under the ultraviolet light, the photoinitiators will break and produce active radicals. The radicals will then attack the unsaturated double bond of ESBO and wax esters in the formulation and start the crosslinking process. More crosslinking occurs if the process is repeated, resulting in a higher percentage of gel content. As shown in Figure 2, more than 69% of gel contents were found in Formulations 1-4, representing a well cross-linking behavior amongst the various constituents present in different formulations. It was found that as the proportion of epoxy acrylates in the formulations decreased, the gel content values of the film were found to gradually decrease. Formulation 1, which contained ESBO with a high oxirane number and the highest vinyl group from acrylates, had the highest gel content value (79.53%). It is known that oxirane and vinyl groups have a branching effect and can yield more crosslinking in the cured film as compared to double bonds and a hydroxyl group.

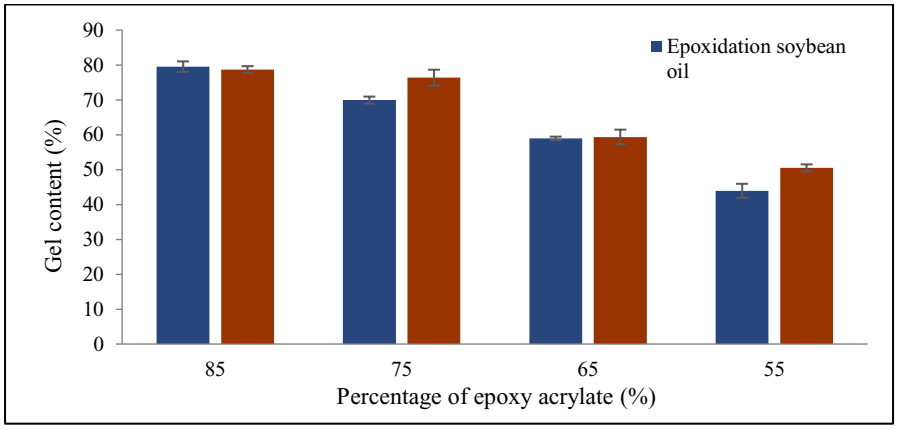

Figure 2. The effect of reduced-epoxy acrylate formulations containing epoxidation soybean oil (ESBO) and a mixture of 1,5-pentanediol diricinoleate and dioleyl adipate (1:1, w/w) on the gel content of coating cured by UV light

Pendulum hardness

One of the most important parameters to ensure scratch resistance in coating formulation is the pendulum hardness. Formulations 1-4 successfully dried in a single exposure to UV curing. Meanwhile, Formulations 5-8 required more UV exposure of up to six passes to completely dry. The formulation was then applied onto glass to test the pendulum hardness. The level of hardness varies depending on the final application, but a pendulum hardness of 40% can be considered as a minimum in many applications. The hardness of coating was found to increase in parallel with the number of passes under UV-light until maximum exposure was reached, at which the point of hardness value remained constant. The hardness percentage of Formulations 1-8 after being exposed to the UV-light until completely dry is shown in Table 3.

From the results obtained, it can be noticed that a higher percentage of reactive diluents including both epoxide and mixed esters in the coating formulation reduced stiffness. Besides, the hardness of Formulations 5 and Formulation 7 could not be measured due to the large amount of ESBO used and the formulations were difficult to dry completely. Formulations 1-3 meets the minimum hardness requirement, which is more than 40%. However, Formulation 1 and Formulation 3 containing 15% and 25% ESBO, respectively, showed greater hardness than Formulation 2 containing a mixture of 15% of pentanediol diricinoleate and dioleyl adipate. This is possibly due to the presence of oxirane ring and more double bonds in ESBO than diricinoleate and dioleyl adipate, which only having two double bonds for crosslinking [23].

Table 3. The percentage of pendulum hardness of coatings cured by UV light

Formulation	Amount of Epoxy Acrylate (%)	Pendulum Hardness (%)
Epoxidation of soybean oil		
1	85	61.02
3	75	44.63
5	65	Not applicable
7	55	Not applicable
Mixture of 1,5-pentanediol diricinoleate and dioleyl adipate (1:1, w/w)		
2	85	43.50
4	75	32.77
6	65	14.69
8	55	9.04

Surface resistance

The ability of a good drying and high-quality formulation was evaluated by fingernail mar and chemical resistance tests as tabulated in Table 4. The coating must endure marring stress and exposure to a wide range of chemicals with various acidity and basicity without staining and losing gloss. The results showed that both mar and chemical resistance performances were reduced as the amount of epoxy acrylate was decreased. No fingernail marring was produced in a formulation containing more than 75% epoxy acrylate. Therefore, only Formulations 1-4 were chosen for further evaluation in the chemical resistance test. The test was simulated by exposing the cured film to different types of liquids including alcohol, coffee, water, and grease. Formulation 2 exhibited excellent resistance towards all the tested liquids after being exposed for up to 24 hours. However, limited exposure to alcohol was observed in Formulation 1 as a slight variation in gloss was noticed after the exposure.

Therefore, formulation containing 85% epoxy acrylate and 15% mixture of pentanediol diricinoleate and dioleyl adipate was able to provide the best coating characteristics and possessed a potential for industrial application.

Table 4. The performance of formulations as wood coatings in mar and chemical resistance

Formulation (+ 6% Photoinitiator)	Fingernail Mar Resistance	Chemical Resistance			
		Alcohol	Coffee	Water	Grease
1	No fingernail marring	L	R	R	R
2	No fingernail marring	R	R	R	R
3	No fingernail marring	NR	R	R	R
4	No fingernail marring	NR	NR	NR	NR
5	Fingernail marring	NA	NA	NA	NA
6	Fingernail marring	NA	NA	NA	NA
7	Fingernail marring	NA	NA	NA	NA
8	Fingernail marring	NA	NA	NA	NA

R: recommended; L: limited exposure; NR: not recommended, NA: not available

Conclusion

This work proposed up to 15% reduction of epoxy acrylate by replacing it with enzymatically synthesized epoxide from soybean oil (ESBO) or wax esters mixture of dioleyl adipate and 1,5-pentanediol diricinoleate (1:1, w/w) to produce high-quality and transparent coating formulations. The reduced acrylate formulations were found to perform well in terms of pendulum hardness test and surface resistance. Moreover, the effect of irradiation doses on the gel content of coated film cured by UV light could reach almost 80%. Therefore, the enzymatically synthesized renewable monomers including ESBO and wax esters could be used as a potential reactive diluent in UV-curable wood coating to reduce the proportion of highly toxic acrylate products.

Abstract

3-monochloropropane-1,2-diol (3-MCPD) and its ester are categorized as food toxicants that formed during high-temperature processing of fat-based matrices. It has been classified as a possible human carcinogen (Group 2B) due to its potential to induce cancer in humans. This study investigated the level of 3-MCPD esters in palm oil and other edible plant oils available in the Malaysian market. The samples were analyzed using indirect methods involving acidic transesterification, then quantified by gas chromatography-mass spectrometry (GC-MS) equipped with BPX-5 capillary column using selected ion monitoring (SIM) mode. The method performance showed good recovery between 92.80% to 105.22% and good reproducibility with RSD of 4.18% to 5.63% for three different concentrations of spiked 3-MCPD. The limits of detection (LOD) and quantification (LOQ) were 0.11 mg kg^{-1} and 0.14 mg kg^{-1}, respectively. The highest concentrations of 3-MCPD esters were detected in refined palm oil, ranging from 2.29 to 4.10 mg kg^{-1}, while 3-MCPD esters in other edible plant oils varied from <LOQ to 3.75 mg kg^{-1}. The validated results are presented to attract policymakers' attention and achieve the goal of ensuring consumer rights while monitoring food safety and quality.

Keywords: 3-monochloropropane-1,2-diol, gas chromatography-mass spectrometry, edible plant oils, food safety, food control

Abstrak

3-monokloroprapana-1,2-diol (3-MCPD) dan esternya dikategorikan sebagai bahan toksik makanan yang terbentuk semasa pemprosesan bersuhu tinggi matriks berasaskan lemak. Ia telah diklasifikasikan sebagai karsinogen manusia yang berkemungkinan (Kumpulan 2B) kerana potensinya untuk menyebabkan kanser pada manusia. Kajian ini dijalankan untuk menyiasat tahap ester 3-MCPD dalam minyak sawit dan minyak tumbuhan boleh dimakan lain yang terdapat di pasaran Malaysia. Sampel dianalisis

menggunakan kaedah tidak langsung yang melibatkan transesterifikasi berasid, yang kemudiannya dikuantifikasi oleh kromatografi gas-spektrometri jisim (GC-MS) yang dilengkapi dengan turus kapilari BPX-5 menggunakan mod pemantauan ion (SIM) terpilih. Prestasi kaedah menunjukkan perolehan semula yang baik antara 92.80% hingga 105.22% dan juga kebolehulangan yang baik dengan RSD sebanyak 4.18% hingga 5.63% untuk tiga kepekatan berbeza 3-MCPD terpaku. Had pengesanan (LOD) dan kuantifikasi (LOQ) didapati masing-masing pada 0.11 mg kg^{-1} dan 0.14 mg kg^{-1}. Kepekatan tertinggi ester 3-MCPD dikesan dalam minyak sawit ditapis, antara 2.29 hingga 4.10 mg kg^{-1}, manakala ester 3-MCPD dalam minyak tumbuhan boleh dimakan lain berbeza daripada <LOQ hingga 3.75 mg kg^{-1}. Keputusan yang disahkan dibentangkan dengan harapan dapat menarik perhatian penggubal dasar dan mencapai matlamat untuk memastikan hak pengguna sambil memantau keselamatan dan kualiti makanan.

Kata kunci: 3-monokloropropana-1,2-diol, kromatografi gas-spektrometri jisim, minyak tumbuhan boleh dimakan, keselamatan makanan, kawalan makanan

Introduction

Edible plant oils, also known as vegetable oils, are extracted from seeds, fruits, nuts, legumes, and pulps of plants. They are mainly used in cooking to change the flavor, color, and fragrance of foods and provide diversified flavor and enrich the sense of satiety during the cooking process [1]. In 2019, the global market of vegetable oils was almost 203 million tons [1]. With the increasing demand for edible plant oils globally, their quality and safety have gained significant attention as they play an essential role in human dietary nutrition. Hence, oils undergo a refining process to enhance their stability and quality. Although unwanted impurities are removed from the oils, refining often originates new contaminants such as chloropropanols and glycidols that can cause additional health hazards to consumers [2].

3-monochloropropane-1,2-diol (3-MCPD) and its esters are a class of food processing contaminant that belongs to chloropropanols, a group of alcohols comprised of a 3-carbon backbone substituted with one or two chlorine atoms [3]. The formation of such contaminants is mainly due to the high-temperature processing of fat-based matrices [4, 5]. 3-MCPD was first identified in its free form by Velisek et al. in acid-hydrolyzed vegetable proteins (acid-HVP) used in soy sauce production, while its esterified (bound) form was then discovered in 1980 [6, 7]. Their occurrence existed in soy sauces and other flavoring materials and foodstuffs such as edible oils, heat-processed foods, cereal, meat products, infant formula, and even human breast milk [8-12].

Previous studies have reported that high 3-MCPD esters were found in refined edible oils, especially palm oils [10]. They were formed during the refining process of vegetable oils in the deodorization step at high temperatures exceeding 200 °C to remove free fatty acid contents in oils while giving a good color and odor [13]. The potential risks of such contaminants have raised immediate concern among the public since 3-MCPD esters can be metabolized to release free 3-MCPD in the human gastrointestinal system [14]. In addition, 3-MCPD has been categorized as a possible human carcinogen (Group 2B) by the International Agency for Research on Cancer (IARC) due to its potential to induce cancer in experimental animals [15]. Hence, it is vital to have a sensitive and robust method to determine the concentration of 3-MCPD in edible oils and fats.

The European Food Safety Authority (EFSA) published a scientific opinion in May 2016 based on a survey done by the Panel on Contaminants in Food Chain (CONTAM) regarding the issue of contaminants found in processed vegetable oils and foods. They stated that the highest levels of 3-MCPD esters were found in palm oil [16]. Previous literature reports indicated that refined palm oil contained the highest levels of 3-MCPD esters [10, 17]. Due to the rising concern about the 3-MCPD potential health risk to humans, the European Commission (EC) Scientific Committee on Food and the Joint FAO/WHO Expert Committee on Food Additives (JECFA) have set a maximum tolerable daily intake (TDI) of 2 μg kg^{-1} of body weight of 3-MCPD levels [18, 19]. Such food safety issues from 3-MCPD cause implications for major vegetable oil producers, especially Malaysia, with high palm oil production [20]. Furthermore, about 85% of global palm oil produced was used in food applications [21]. Therefore, it is of utmost importance to identify the 3-MCPD levels in various edible plant oils so that the researchers and

manufacturers can control and mitigate the occurrence and intensity of 3-MCPD esters formation to ensure the refined oils are safe and of the best quality for consumers [20].

Several analytical methods have been developed and published over the years to determine 3-MCPD esters in edible oils. Generally, there are two main approaches for detecting 3-MCPD esters in edible oils: the direct and indirect analysis methods. Direct methods involve the direct determination of individual MCPD esters using liquid chromatography coupled with time-of-flight mass spectrometry (LC-TOFMS) [22, 23]. This method has the advantage of being simple, requiring a minor degree of sample preparation without any additional steps of analyte transformation, is not time-consuming, and gives detailed information on the chemical structure of the esters [24]. However, it has not been widely used in routine analysis due to its high cost and the possibility of contamination of complex matrices on the instrument [24]. In contrast, indirect methods involve quantifying the total content of free 3-MCPD released from their esterified form mainly by using gas chromatography-mass spectrometry (GC-MS) [25]. Due to the detection of only a single analyte (free 3-MCPD) and the need for just a single internal standard, this method provides higher sensitivity for the quantification of 3-MCPD. It is more suitable for routine analysis [4]. Indirect methods follow similar protocols, which are the addition of an internal standard to the sample (either free or esterified form of 3-MCPD-d5) for quantification purposes, acid or alkaline transesterification to release free 3-MCPD from its esterified form, followed by neutralization and salting out, derivatization of the extracted 3-MCPD, extraction of the derivative, and finally GC-MS analysis [5].

This research aims to determine the levels of 3-MCPD esters in edible plant oils. The validated results are presented to attract policymakers' attention and ensure consumer rights while monitoring food safety and quality. Palm oil and other edible plant oils such as peanut oil, corn oil, sunflower oil, and olive oil were analyzed using a GC-MS equipped with a BPX-5 capillary column and selected ion monitoring (SIM) mode to determine and quantify the concentration of 3-MCPD esters. Because the performance of the BPX-5 column for detecting 3-MCPD esters has not been reported, its performance for the analysis of the target analyte was also a focus of this study. This research aimed to identify the concentration of 3-MCPD esters in two different local brands of unrefined and refined palm oil and two different brands of peanut oil, corn oil, sunflower oil, and olive oil available in the Malaysia market. The results obtained from the analysis were used to compare the levels of 3-MCPD esters among the edible plant oils and different brands for each type of oil sample.

Materials and Methods

Chemicals and samples

3-monochloropropane-1,2-diol (3-MCPD, 98%) was purchased from Sigma-Aldrich (St. Louis, MO, USA), while the internal standard deuterated 3-monochloropropane-1,2-diol (3-MCPD-d5, 98.7%) was purchased from Dr. Ehrenstorfer (Augsburg, Germany). Tetrahydrofuran (≥99.9%), sulfuric acid (H_2SO_4, 95-97%), methanol (≥99.8%), sodium sulfate (Na_2SO_4, ≥ 99.0%), sodium bicarbonate ($NaHCO_3$, ≥99.0%, and n-hexane (≥99.0%) were purchased from Merck (Selangor, Malaysia). Phenylboronic acid (PBA, ≥ 97.0%) was purchased from Sigma-Aldrich (St. Louis, MO, USA). All chemicals used were of analytical and LC grades.

Twelve edible oil samples were used to analyze 3-MCPD esters by the indirect method, including two different local brands of unrefined and refined palm oil, two different local brands of peanut oil, corn oil, sunflower oil, and olive oil, respectively. An extra virgin olive oil was used as a blank sample for method performance and validation. All the edible oil samples were obtained from local supermarkets and were stored at room temperature (25 °C) before analysis.

Preparation of reagents and standards solutions

Methanolic sulfuric acid solution (1.8%, v/v) used in acidic transesterification was prepared by dissolving 1.8 mL of sulfuric acid in 100 mL of methanol. The saturated solution of sodium bicarbonate was prepared by mixing 4.8 g of $NaHCO_3$ in 50 mL of ultra-pure water. In contrast, sodium sulfate solution (20%, w/v)

was prepared by dissolving 20 g of Na_2SO_4 in 100 mL of ultra-pure water. The derivatization agent, PBA solution (25%, w/v), was prepared by dissolving 1 g of PBA in 4 mL of acetone: water mixture (19:1, v/v).

The concentration of 1 mg mL^{-1} of 3-MCPD stock solution was prepared by weighing 10 mg (± 0.1 mg) of the 3-MCPD standard into a 10 mL volumetric flask and diluted to the mark with tetrahydrofuran. 10 µg mL^{-1} of 3-MCPD standard solution (S1) was prepared by pipetting 100 µL 3-MCPD stock solution into a 10 mL volumetric flask and filled up to the mark by diluting it with tetrahydrofuran. In comparison, 1 µg mL^{-1} of 3-MCPD standard solution (S2) was then prepared by pipetting 1 mL of 3-MCPD standard solution (S1) into a 10 mL volumetric flask and filled up to the mark by diluting it with tetrahydrofuran. Both S1 and S2 3-MCPD standard solutions were used for calibration purposes.

0.5 mg mL^{-1} of 3-MCPD-d5 stock solution was prepared by weighing 5 mg (± 0.1 mg) of 3-MCPD-d5 into a 10 mL volumetric flask and diluted to the mark with tetrahydrofuran. The working solution of 3-MCPD-d5 was used as the internal standard. It was prepared by pipetting 100 µL of its stock solution into a 10 mL volumetric flask and diluted to the mark with tetrahydrofuran to give a final concentration of 5 µg mL^{-1}. All the standard solutions prepared were stored at 4 °C for up to 3 months.

Determination of 3-MCPD esters using the indirect method

Analysis of 3-MCPD esters in edible oil samples was carried out using the indirect method of acidic transesterification by Zelinková et al. and Hrncirik et al. [5, 10]. 100 mg (± 5 mg) of oil sample was weighed in a clean glass tube, dissolved in 0.5 mL of tetrahydrofuran, and vortexed for 20 s. 80 µL of the internal standard solution, 3-MCPD-d5, was then added to the sample, followed by 1.8 mL of methanolic sulfuric acid solution (1.8%, v/v) vortexed for another 20 s. The tube was capped and incubated in a water bath at 40 °C for 16 hours. After the incubation period, 0.5 mL of a saturated aqueous sodium bicarbonate solution was added to the tube to stop the reaction and vortexed for 10 s. The organic solvents were evaporated to dryness at 55 °C by using a vacuum rotary evaporator.

Then, 2 mL of aqueous sodium sulfate solution (20%, v/v) was added to the mixture, followed by liquid-liquid extraction with n-hexane (2×2 mL) to remove the fatty acid methyl esters (FAMEs). FAMEs were removed by discarding the organic phase (upper layer) after phase separation. 250 µL of PBA derivatizing solution (25%, w/v, acetone/water, 19/1, v/v) was added to the aqueous extract. The tube was capped, sealed, vortexed for 15 s, and heated in a water bath at 80 °C for 20 min. After 20 min, the tube was allowed to cool to room temperature (25 °C). N-hexane (2×1 mL) was added, and the tube was vortexed for 30 s to extract the 3-MCPD-PBA derivative. The tube was allowed to stand for phase separation, and the supernatant (n-hexane) was transferred to a clean tube. A small amount of anhydrous sodium sulfate was added to the supernatant to remove any excess water. Finally, the supernatant was transferred to a sterile vial. 1 µL of the sample was injected and analyzed using GC-MS. The analysis was carried out in triplicate.

Gas chromatography-mass spectrometry analysis

Analyte detection was performed by a single quadrupole gas chromatography-mass spectrometer GCMS-QP2010 Plus equipped with an AOC-20i auto-injector from Shimadzu (Kyoto, Japan). 1 µL of the sample was introduced into the injector operating at 280 °C in splitless mode. The chromatographic separation was carried out on a bonded, poly(dimethylsiloxane) capillary column BPX-5 (SGE Analytical Science, 30 m length, 0.25 mm id, 0.25 µm film thickness). Helium (99.999%) was used as a carrier gas set at a constant flow of 1.2 mL min^{-1}. The column temperature was programmed at 60 °C for 1 min, which increased to 150 °C at the rate of 6 °C min^{-1} and held for another 2 min. The temperature was further increased to 280 °C at the rate of 10 °C min^{-1} and held constant for 5 min. The mass spectrometer was operated in electron ionization (EI) mode at 70 eV ionization energy. The MS transfer line temperature was maintained at 280 °C, while the ion source and quadrupole temperatures were at 250 °C and 150 °C, respectively. Qualitative analysis was carried out by running the mass spectrometer in a full-scan

mode over m/z 50 to 400 for peak confirmation. The quantitative analysis was performed by selected ion monitoring (SIM) mode to monitor characteristic ions at m/z 91, 147, and 196 for 3-MCPD derivatives, while for 3-MCPD-d5, the characteristic ions were at m/z 93, 150, and 201.

Method validation

A calibration curve was established by spiking a blank sample with eight different concentration levels of 3-MCPD. 100 mg (± 5 mg) of the blank sample (extra virgin olive oil), with no detection of the 3-MCPD esters, was spiked with different concentrations of the 3-MCPD standard. The concentrations of spiked 3-MCPD were 0.25, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, and 6.0 mg kg^{-1} of 3-MCPD per 100 mg of sample, respectively. The known amount of 3-MCPD-d5 internal standard (4.0 mg kg^{-1} per 100 mg of the sample) was also spiked before extraction based on the sample preparation procedure.

Recovery and repeatability were evaluated by selecting three different concentrations of 3-MCPD (low, medium, and high: 0.25, 3.0, and 6.0 mg kg^{-1}), prepared for six replicates (n = 6), and subjected to 3-MCPD analysis. Besides, within-laboratory reproducibility was also conducted by measuring three different concentrations of 3-MCPD (low, medium, and high: 0.25, 3.0, and 6.0 mg kg^{-1}), with six replicates for each concentration level (n = 6) for three consecutive days. Limit of detection (LOD) and limit of quantification (LOQ) were performed by preparing one lowest concentration of 3-MCPD and subjected to 3-MCPD analysis. The same concentration was then repeated ten times. LOD and LOQ were calculated as three- and ten-fold standard deviations of ten independent samples.

Statistical evaluation

The oil samples were analyzed in triplicate. General statistical evaluation was carried out using Microsoft Office Excel 365. The average of triplicate analyses was reported together with the standard deviation (± SD). Significant differences between the results obtained were examined using Student's t-test with a 95% confidence interval ($p < 0.05$).

Results and Discussion

3-MCPD-PBA derivative chromatogram

This study was conducted using the BPX-5 capillary column, which directly replaces the GC columns used by previous literature, such as HP-5MS and DB-5MS [13, 26, 27]. These columns have similar phases of (5%-phenyl)-methylpolysiloxane (non-polar) with very low bleed characteristics, making them ideal for GC-MS applications. The BPX-5 capillary column is a multi-purpose column that can be used for a wide range of applications and is suitable for almost 80% of routine GC analyses, such as ultra-trace analyses, hydrocarbons, pesticides, herbicides, and triglycerides. Nonetheless, the BPX-5 column has not been applied and reported to detect 3-MCPD-PBA derivatives. Although the BPX-5 and HP/DB-5MS columns have similar phases in general, the retention times of the target analytes with similar characteristic ions may be slightly different. Likewise, retention times also vary depending on the type of columns employed and the analysis method. Several factors such as column length, column temperature, oven temperature, or gas flow rate may influence the retention time of a target analyte even if similar phases of GC columns are used. For example, the retention times for both 3-MCPD esters and their deuterated form varied between 14.50 min to 17.17 min [13, 26, 27].

The gas chromatograms for both 3-MCPD esters and their deuterated form in the spiked blank samples are shown in Figure 1. The retention time of 3-MCPD-d5 was 17.08 min, while the retention time of 3-MCPD esters was 17.17 min. The EI mass spectra for the PBA derivative of 3-MCPD and 3-MCPD-d5 were also illustrated in Figure 2. SIM mode was used for GC-MS quantification, where m/z 147 and m/z 150 were served as the quantifier ions for 3-MCPD derivatives and 3-MCPD-d5, respectively. In addition, m/z 91 and 196 were used as the qualifier ions for 3-MCPD derivatives and m/z 93 and 201 for 3-MCPD-d5. Table 1 shows detailed information on the retention times and characteristic ions used for GC-MS analysis.

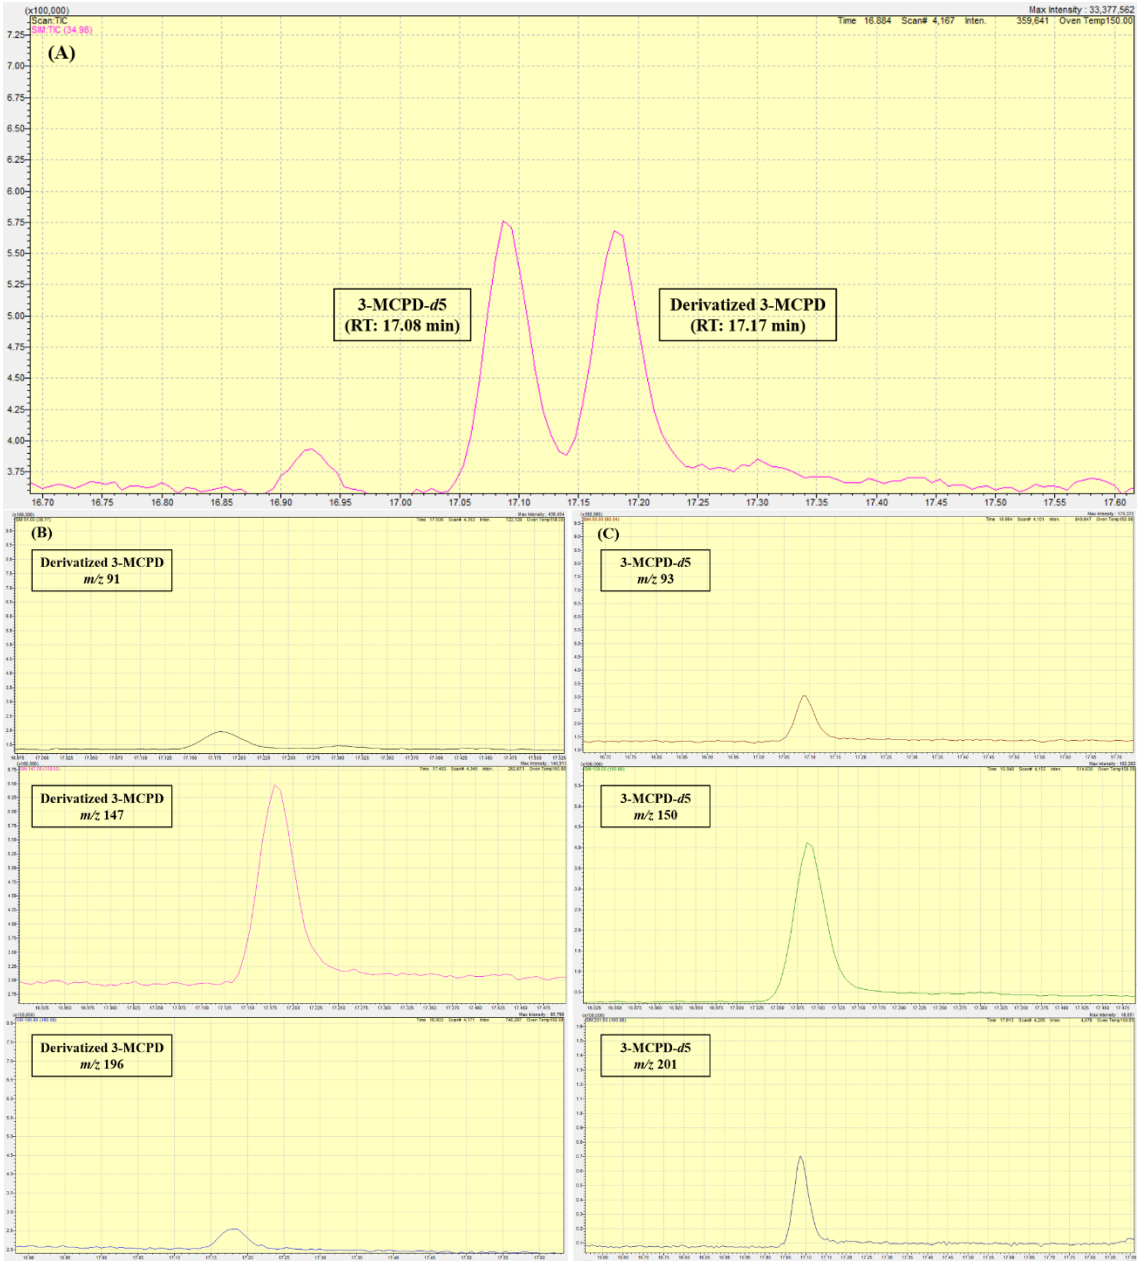

Figure 1. GC chromatograms of 3-MCPD esters and 3-MCPD-d5 in spiked blank samples (RT = retention time). (A) TIC of derivatized 3-MCPD, (B) SIM chromatogram of 3-MCPD esters, (C) SIM chromatogram of 3-MCPD-d5

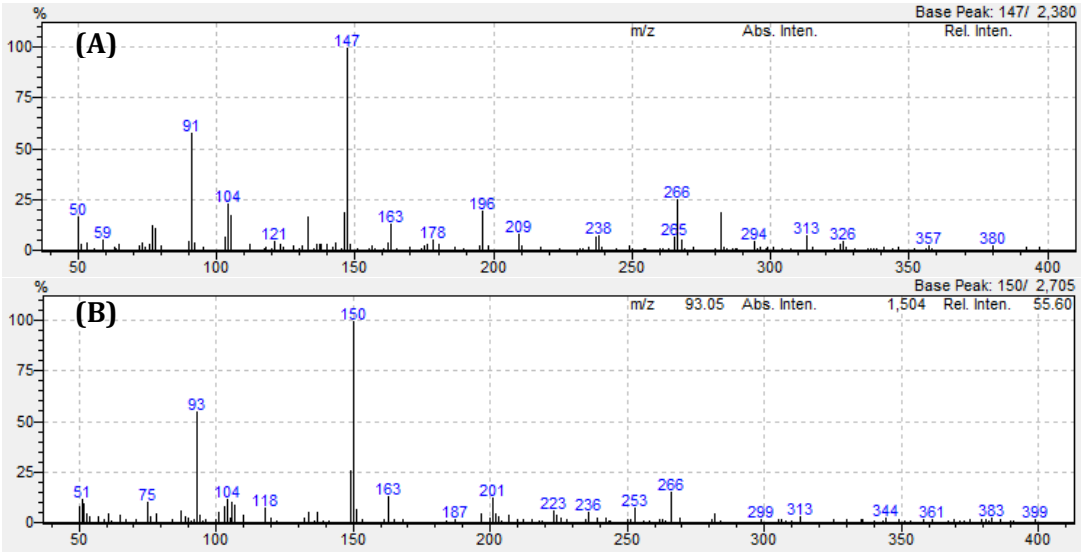

Figure 2. EI mass spectra for PBA derivatives of (A) 3-MCPD and (B) 3-MCPD-d5

Table 1. Retention times and characteristic ions used for SIM mode in GC-MS analysis

Analyte	Retention Time (min)	Quantifier Ion (m/z)	Qualifier Ion (m/z)
3-MCPD-d5	17.08	150	93 & 201
3-MCPD	17.17	147	91 & 196

Method validation

Method validation for the analysis of 3-MCPD esters using GC-MS was conducted about linearity, recovery, precision (repeatability and within-laboratory reproducibility), LOD, and LOQ. Linearity was evaluated using eight calibration points from 0.25 mg kg^{-1} to 6.0 mg kg^{-1} of the 3-MCPD standard. The calibration curve was constructed by plotting the response ratio of the 3-MCPD standard and 3-MCPD-d5 internal standard against the concentration of the 3-MCPD standard, as illustrated in Figure 3. The results showed a linear relationship between the concentration of 3-MCPD standards and the area ratio of 3-MCPD/3-MCPD-d5, with the linearity was verified at $r^2 \geqslant 0.99$. The calibration curve obtained shows that the area ratio of 3-MCPD/3-MCPD-d5 is directly proportional to the concentration of spiked 3-MCPD standards, which obeys Beer's law. The linear range is broad enough to cover the total concentration of 3-MCPD esters found in most edible oils.

In addition, method validation was also conducted based on the recovery test. The result in Table 2 shows the percentage recovery for three different concentrations of 3-MCPD, with the lowest recovery of 92.80% was obtained for the lowest concentration of 3-MCPD (0.25 mg kg^{-1}), while the highest concentration of 3-MCPD (6.0 mg kg^{-1}) recorded the highest recovery of 105.22%. Apart from the recovery determination, the intra-day and inter-day (intermediate) precision were also performed in this study to determine the repeatability and within-laboratory reproducibility of the method, respectively. The RSD percentage obtained for repeatability was 4.30%, 6.38%, and 5.01% for 3-MCPD levels of 0.25, 3.0, and 6.0 mg kg^{-1}, respectively (Table 2). On the other hand, the percentage of RSD

obtained for within-laboratory reproducibility was 5.63% for the lowest concentration (0.25 mg kg^{-1}), 5.32% for the intermediate concentration (3.0 mg kg^{-1}), and 4.18% for the highest concentration of 3-MCPD (6.0 mg kg^{-1}) (Table 2). The low RSD of the replicates showed the reliability of the data acquired by an indirect method and the usage of the BPX-5 column, which attest to satisfactory repeatability and reproducibility. The high accuracy, good repeatability, and reproducibility are crucial in method validation as these parameters build a degree of confidence in obtaining the results. For instance, the RSD values must show the degree of variation expected when the method was repeated several times under standard situations [28]. Any tedious repeats can be eliminated, resulting in better time management for subsequent analyses using the same procedure and settings.

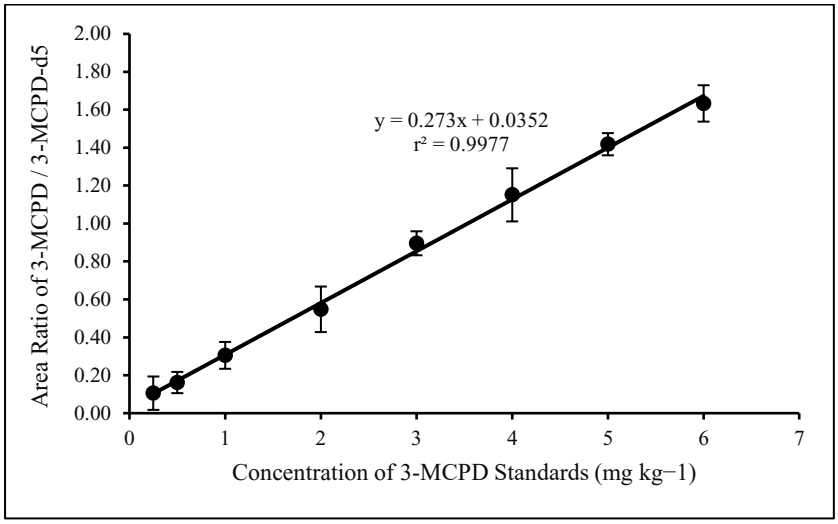

Figure 3. Calibration curve of 3-MCPD esters. Error bars are standard deviations obtained from the triplicate analysis

Table 2. Recovery and precision (repeatability and within-laboratory reproducibility) for 3-MCPD esters (n = number of replicates for each spike level)

Concentration of 3-MCPD (mg kg^{-1})	**% Recovery (n = 6)**	**RSD (%)**	
		Repeatability (n = 6)	**Within-Laboratory Reproducibility**
0.25	92.80 ± 4.21	4.30	5.63
3.0	104.65 ± 6.70	6.38	5.32
6.0	105.22 ± 5.28	5.01	4.18

According to the guidelines in EURACHEM, a blank sample containing no detectable or too low level of analyte might need to be spiked for specific analytical techniques such as chromatography to obtain a non-zero standard deviation [29]. In this study, the LOD and LOQ were estimated by calculating the mean and standard deviation of ten spiked blank samples (extra virgin olive oil) corresponding to the lowest point of the calibration curve. The calculated mean and standard deviation values were fitted into the following equations for the estimation of LOD and LOQ,

$$LOD \cong \bar{x}_{blank} + 3\ SD_{blank} \quad (1)$$

$$LOQ \cong \bar{x}_{blank} + 10\ SD_{blank} \quad (2)$$

where $\bar{x}_{blank}$ is the mean of the spiked blank sample and SD_{blank} is the standard deviation of the spiked blank sample. Hence, the LOD and LOQ of the method obtained in this study were 0.11 mg kg^{-1} and 0.14 mg kg^{-1}, respectively.

Table 3 compares the analytical performances of this study (validated method) to those of other indirect methods previously reported. Except for the slightly lower recovery reported by Abd. Razak et al., who employed the AOCS official method, all the procedures mentioned here exhibited good recovery (> 85%) and repeatability (RSD <10%). The linear range in this study was significantly more extensive than the AOCS official method and the method reported by Arisseto et al., which can determine a wide range of target analyte concentrations without excessive dilution. However, the LOQ was established at a minimum of 0.10 mg kg^{-1}, implying that none of the methods given are sensitive enough to detect 3-MCPD esters within the maximum tolerable limit of 0.002 mg kg^{-1} set by the Scientific Committee on Food (SCF) of the European Commission [18]. This suggests that all of the reported indirect methods (including direct HPLC methods) cannot reliably detect edible oil samples with low concentrations of 3-MCPD esters (below the maximum tolerable limit of 0.002 mg kg^{-1}). In other words, all indirect methods face the same challenges and have the same limitation. The detectable 3-MCPD esters in most edible oils are much greater than the maximum tolerable limit, even though the indirect method's LOD and LOQ are higher than the maximum tolerable limit of 0.002 mg kg^{-1}. In summary, this indirect method, combined with the BPX-5 capillary column, is suitable for routine analysis in practice.

Table 3. Comparison of the analytical performance of the current method with other indirect methods that have been reported

Methods	BfR Method 008 (Column: HP-5MS)	BfR Method 008 (Column: DB-5MS)	AOCS Official Method Cd 29a-13 (Column: HP-5MS)	Acid Cleavage	Acid Cleavage	Special Remark
Linear Range (mg kg^{-1})	0.25-6.00	0.25-6.00	0.08-2.39	0-4.00	0.25-6.00	Compared to the official AOCS method, this method has a wider linear range.
Recovery (%)	97.60-107.90	85.40-110.50	80.30-85.80	101.00-110.00	92.80-105.22	The recovery % range is narrower and closer to 100%.
Repeatability (RSD, %)	0.02-0.12 (n = 6)	4.18-4.79 (n = 8)	7.00-10.20 (n = 7)	4.40–8.40 (n = 6)	4.30-6.38 (n = 6)	This method outperforms the standard AOCS method in terms of precision.

3-MCPD esters in edible plant oils

The indirect method with PBA as the derivatizing agent was applied in this study as it readily reacts with 3-MCPD to form a stable derivative 4-chloromethyl-2-phenyl-1,3,2-dioxaborolane. Due to its high selectivity and ability to extract with non-polar solvents such as n-hexane, PBA was suitable for the choice of derivatization agent for GC-MS analysis. In this study, a total of 12 edible plant oils available in local supermarkets were analyzed to detect their 3-MCPD esters content, with two different brands for each type of oil. The concentrations of 3-MCPD esters in these samples ranged from <LOQ to 4.10 mg kg^{-1}, as shown in Figure 4.

Since Malaysia is the second-largest producer of palm oil in the world, with approximately 85% of global palm oil produced was used in food applications, the levels of 3-MCPD esters in palm oil were studied in this research because once the validated results are reported in a scientific journal or a media article, it will draw the attention of policymakers. In short, it fulfills the objective of ensuring consumers' rights while monitoring food safety and quality. The concentration of

3-MCPD esters was compared among red palm oil and refined palm oil, in which refined palm oil comprised a higher concentration of 3-MCPD esters, ranging from 2.29 ± 0.09 to 4.10 ± 0.06 mg kg^{-1} when compared to red palm oil (0.41 ± 0.03 to 3.40 ± 0.25 mg kg^{-1}). Red palm oil is often referred to as unrefined palm oil, and it is dark red due to the high content of carotenoids. Thus, it is vital to perform deodorization at low temperatures to avoid the thermal destruction of carotenoids [32]. Conversely, refined palm oil is light yellow and odorless as it undergoes deodorization at a high temperature of around 250 °C to remove any FFA and volatile components [32]. Such a process led to the formation of high 3-MCPD esters levels in refined palm oil. As shown in Figure 4, a low concentration of 3-MCPD esters with a value of 0.41 ± 0.03 mg kg^{-1} was identified in red palm oil (brand B). However, the other brand of red palm oil (brand A) detected a high concentration of 3-MCPD esters with a value of 3.40 ± 0.25 mg kg^{-1}. This suggested that the oil extraction conditions, for instance, the red palm oil sample (brand A), may consist of a mixture of unrefined and refined oils that eventually led to the occurrence of 3-MCPD esters.

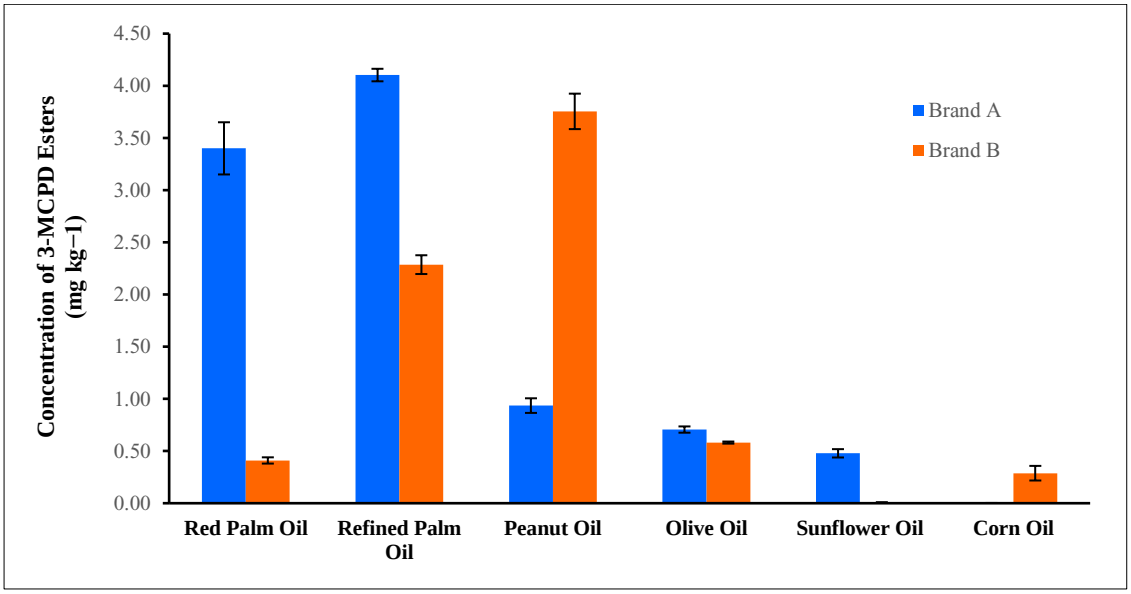

Figure 4. 3-MCPD esters levels determined in edible plant oils by indirect acidic transesterification methods and the BPX-5 capillary column, with two different brands for each type of oil

Besides palm oil, the other edible plant oils that consumers commonly used were also analyzed for the presence of 3-MCPD esters. Overall, olive oil, sunflower oil, and corn oil contained lower levels of 3-MCPD esters varied from <LOQ to 0.71 ± 0.03 mg kg^{-1}, a meanwhile higher concentration of 3-MCPD esters was found in refined palm oil and peanut oil, ranging from 0.94 ± 0.07 to 4.10 ± 0.06 mg kg^{-1} (Fig. 4). Sunflower oil and corn oil consisted of slightly lower concentrations of 3-MCPD esters (<LOQ to 0.48 ± 0.04 mg kg^{-1}) as compared to olive oil (0.58 ± 0.01 to 0.71 ± 0.03 mg kg^{-1}). Extra virgin olive oil was produced by physical pressing at low temperature (below 27 °C) without heating and therefore consisted of deficient levels of 3-MCPD esters [33]. In contrast, a higher temperature (150 °C) during deodorization involved in the production of refined olive oil resulted in higher content of 3-MCPD esters [33]. Since olive oil is a blend of both extra virgin olive oil and refined olive oil, thus it contains a higher concentration of 3-MCPD esters due

to the combination of unrefined and refined olive oil in various ratios. Such a trend of results confirmed the previous literature by Zelinková et al. (2006) that reported a higher concentration of 3-MCPD esters was detected in refined olive oil than that of sunflower oil and corn oil [10]. The highest concentration of 3-MCPD esters was found in refined palm oil (2.29 ± 0.09 to 4.10 ± 0.06 mg kg^{-1}), which was then followed by peanut oil (0.94 ± 0.07 to 3.75 ± 0.17 mg kg^{-1}). Peanut oil used in this study was a blended oil containing refined palm oil and peanut oil (as indicated on the product package and labeled). High deodorization temperature in the refining process further contributed to the formation of 3-MCPD esters in refined palm oil and peanut oil. Generally, refined fruits oil such as palm oil and olive oil generate higher levels of 3-MCPD esters than seed oils like sunflower oil and corn oil [10]. Palm oil derived from the mesocarp (pulp) of the fruit has a different composition from seed oils, which contain relatively high levels of potential precursors of 3-MCPD esters such as chloride ions and partial acylglycerols [34]. This eventually contributes to the high concentration of 3-MCPD esters in palm oil.

By comparing different brands for each type of oil sample, there is a significant variation in the concentration of 3-MCPD esters in all the oil samples, except olive oil (Figure 4). A significant difference was observed at a 95% confidence interval using Student's t-test with a p-value less than 0.05 between two different brands of oil samples, with red palm oil and peanut oil specifically, as shown in Figure 4. The reason for the significant variation in the concentration of 3-MCPD esters found between two different brands of red palm oil was explained previously. The same goes for peanut oil. The refining process involving bleaching and deodorization may be one of the factors that cause the differences in the 3-MCPD esters levels between the two different brands. It may also link to the preliminary heat treatment of seeds, such as roasting peanuts, which results in a variation of 3-MCPD esters among different peanut oil brands. For other types of oil samples, it isn't easy to justify these variations because the main precursors in the reaction and the actual mechanism of 3-MCPD esters formation were not completely understood. The formation of 3-MCPD esters during the production of edible oils might be due to the presence of chlorine as a donor. Plants took up chloride ions via the soil either by the natural occurrence or through the fertilizers, which then further metabolized into hydrophilic chloride substances that may generate hydrochloric acid upon high-temperature treatment, thereby leading to the occurrence of 3-MCPD esters [3]. Table 4 compares the trend of 3-MCPD esters levels in different types of plant edible oil samples from this study to those from previous studies. It should be noted that this study and earlier literature found that among the six types of edible oils, refined palm oil had the most significant level of 3-MCPD esters. In contrast, corn oil had the lowest 3-MCPD esters, regardless of where the edible oil samples originated. Except for the high concentration of 3-MCPD esters identified in this study due to the type of red palm oil used for analysis, the concentration range of 3-MCPD esters for unrefined or red palm oil is essentially similar. This investigation suggests that the BPX-5 capillary column utilized has good separation performance, comparable to previously published analysis trends, indicating that this column could be useful in identifying 3-MCPD esters in a variety of edible oils.

Several factors such as thermal treatment, the presence of precursors, or soil conditions might trigger the formation of 3-MCPD esters beyond the maximum tolerable limit. Since 3-MCPD is a type of food-borne toxicant, it is vital to analyze and detect the content of 3-MCPD esters in edible oils as they have been widely used in our everyday life. Consumers have the right to choose the healthiest plant edible oils to be consumed. Consequently, continue researching on all possible pathways for the formation and mitigation of 3-MCPD esters should be done by researchers to ensure that the processed plant-based oils consumed by consumers are safe while maintaining the best nutritious quality of oils.

Conclusion

An indirect method involving acidic transesterification was used to detect and quantify 3-MCPD esters in various edible plant oils. PBA was chosen as the derivatizing agent since it reacts specifically with 3-MCPD to form a stable non-polar cyclic derivative (4-chloromethyl-2-phenyl-1,3,2-dioxaborolane) extractable with n-hexane. The use of the BPX-5 capillary column in GC-MS analysis was a direct replacement for other GC capillary columns that have been primarily used in previous literature. This provides researchers with a promising alternate choice/method for detecting 3-MCPD esters in various edible plant oil samples. The method validation verified that a linear calibration curve with extra virgin olive oil as a blank sample and spiked with eight different concentrations of 3-MCPD standards was established with $r^2 \geq 0.99$. Besides, the applied indirect method also showed the percentage recovery of three different concentration levels of 3-MCPD fell from 92.80% to 105.22%, together with RSD of 4.30% to 6.38% and 4.18% to 5.63% for both repeatability and within-laboratory reproducibility, respectively. The LOD and LOQ of the method were identified at 0.11 mg kg^{-1} and 0.14 mg kg^{-1}, respectively. As a result, this indirect method showed good accuracy and repeatability for the analysis of 3-MCPD esters in all studied edible plant oils.

From the results obtained for a total of 12 edible plant oils, 3-MCPD esters were found to be the lowest in corn oil (<LOQ to 0.29 mg kg^{-1}) and highest in refined palm oil (2.29 to 4.10 mg kg^{-1}). Refined palm oil contained a higher concentration of 3-MCPD esters than red palm oil (unrefined palm oil) due to high temperature during the deodorization step, contributing to the formation of 3-MCPD esters. Different brands for each type of edible plant oil samples also showed significant variation in 3-MCPD esters levels. Several factors, such as the refining process and the crude oil's quality, may contribute to forming 3-MCPD esters in various plant oils. Since 3-MCPD is a type of process contaminant that induces possibly carcinogenic to humans, it is significant to have potential mitigation of 3-MCPD in oils for the safety of consumers. Improvement can be made by upgrading the current technology of the refining process, for example, by implementing a more flexible deodorizing technology that could be carried out at low temperature (<250 °C) so that the occurrence of 3-MCPD in edible plant oils can be permanently reduced or eliminated in the future, without tarnishing the premium quality of the edible plant oils.

Abstract

Coscinium fenestratum (family: Menispermaceae), which is locally known as *akar sekunyit*, is one of the endangered species in Malaysia. *C. fenestratum* is wildly grown in the forest reserve, Paya Bungor, Pahang. This study aims to investigate the potential of *C. fenestratum* as an antibacterial, antifungal, and antioxidant agent as well as its total phenolic content. Four types of extracts were prepared from the consecutive soaking using hexane, dichloromethane (DCM), ethyl acetate (EA), and methanol. All types of extracts were assessed for their antibacterial and antifungal activities using the disc diffusion method against *Salmonella thypi* ATCC 10708, *Staphylococcus aureus* ATCC 43300, *Escherichia coli* UPMC 25922, *Candida albicans* ATCC 90028, and *Aspergillus brasiliensis* ATCC 16404. The potency of this species as an antioxidant agent was evaluated using semiquantitative staining dot blot assay against DPPH (2,2-diphenyl-1-picrylhydrazyl). The total phenolic content was assessed using the Folin-Ciocalteu method. The phytochemical screening for all types of extracts revealed the presence of alkaloid, terpenoid, phenolic, and saponin. All extracts with the concentration of 1,000 ppm demonstrated antibacterial and antifungal activities against *S. aureus* ATCC 43300 and *C. albicans* ATCC 90028 but none for the rest of the bacteria and fungi. The methanol extract was more active with a moderate inhibition zone. The semiquantitative staining dot blot assay against DPPH revealed that the lowest concentration of methanol extract for DPPH inhibition was at the concentration of 0.012 mg/ml, and the DCM extract showed that the DPPH inhibition was at 0.006 mg/ml. However, the methanol extract of *C. fenestratum* had a higher total phenolic content (TPC) with the value of 12.722 mg GAE/g sample compared to the DCM extract at 8.627 mg GAE/g sample. Hence, both methanol extract and DCM extract of *C. fenestratum* exhibited stimulating antimicrobial and antioxidant properties with potent phenolic content.

Keywords: *Coscinium fenestratum*, antibacterial, antifungal, akar sekunyit, antioxidant

Abstrak

Coscinium fenestratum (keluarga: Menispermaceae) yang dikenali sebagai akar sekunyit adalah salah satu spesies terancam di Malaysia iaitu Pahang dan ia tumbuh secara liar di hutan simpan Paya Bungor Pahang. Kajian ini bertujuan untuk menyiasat potensi *C. fenestratum* sebagai agen antibakteria, antikulat dan antioksidan serta jumlah kandungan fenolik. Empat jenis ekstrak

telah disediakan daripada rendaman berturut-turut menggunakan heksana, diklorometana (DCM), etil asetat dan metanol. Semua jenis ekstrak telah dinilai untuk aktiviti antibakteria dan antikulat menggunakan kaedah penyebaran cakera terhadap *Salmonella thypi* ATCC 10708, *Staphylococcus aureus* ATCC 43300, *Escherichia coli* UPMC 25922, *Candida albicans* ATCC 90028 dan *Aspergillus brasiliensis* ATCC 90028. Keupayaan spesies ini sebagai agen antioksida dinilai daripada ujian bintik-bintik pewarnaan semikuantitatif terhadap DPPH (2,2-difenil-1-pikrilhidrazil). Jumlah kandungan fenolik dinilai menggunakan kaedah Folin-Ciocalteu. Pemeriksaan fitokimia untuk semua jenis ekstrak mendedahkan kehadiran alkaloid, terpenoid, fenolik dan saponin. Semua ekstrak dengan kepekatan 1,000 ppm menunjukkan aktiviti antibakteria dan antikulat terhadap *S. aureus* ATCC 43300 dan *C. albicans* ATCC 90028, tetapi aktiviti itu tidak dapat dilihat untuk bakteria dan kulat yang lain. Ekstrak metanol didapati sebagai ekstrak yang lebih aktif dengan zon perencatan sederhana berbanding dengan ekstrak yang lain. Ujian bintik-bintik pewarnaan separa kuantitatif terhadap DPPH mendedahkan bahawa kepekatan terendah ekstrak metanol untuk perencatan DPPH adalah pada kepekatan 0.012 mg/ml dan ekstrak DCM menunjukkan perencatan DPPH pada 0.006 mg/ml. Walau bagaimanapun, ekstrak metanol *C. fenestratum* mempunyai jumlah kandungan fenolik yang lebih tinggi dengan nilai 12.722 mg sampel GAE/g berbanding ekstrak DCM pada 8.627 mg sampel GAE/g. Oleh itu, adalah disahkan bahawa kedua-dua ekstrak metanol dan ekstrak DCM *C. fenestratum* mempamerkan sifat antimikrob dan antioksida yang baik dan sederhana dengan kandungan fenolik yang memberangsangkan.

Kata kunci: *Coscinium fenestratum*, antibakteria, antikulat, akar sekunyit, antioksida

Introduction

Many medicinal plants have a high content of antioxidants such as vitamin C, vitamin E, polyphenols, and phytochemical substances of antimicrobial agents. Most antimicrobial plant compounds are identified as secondary metabolites that mainly originated from the family of terpenoid or phenolic. To date, herbal extracts are well-known for defeating various infectious diseases. Many plant species have been investigated for their effectiveness to combat microbes that cause disease but the investigation is still insufficient. Some medicinal plants are rich in natural antioxidants and have fewer side effects compared to synthetic antioxidants which can reduce the risk of certain diseases such as heart disease and cancer. It has been discovered that plant species with polyphenolic compounds enhance antioxidant activities [1]. The polyphenolic compounds react as a hydrogen donor or an electron donor to stabilise the toxic radical that causes harmful diseases.

Coscinium fenestratum belonged to the family Menispermaceae, is known as akar sekunyit in Malaysia, and has been vastly used as a traditional medicine to treat snake bites, lower blood sugar and blood cholesterol, and stabilise blood pressure [2]. It is reported that the stem of *C. fenestratum* is anti-inflammatory and antiseptic, has a bitter taste, and has a potential in pharmacological studies to exhibit antifungal, antibacterial, antifungal, and antiproliferative activities [3]. *C. fenestratum* is considered a critically endangered medicinal species as a result of its high demands in traditional practice. It is reported that the function of *C. fenestratum* ethanolic extract irradiated with a gamma ray acts as an antimicrobial agent and is outstanding against *Staphylococcus aureus* with the inhibition zone of 16.3-17.5 mm as well as the antioxidant activity [4]. However, the effect of gamma irradiation was insignificant to enhance the TPC of the crude extract. This study aims to evaluate the antimicrobial, antioxidant, and TPC of four crude extracts of *C. fenestratum* stem from Paya Bungor, Pahang, Malaysia.

Material and Methods

Plant material

The stems of *C. fenestratum* (Menispermaceae) were collected from Paya Bungor forest, Kuantan, Pahang. Fresh samples were cut into small pieces and air dried at room temperature. The small pieces of dry samples were grounded into powder using a grinder before proceeding to the extraction process.

Preparation of extracts from the stem of *C. fenestratum*

About 1kg of *C. fenestratum* stem was subjected to consecutive soaking with hexane, dichloromethane, ethyl acetate, and methanol to obtain four different types

of crude extracts. After three times of soaking in each solvent, the extracts were filtered and evaporated until they are dried using a rotary evaporator. The crude extracts were kept in the refrigerator before use.

Antibacterial and antifungal activity assay

The assay was conducted to evaluate the potency of *C. fenestratum*'s crude extracts against selected fungi and bacteria such as *Salmonella thypi* ATCC 10708, *Staphylococcus aureus* ATCC 43300, *Escherichia coli* UPMC 25922, *Candida albicans* ATCC 90028, and *Aspergillus brasiliensis* ATCC 16404. The sterile discs of all crude extracts with the concentration of 1,000 ppm were prepared for antibacterial and antifungal works and were used in the disc diffusion method. The antibacterial work of all crude extracts against *S. thypi*, *S. aureus*, and *E. coli* and the antifungal work against *C. albicans* and *A. brasiliensis* were slightly modified according to our previous study [5,6]. The positive standard discs were streptomycin and nystatin.

Thin layer chromatography analysis

The TLC method was conducted to screen phytochemicals such as alkaloid, phenolic compounds, and terpenoid. Spraying reagents such as the Dragendorff's solution, ferric chloride solution, and vanillin/H_2SO_4 were used to screen the presence of alkaloid, phenolic, and terpenoid, respectively [6].

Antioxidant activity

Semiquantitative DPPH staining dot blot assay

This method was modified from our previous work [7] and was conducted to measure the lowest concentration of *C. fenestratum*'s extracts to scavenge the free radical of DPPH by observing the formation of yellow spots against the purple background of the marked TLC plate. The extracts were two-fold serially diluted ranging from 100 mg/mL to 0.003 mg/mL. Then, 10µL of each prepared extract was dripped into the marked TLC plate and was allowed to dry for about 30 min under the fume hood. After completing the drying process, the TLC plate was carefully sprayed with 0.05% DPPH solution in methanol. The results were determined by observing the formation of yellow spots around the applied extracts. The yellow spot indicates the amount and nature of radical scavengers in the extracts. The experiment was also conducted for isolated compound alkaloid and ascorbic acid as the positive standard.

Total phenolic content (TPC)

About 5 mg of each extract or standard ascorbic acid was measured and diluted with 5 mL of suitable solvent to produce the final concentration of 1 mg/mL (1,000 ppm). Then, 0.5 mL of each extract was mixed with 2.5 mL Folin-Ciocalteu reagent (10 times dilution) and left for 2 min. Then, 2 mL of 7.5% w/v Na_2CO_3 solution was added to the mixture and incubated for 30 min. After reaching the incubation time, the absorbance of all samples was determined using UV-VIS Spectrometer (Secomam, France) at 765 nm [8]. The method was repeated for the standard solution of gallic acid (1000, 500, 250, 125, 62.5, 31.25 ppm). The blank was made with the same procedure without any extract or standard. The standard curve was plotted using the value absorbance of standard gallic acid solution.

Results and Discussion

Phytochemical analysis

The present study of the TLC phytochemicals screening test was conducted on four different types of extracts namely hexane, DCM, EA, and methanol extracts of the stem of *C. fenestratum.* The test revealed the presence of some medicinally active constituents in a TLC fingerprint of extracts. The common phytochemical constituents found were alkaloid, phenolic, terpenoid, and saponin in each extract of the stem of *C. fenestratum* as summarised in Table 1. DCM, EA, and methanol extracts were screened and contained the most phytochemicals. The hexane extract only showed the positive appearance of terpenoid compounds. The screening of these important phytochemicals is important as they are attributed to antimicrobial action and antioxidant activity. It was reported that the phenolic compounds of white cabbage have retarded lipid oxidation and microbial growth of foodborne pathogenic bacteria and fungi [9].

Figure 1 depicts some TLC fingerprints that screen the presence of alkaloid and phenolic in methanol extract and DCM extract. TLC A shows the obvious presence of alkaloid from the methanol extract compared to the alkaloid in the DCM extract in TLC D, which is

consistent with the previous finding [10, 11]. TLC B and TLC C of methanol extract show that alkaloid behaves as an antioxidant agent as the placement of alkaloid on TLC B is similar to the yellow spot of antioxidant on TLC C. TLC E and TLC F of DCM extract reveal the presence of antioxidative phenolic compounds. The observations of TLC D, TLC E, and TLC F of DCM extract show that alkaloid and phenolic compounds were also antioxidative.

Table 1. Phytochemicals in the stem of *C. fenestratum*

Types of extracts	**Phytochemicals**			
	Alkaloid	**Phenolic**	**Terpenoid**	**Saponin**
Hexane	x	x	√	x
DCM*	√	√	√	x
Ethyl acetate* (EA)	x	√	√	x
Methanol*	√	√	√	√

√ = present; x = not present; * = antioxidative; DCM: dichloromethane

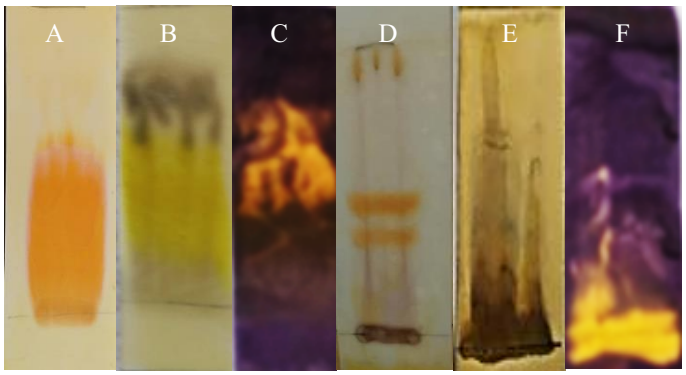

Figure 1. TLC fingerprint of alkaloid, phenolic, and antioxidant

A. The orange spot against the yellow background indicates the presence of alkaloid in the methanol extract after spraying with Dragendorff's reagent.
B. The black area indicates the presence of phenolic compounds in the methanol extract after spraying ferric chloride solution; The yellow area indicates the presence of alkaloid.
C. The yellow spot against the purple background indicates the presence of antioxidant in the methanol extract.
D. The orange spot against the yellow background indicates the presence of alkaloid in the DCM extract after spraying with Dragendorff's reagent.
E. The black spots indicate the presence of phenolic compounds in the DCM extract after spraying with ferric chloride solution
F. The yellow spot against the purple background indicates the presence of antioxidant in the DCM extract.

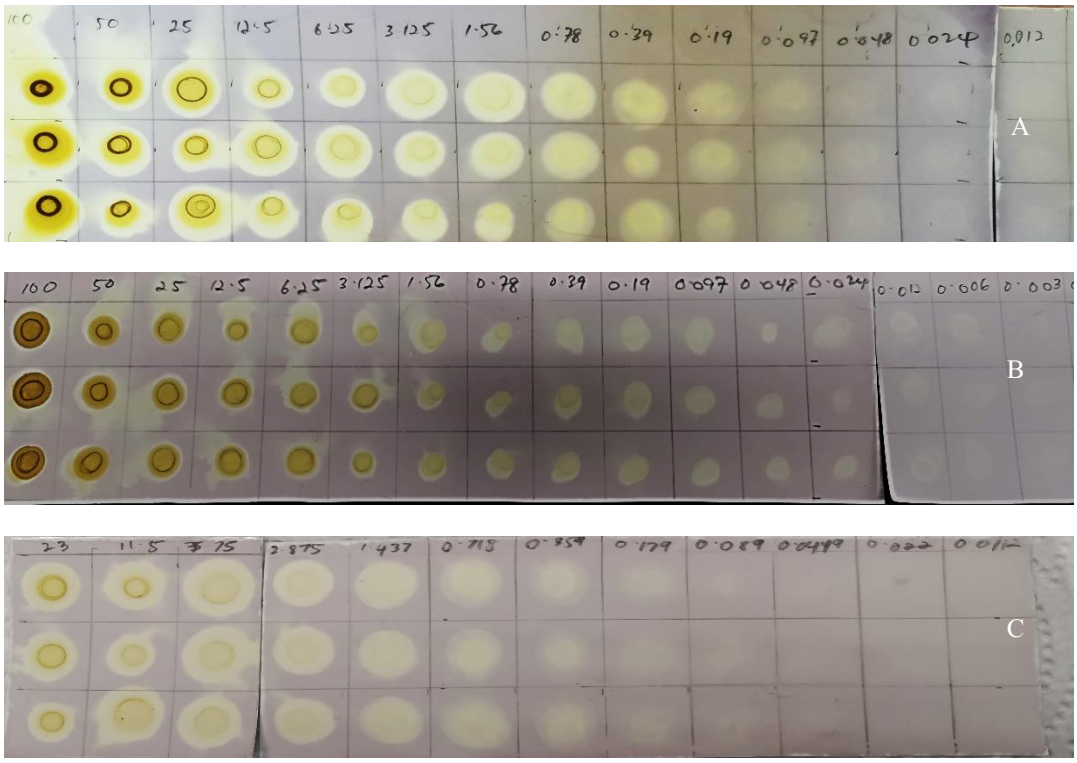
Antimicrobial activity of *C. fenestratum* stem

The results of antifungal and antibacterial activities in Table 2 indicate no inhibition zone towards *S. thypi*, *E. coli*, and *A. brasiliensis* for all crude extracts. All extracts were susceptible to *S. aureus* and *C. albicans* due to the use of a low concentration (1,000 ppm) of

extracts which causes no visible inhibition zone against *S. thypi*, *E. coli*, and *A. brasiliensis*. However, a previous study [12] revealed that the methanol extract attempted to inhibit the growth of *E. coli* moderately at the concentration of 150 mg/ml with the zone inhibition of 17 mm. This finding confirms that the extracts may have the capability to block the growth of all tested microbes at a higher concentration of more than 1,000 ppm. Among the extracts, the methanol extract was moderately inhibiting the growth of *C. albicans* and weakly inhibits *S. aureus* compared to other extracts. The richness of secondary metabolites mainly alkaloid in the methanol extract could be the main reason for the antimicrobial action. This scientific finding is also in line with other previous reports where alkaloid berberine from the stem of *C. fenestratum* was responsible for the antibacterial activity against several human pathogenic bacteria [10]. Alkaloid berberine also displayed remarkable antimicrobial activities against phytopathogenic fungi [12]. The current investigation [13] revealed that the methanol extract of *C. fenestratum* has promising antibacterial activity against the plant pathogen *Erwinia chrysanthemi* with an inhibition zone of about 19 mm. Thus, the result of *C. fenestratum* methanol extract which behaves as a potent antimicrobial agent is in the line with the previous research.

Table 2. Antibacterial and antifungal activities of *C. fenestratum*

Types of Extracts (1,000 ppm)/Standard	**Diameter of Inhibition Zone (mm)**				
	S. thypi	***S. aureus***	***E. coli***	***C. albicans***	***A. brasiliensis***
Hexane	-	+	-	+	-
DCM	-	+	-	+	-
EA	-	+	-	+	-
MeOH	-	+	-	++	-
Streptomycin	+++	+++	+++	-	-
Nystatin	-	-	-	+++	+++



+++: strongly inhibited; ++: moderately inhibited; +: weakly inhibited; -: no inhibition zone; DCM: dichloromethane; MeOH: methanol; EA: ethyl acetate

Antioxidant activity and total phenolic content

DPPH dot blot assay is a semiquantitative antioxidant activity method that has been used on *C. fenestratum* by referring to its ability to reduce the DPPH – a stable free radical. The antioxidant activities of different concentrations (two-fold serially diluted) of methanol extract, DCM extract, EA, alkaloid, and ascorbic acid were evaluated through the observation of the appearance of yellow colour against the purple background on the marked TLC as illustrated in Figure 2. The hexane extract was not further evaluated for its antioxidant activity since it had been previously screened and did not display any trace of yellow colour indicating the presence of antioxidants. Table 3 shows the dot blot assay where both DCM extract and methanol extract have comparable values of their lowest concentration to scavenge DPPH radical at 0.006 mg/mL and 0.012 mg/mL, respectively. EA extract started to scavenge DPPH radical at the concentration of 0.089 mg/mL as the yellow spot first appeared at this concentration. The concentration where the yellow colour was firstly observed on the marked TLC is considered the lowest concentration of extracts that scavenged the DPPH radical as illustrated in Figure 2. The isolated compound alkaloid scavenged the DPPH radical at a slightly higher concentration of 0.625 mg/mL. In this case, any compounds or extracts that can scavenge DPPH radical at a lower concentration are said to function as a good scavenger. This result explains that the methanol extract and DCM extract were more antioxidative as they scavenged DPPH radical at a lower

concentration compared to the EA extract and isolated compound alkaloid.

The antioxidant activities of DCM and methanol extract might be attributable to the presence of phenolic compounds in both extracts. The presence of phenolic compounds was authenticated from the determination of TPC values using the Folin-Ciocalteu method. Table 3 shows the methanol extract of *C. fenestratum* that contained a larger TPC value of 12.722 mg GAE/g sample compared to the DCM with a TPC value of 8.627 mg GAE/g sample. The result is parallel with a previous study [9] that determined the TPC value of methanol extract of *C. fenestratum* in Western Ghats, India at 18.35 mg GAE/g sample. It was reported that the phytochemical phenolic compounds were the main cause of methanol extract of *Coscinium blumeanum* for having a moderate antioxidant activity with an EC_{50} value of 50.1 µg/mL [14]. However, the scavenging of DPPH radical by the EA extract at 0.089 mg/ml was not responsible for the presence of phenolic content as it had a negative value of TPC. The activity might be due to the presence of terpenoid as depicted in Table 1. The synergistic action between alkaloid, terpenoid, and phenolic in the DCM extract could cause the DCM extract to scavenge DPPH radical at a lower concentration compared to the methanol extract although it contains a lower TPC value compared to the methanol extract.

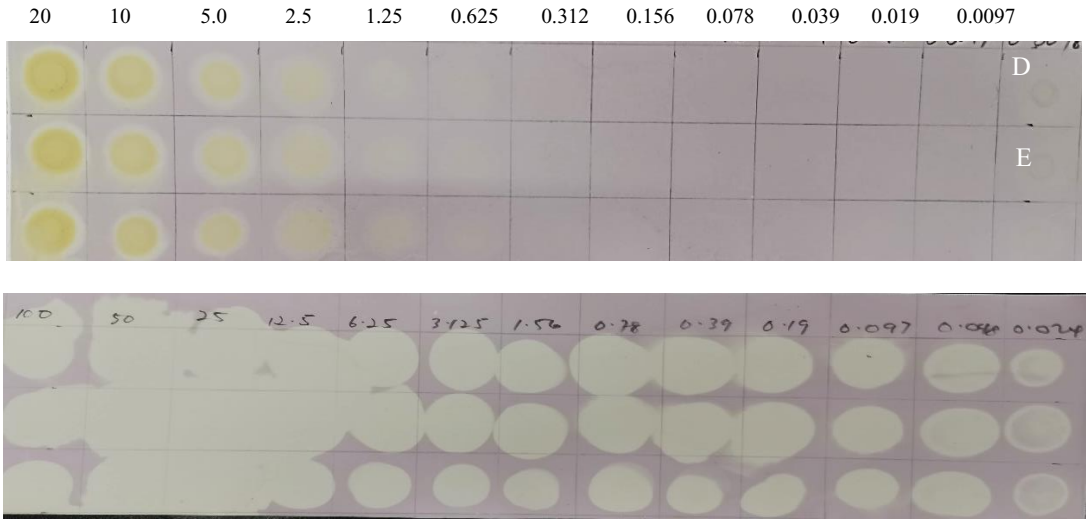


Figure 2. DPPH staining dot blot assay of *C. fenestratum* extracts, alkaloid, and standard ascorbic acid

A. DPPH staining of two-fold serial dilution of methanol extract
B. DPPH staining of two-fold serial dilution of DCM extract
C. DPPH staining of two-fold serial dilution of EA extract
D. DPPH staining of two-fold serial dilution of alkaloid from methanol extract
E. DPPH staining of two-fold serial dilution of standard ascorbic acid

Table 3. Semiquantitative antioxidant activity from DPPH staining dot blot assay and total phenolic content

Extract/Standard	**Lowest Concentration for DPPH Inhibition (mg/mL)**	**Total Phenolic Content, mg GAE/g sample**
Dichloromethane (DCM)	0.006	8.627
Ethyl acetate (EA)	0.089	negative
Methanol	0.012	12.722
Alkaloid (isolate from methanol extract)	0.625	negative
Standard ascorbic acid	< 0.006	693.416

Conclusion

We concluded that the methanol extract of *C. fenestratum* acts as a potent antibacterial and antifungal agent. The dichloromethane and methanol extracts scavenged the DPPH radical at the concentration of 0.006 mg/ml and 0.012 mg/ml, respectively. The highest TPC value among the extracts belonged to the methanol extract with a TPC value of 12.722 mg GAE/g sample. It is recommended that future work uses different concentrations of extracts tested on fungi that cause superficial skin disease and other bioactivity assays such cytotoxicity and anti-inflammatory and antiviral activities.

Abstract

Mango (*Mangifera indica* Linn) is a popular tropical fruits that is widely available in the market. In order to reduce food waste, mango kernels are usually treated as waste mango kernel flour due to their nutritional composition and bioactive compounds. However, the processing method used during the production of mango kernel flour has lowered its nutritional value and affected the quality of the mango kernel flour. In addition, the anti-nutritional found in the mango kernel influences the flour's quality. Hence, this review provides an overview of the effect of processing parameters on the quality of mango kernel flour (in terms of nutritional, functional properties, and bioactive compounds) and the application of mango kernel flour in baking products. The findings proposed that the soaking, blanching, and drying processes have an impact on the nutritional value, functional properties, and bioactive compounds of mango kernel flour. Further investigation into optimising processing parameters is required to obtain high-quality mango kernel flour.

Keywords: mango kernel flour, soaking, blanching, nutritional composition, anti-nutrient

Abstrak

Mangga (*Mangifera indica* Linn) merupakan salah satu buah tropika yang terkenal di pasaran. Bagi mengurangkan sisa biji manga, biji mangga biasanya diproses menjadi tepung biji mangga kerana komposisi nutrisi dan sebatian bioaktifnya. Bagaimanapun, kaedah pemprosesan semasa penghasilan tepung biji manga telah mengurangkan nilai nutrisi dan mempengaruhi kualiti tepung biji mangga. Selain itu, anti-nutrien yang terdapat di dalam biji mangga juga mempengaruhi kualiti tepung. Oleh itu, ulasan ini memberikan gambaran keseluruhan kesan parameter pemprosesan ke atas kualiti tepung biji mangga (dari segi komposisi nutrisi, sifat fungsi dan sebatian bioaktif) dan penggunaan tepung biji mangga dalam produk bakeri. Hasil kajian menunjukkan bahawa proses rendaman, penceluran dan pengeringan adalah faktor yang mempengaruhi nilai nutrisi, sifat berfungsi dan sebatian bioaktif

dalam tepung biji mangga. Siasatan lanjut keatas pengoptimuman parameter pemprosesan diperlukan bagi mendapatkan tepung biji mangga yang berkualiti tinggi.

Kata kunci: tepung biji mangga, rendaman, blanching, komposisi nutrisi, anti-nutrien

Introduction

Mangifera indica Linn, or commonly known as mango, belongs to the family of Anacardiaceae. Mango is well grown in the tropical and subtropical regions [1]. The production of mango throughout the year is about 42 million tonnes [2], and it is considered the second most traded fruit globally after bananas [3]. Countries that largely produce mangoes are India, Mexico, Thailand, China, and Indonesia [4]. Among these countries, India is the largest producer of mango [5], whereas Mexico is the largest exporter of mango, as it exports about 287,771 tonnes per annum [6]. Generally, mangoes are rich in dietary fibre, carbohydrates, fats, protein, phenolic compounds and provide high energy. Those nutrients found are crucial for the growth development and health of well-being [7]. Besides that, mango is also known as a super fruit due to its functionality as a food and an ingredient in new food product development [8]. Since mango is one of the most widely produced tropical fruits in the world, the waste generated from its processing is massive. It is estimated that about 35% to 60% [6] of mango by-products such as seeds and kernels have been discarded as waste [9], subsequently causing environmental pollution. In line with the concept of waste to wealth, mango kernels (Figure 1) usually undergo further processing into raw materials or food sources, such as mango kernel flour (Figure 2). According to Shabeer et al. [10], mango kernels can be used to replace wheat flour in the composite flour technology for baked products. Nevertheless, the production processes of mango kernel flour, such as soaking, blanching, and drying are known to affect the quality of mango kernel flour. The presence of anti-nutrient components also restricted the application of mango seed kernels in the food industry. This review aims to provide an overview of their past and current perspectives. This review will cover the effect of processing parameters on the quality of mango kernel flour in terms of nutritional composition, functional properties, bioactive compounds, and their application in the food industry.

Figure 1. Mango kernel seed [11]

Figure 2. Processed mango kernel flour [11]

Overview of mango

Mangoes are grown in over 90 countries. According to the Food and Agriculture Organization (FAO), the harvested mangoes were over 28 million tonnes in 2014, accounting for 35% of global tropical fruit production. Asia accounts for around 77% of the worldwide mango supply, followed by the America and Africa, accounting for 13% and 9%, respectively. The Asian countries include India, China, Thailand, Indonesia, Pakistan, the Philippines, and Bangladesh. However, cultivation has extended to Mexico, Brazil, Madagascar, Tanzania, the Dominican Republic, Haiti, Brazil, and Australia [12]. Meanwhile, in Malaysia, mangoes are mostly found in northern regions such as Perlis, Kedah, and Northern Perak as they can thrive well under humid and dry conditions [13]. The most popular export mango cultivars are Kent, Tommy Atkins, Haden, and Keitt, which have a red blush and are fibreless, harder, and more suited for long-distance shipping compared to other cultivars [12]. Whereas in Malaysia, the famous

mango clones planted are 'Harumanis', 'Maha 65', 'Masmuda', 'Sala', 'Chok Anan', and 'Siam Panjang' [13]. Generally, mango has an oval shape covered with leathery skin that changes colour from green to yellow when ripe [14] (Figure 3). The ripening stage of mango can be identified by its colour and texture, as it will turn from green to reddish orange [15] or yellow when ripe [16]. Unripened mangoes are extremely popular in Asia, but ripe mangoes are mostly consumed in the West [17].

The term "beak" is used to describe the shape of the mango as it has the characteristic of a conical projection. Large and fleshy mango fruits can vary depending on their shape, size, colour, fibre content, flavour, and aroma [18]. Depending on the cultivar, mango seeds appeared hairy or fibrous on the surface of the single flat oblong [19]. According to Beyene and Araya [15], the weight of mangoes can be up to one kilogramme depending on the cultivars, and it takes about three to six months to fully mature. The mango seed makes up roughly 10-25% of the overall weight of the fruit, while the kernel makes up about 45–85% of the seed's weight, which is about 20% of the total weight of the fruit [19]. In addition, the size of a mango and its kernel followed by their nutritional value can be determined by the mango's type, climate, ripening stage, cultivation, region, or harvesting time [20]. Moreover, Asia has the highest consumption levels, followed by Latin America, Africa, and Australia [17].

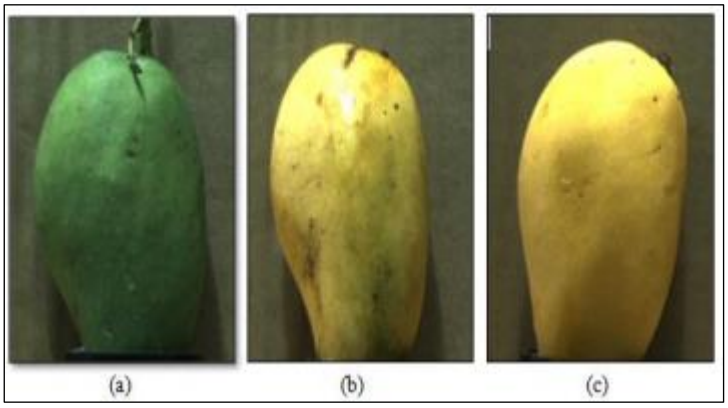

Figure 3. Different ripening stages of Chokanan mango: (a) Unripe fruit, (b) Yellowish-green peel, (c) Ripe fruit [14, 21]

Application of mango kernel flour in food industry

The demand for bakery products has increased the use of wheat flour [11, 22]. However, problems such as inadequate supply of wheat flour [23], higher cost, and geographical scarcity [11] have become the main factors in political and economic issues [23]. Therefore, a new alternative source of flour was introduced by converting mango kernels into mango kernel flour. Wheat flour can be substituted partially with mango kernel flour as composite flour due to its aesthetic chemical and functional properties. According to Das et al. [22], mango kernel flour can be a rich source of dietary minerals as the amount of ash in mango kernel flour (2.16%) is higher than in wheat flour (0.54%). Furthermore, the incorporation of mango kernel flour in the production of bakery products can lower the use of shortening agents as the fat content in mango kernel flour is 12 times higher than the fat content in wheat flour. Mango kernel flour has a lower swelling index compared to wheat flour, making the flour ideal and acceptable to be applied in extruded products such as noodles [22, 26]. Mango kernel flour and wheat flour had a crude fibre content of 1.16% and 0.42%, respectively. Because of its high fibre content, mango kernel flour can assist in improving digestion. On top of that, the amount of oil absorption capacity for mango

kernel flour (0.94 grams) is lower than wheat flour (1.26 grams) [22]. The capability of medium oil absorption by flour implies that it may be used to make bread items [26]. This is because oil functions as a flavour keeper and enhances mouthfeel; thus, flour's capacity to absorb oil is critical as it is also related to the occurrence of rancidity and storage stability [29].

Several studies have described the application of mango kernel flour in cake production as it consists of many nutritional compositions such as fat, energy, protein, calcium, potassium, and magnesium [11]. Aside from cakes, the addition of up to 25% mango kernel flour to wheat flour produced cookies with satisfactory sensory properties and improved the quality of cookies in terms of physical properties and colour [1]. Gumte et al. [24] concluded that 30% mango kernel flour is the optimum amount to be added in the biscuits production because the proximate composition of the whole biscuit is 2.56% moisture, 5.21% protein, 14.06% fat, 1.92% ash, and 74.68% carbohydrate. This indicates that adding mango kernel flour to biscuits can produce a product with nutraceutical properties and good sensory evaluation results. Moreover, adding 20% of defatted mango kernel flour to bread also increases the nutritional properties [25]. According to Lakshmi et al. [26], mango kernel flour has a good foaming capacity and is suitable to be used in the preparation of whipped topping, ice cream, frozen desserts, breads, and cakes. Overall, mango kernel flour seems to potentially minimise the use of wheat flour, which can be incorporated into different baking products such as cakes, cookies, biscuits, and bread.

Effect of processing parameters

Research gaps on the mango kernel flour

The processing parameters involved in the production of mango kernel flour include soaking, blanching, and drying steps. Table 1 shows various ranges of processing parameters result in different properties of mango kernel flour. The purpose of soaking is to soften the kernels and remove anti-nutrients [11]. Mango kernels are recommended not to soak for more than 24 hours as it will reduce the protein content due to protein solubilisation. Moreover, the ash level at 72 hours is the lowest, which might be attributed to mineral leaching from the kernel, particularly the more soluble ones [8]. This can be supported by Mwaurah et al. [3] as the soaking process needs to be minimised in order to get a high amount of protein and fat content. Meanwhile, Gumte et al. [27] concluded that the soaking time used is best at 18 to 20 hours, but different results were obtained when the kernel was soaked for only 30 minutes in another study conducted by Das et al. [22]. Therefore, a maximum of 24 hours of soaking time is recommended for processing mango kernel flour in order to ensure excellent nutritional status since, at this level, the reduction of anti-nutrients to an acceptable level and an insignificant decrease of minerals is assured [8].

Blanching aims to inactivate the polyphenol oxidase (PPO) enzyme in order to preserve the quality and increase the shelf life of the food during storage. However, blanching also induces chemical changes in fruit by reducing the phytochemical compounds and organoleptic properties. Based on Ojha et al. [28], blanching the mango kernel flour at 45°C for 2 minutes caused a reduction in water absorption capacity (131.67%) and oil absorption capacity (72.60%) as compared to untreated mango kernel flour, whereby the reported water absorption capacity and oil absorption capacity were 173.33% and 80.00%. In contrast to Florence et al. [29], blanched mango kernel flour has a higher water absorption capacity (230.75%) and oil absorption capacity (212.60%) as compared to unblanched mango kernel when the blanching parameter was set at 100°C for 10 minutes. This indicates that the blanching process has improved the functional properties of the mango kernel flour. Nevertheless, further research should be conducted to investigate the optimum parameters of the blanching process in producing high quality mango kernel flour.

Drying is one of the popular technological methods used to inactivate the enzymatic degradation and extraction of functional components [30]. For example, Uzombah et al. [8] demonstrated the effect of different drying temperatures on the quality of mango kernel flour at 65°C, 75°C, and 85°C for 24 hours. The results showed that the drying process affected the fat, protein, ash, and fibre content, in which the amount of nutrients decreased

with increased temperature. Ekorong et al. [30] reported that the effects of drying time and temperature play a role in the moisture content and total polyphenol of mango seed kernels. Figure 4 illustrates that the increment of drying temperature from 40℃ to 80℃ resulted in a reduction of moisture content of 13.1%, which is caused by the increase in permeability to vapour. For drying time, the moisture content of the mango seed kernels initially dropped from 23.20% w/w at 6 hours to a minimum of 9.30% w/w at 56 hours and then rose up to 10.30% w/w at 69 hours. This can be explained by the fact that when air contained the maximum amount of vapour possible, the vapour exerted a saturation vapour pressure because the quantity of water vapour present was less than the maximum, thus the air took up more moisture.

Meanwhile, the decrease in total polyphenol from 1.20 mg/g to 0.20 mg/g is due to the degradation of phenolic compounds at a higher temperature. Therefore, a drying step is needed to obtain the product in powder form and reduce the moisture content for better storage stability. Even though phenolic compounds are heat-sensitive, an increase in total polyphenols was detected as the drying duration increased. As shown in Figure 5, it began at 1.20 mg/g after 6 hours and increased to 1.38 mg/g after 69 hours. According to Ekorong et al. [30], this may be accounted for by the sum of the concentrations of the different phenolic acids in the free fraction, which increased significantly as the drying time increased. Subsequently, study on the optimum drying temperature and time is required to produce high-quality mango kernel flour.

Table 1. Different processing parameters of mango kernel flour

Author	Soaking Time (h)	Blanching Temperature (℃)	Blanching Time (min)	Drying Temperature (℃)	Drying Time (H)	Properties of Mango Kernel Flour
Florence et al. [29]	-	100	10	30	964	● Blanched mango kernel flour has higher water absorption capacity and oil absorption capacity as compared to unblanched mango kernel flour
Ojha et al. [28]	48	45	2	60	7	● Soaking and blanching reduced ash and fibre but increased protein, fat, and carbohydrate content ● Soaking and blanching caused a reduction in water absorption and oil absorption capacity ● Soaking and blanching reduced bioactive compounds (polyphenol, ascorbic acid, flavonoids, and tannin)
Das et al. [22]	0.5	-	-	65	16	● Functional properties: higher bulk density and water absorption capacity than wheat flour ● Nutritional value: higher ash, fibre, fat and energy content than wheat flour

Table 1 (cont'd). Different processing parameters of mango kernel flour

Author	Soaking Time (h)	Blanching Temperature (°C)	Blanching Time (min)	Drying Temperature (°C)	Drying Time (H)	Properties of Mango Kernel Flour
Uzombah et al. [8]	24, 48, 72	100	3	65,75, 85	24	• Soaking time affected the tannin, fibre, ash, and fat content • Dying temperature affect fat, protein, ash, and fibre • Drying and soaking increase the carbohydrate content
Gumte et al. [27]	18–20	-	1–2	60	5	• Reduced nutritional values: protein, ash, and fibre • Reduced tannin and flavonoids

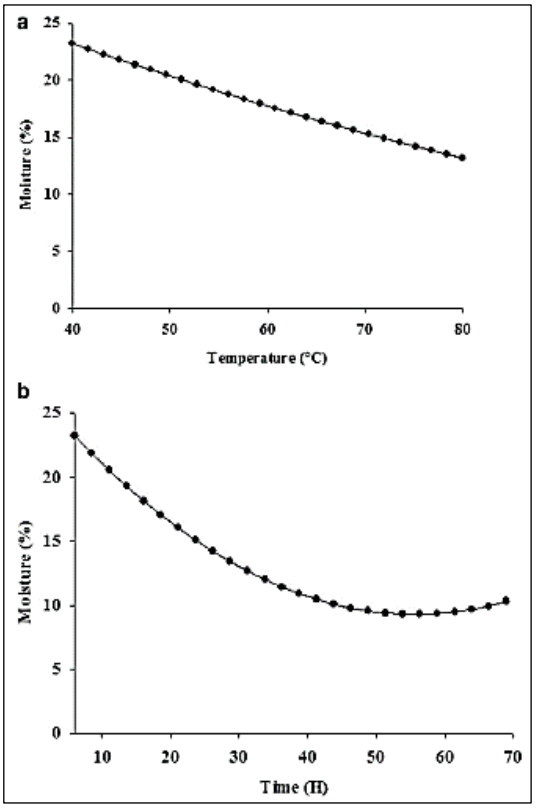

Figure 4. Effects of drying temperature and time on the moisture content of mango seed kernels [30]

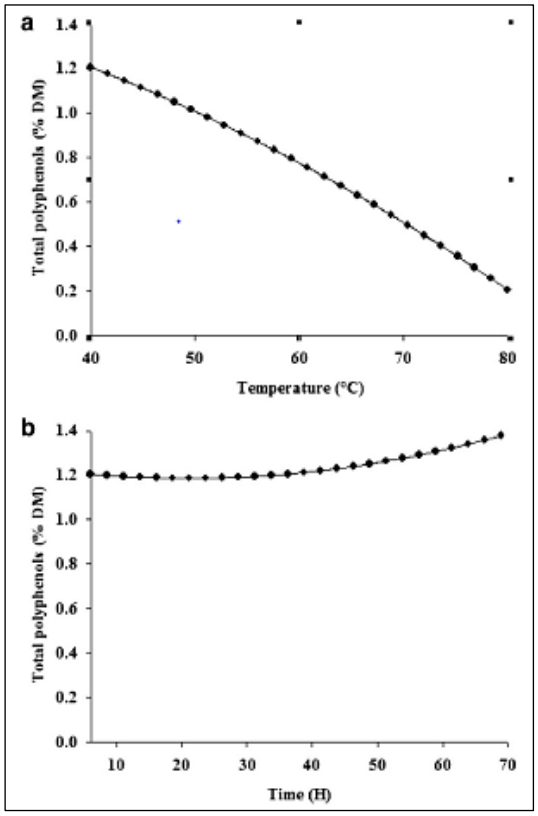

Figure 5. Effects of drying a) temperature and b) time on the total polyphenol content of mango seed kernels [30]

Nutritional composition

Mango kernel flour has shown that it is rich in carbohydrates, protein, and fat, which fit the nutrients that are needed in the human body. According to Mas'ud et al. [19], the nutritional compositions of mango kernel flour include moisture, carbohydrate, crude protein, total lipid, crude fibre, and ash content with their respective values of 9.20–9.60%, 36.20–39.30%, 5.20–6.60%, 6.00–7.20%, 2.20–2.50 %, and 2.90–5.50%, respectively. However, a few processing parameters have been identified to affect the quality of the produced mango kernel flour, including soaking, blanching, and drying time and temperature, as shown in Table 2. According to Uzombah et al. [8], soaking and drying parameters have affected the protein content. This is because of the protein denaturation and solubilisation at higher drying temperatures and longer soaking time. Besides that, Gumte et al. [27] also found the protein content of the raw mango kernel (10.02%) had slightly reduced after being processed into mango kernel flour (9.36%). Das et al. [22] deduced that an increase in drying temperature and time has prolonged the uptake of moisture, hence reducing the moisture content in mango kernel flour.

In addition to this, Sogi et al. [31] mentioned that drying temperature had affected the moisture content by increasing the vapour permeability, allowing the pore structure to remain open, hence decreasing the moisture content. Meanwhile, for fat content, Uzombah et al. [8] reported that an increase in drying temperature resulted in higher fat reduction, which is due to fat oxidation. In contrast to Ojha et al. [28], soaked mango kernel powder has higher fat content (10.17%) as compared to blanched (9.63%) and untreated mango kernel powder (9.53%). They proposed that the soaking process had resulted in the swelling of the kernel, thus increasing the fat content. Similarly, the ash and fibre content in mango kernel flour have also been reduced by the treatment of soaking and blanching due to the leaching loss of minerals [8], [28]. At the same time, soaking and drying have increased the carbohydrate content. This can be explained by the fact that soaking tends to reduce other components such as anti-nutrients that can form complexes with the nutrient. In contrast, increasing the drying temperature has accelerated the moisture removal process, increasing the carbohydrate content [8].

Table 2. Effects of processing parameters on the nutritional compositions of mango kernel flour

Nutritional Composition	Soaking	Blanching	Drying
Protein	• Longer soaking time solubilised the protein, hence reducing the protein content in mango kernel flour [8]	-	• Protein content in mango kernel flour is denatured at higher temperature [8]
Moisture	-	-	• The higher the drying temperature and time, the higher the uptake of moisture [22] • Drying temperature influenced the vapour permeability, thus affecting the moisture content [31]
Fat	• Soaking process caused the kernel to swell, thus increasing the fat content [28]	-	• Reduced the fat content in mango kernel flour through oxidation of fat at higher temperatures [8]

Table 2 (cont'd). Effects of processing parameters on the nutritional compositions of mango kernel flour

Nutritional Composition	Soaking	Blanching	Drying
Ash & Fibre	• Longer soaking time has reduced the amount of ash in mango kernel flour [8]	• Blanching process affected the ash and fibre content through leaching loss of minerals [28]	-
Carbohydrate	• Reduced other components that can form complexes with the nutrients, thus increasing the carbohydrate [8]	-	• Facilitated the concentration of carbohydrates by increasing the removal of moisture at higher temperatures [8]

Functional properties

Table 3 shows the effect of processing parameters on the functional properties of mango kernel flour, such as bulk density, oil absorption capacity, and swelling index. Das et al. [22] found that the bulk density in mango kernel flour is higher (0.63 g/mL) than wheat flour (0.58 g/mL). Based on Ojha et al. [28], the bulk density of mango kernel flour has increased after the treatment of soaking and blanching compared with untreated mango kernel flour. Sogi et al. [31] mentioned that higher amounts of bulk density might be due to excess tissue shrinkage during the drying process. This phenomenon indicates that processing parameters greatly influence the functional properties of mango kernel flour. The amount of oil absorption capacity is crucial in determining the product's sensory properties. This is because oil functions as a flavour keeper and enhances mouthfeel; thus, flour's capacity to absorb oil is critical [26]. Ojha et al. [28] showed that the oil absorption capacity of mango kernel flour has decreased after being soaked for 24 hours and blanched at 45℃ for 2 minutes, where the amount of oil absorption capacity for untreated mango kernel flour (80.00%) is higher than soaked mango kernel flour (60.00%) and blanched mango kernel flour (72.60%). The measurement of the swelling index is used to describe the gelatinisation of starches and flours [26].

Das et al. [22] demonstrated the soaking of mango kernels for 30 minutes and dried at 60–65℃ for 15–16 hours, and the obtained swelling index was 1.45 g/g. Surprisingly, the result is in contrast to Lakshmi et al. [26] as the swelling index for mango kernel flour obtained from three different types of mangoes (Neelam, Totapuri, and Alphonso) is 10.40 to 10.83 g/g in which the stone kernels were soaked for 48 hours and dried at 50℃ for 2 hours. In comparison with wheat flour, the swelling index is 3.54 g/g, while for durian seed flour, the swelling index is 8.03 g/g [32]. The lower amount of swelling index is due to the higher fat content in mango kernel flour, which resists starch gelatinisation [22]. Therefore, the processing parameters in mango kernel flour production should be optimised in order to enhance the functional properties of mango kernel flour and obtain high-quality mango kernel flour.

Table 3. Effects of processing parameters on the functional properties of mango kernel flour

Functional properties	Soaking	Blanching	Drying
Bulk density	• Increased the bulk density of soaked mango kernel flour compared to untreated mango kernel flour [28]	-	• Increased the amount of bulk density through the shrinkage of excess tissue [31]
Oil absorption capacity	• Decreased the amount of oil absorption capacity in soaked mango kernel flour (60.00%) compared to untreated mango kernel flour (80.00%) [28]	• Lowered the oil absorption capacity of blanched mango kernel flour (72.80%) compared to untreated mango kernel flour (80.00%) [28]	-
Swelling index	• The swelling index of mango kernel flour is 1.45 g/g when soaked for 30 minutes [22] • The swelling index of mango kernel flour is 10.40–10.83 g/g when soaked for 48 hours [26]	-	• The swelling index of mango kernel flour is 1.45 g/g when dried at 60–65°C for 15–16 hours [22] • The swelling index of mango kernel flour is 10.40–10.83 g/g when dried at 50°C for 2 hours [26]

Bioactive compounds

Generally, the processing parameters influence the amounts of bioactive compounds in mango kernel flour, such as ascorbic acid, tannin, polyphenol, and antioxidants (Table 4). According to Ojha et al. [28], the value of ascorbic acid present in blanched mango kernel powder is 112.00 mg/100 g, whereas in soaked mango kernel powder it is 119.33 mg/100 g. In contrast to Mas'ud et al. [19], the amount of ascorbic acid obtained in the mango kernel flour is 66.8 to 73.10 mg/100 g. The results are comparable with those of Sogi et al. [31] as the amount of ascorbic acid found in mango kernel powder is 61.22 to 74.48 mg/100 g. The researcher mentioned that the lower value of ascorbic acid is influenced by the thermal degradation and oxidation during the processing method. Tannin is one of the anti-nutritional substances found in raw mango kernel seed [33]. Besides reducing the availability of nutrients, tannin has astringent properties that contribute to the bitter principle and sour taste [27]. Thus, tannin needs to be removed before being applied in food or feed to reduce its toxic effect (about 75% of tannin in hydrolysable form). Soaking is an important step in this process because it promotes the leaching loss of anti-nutrients such as tannin from the mango seed kernel, but it should be done in less than 24 hours to avoid protein loss.

The total polyphenols found in mango seed kernel flour are 62.40 to 72.90 mg [19]. Nevertheless, Ojha et al. [28] stated that the polyphenols consisting of mango kernel flour had been significantly reduced through the process of soaking and blanching as the number of polyphenols recorded in untreated mango kernel powder (1630.00 mg/100 g) is higher than the soaked mango kernel powder (1573.33 mg/100 g) and blanched mango kernel powder (1553.33 mg/100 g). This reveals that the treatments of soaking for 24 hours and blanching at 45°C for 2 minutes have affected the amount of polyphenol. Besides that, drying time and temperature also influenced the polyphenol content since the degradation of phenolic compounds occurs at high temperatures [30]. The antioxidant present in mango seed kernels is the highest compared to other fruit seeds

such as jackfruit, avocado, and logan [34]. Unfortunately, the level of antioxidants found by Ojha et al. [28] in untreated mango kernel flour is 84.33%, which is higher than blanched mango kernel powder (68.33%) and soaked mango kernel powder (79.00%). This showed that the processing parameters of soaking for 24 hours and blanching at 45°C for 2 minutes have negatively affected the concentration of antioxidants exhibited by the mango kernel flour.

Table 4. Effects of processing parameters on bioactive compounds in the mango kernel flour

Bioactive compounds	Soaking	Blanching	Drying
Ascorbic acid	• Soaking process increased the amount of ascorbic acid in mango kernel flour [28]	• Blanched mango kernel flour has a lower amount of ascorbic acid compared to soaked mango kernel flour [28]	• The lower amount of ascorbic acid is affected by the thermal degradation and oxidation [31]
Tannin	• Soaking for less than 24 hours helps in the removal of antinutrients such as tannin.	-	-
Polyphenol	• Soaking for 24 hours affected the amount of polyphenol in soaked mango kernel flour compared to untreated mango kernel flour [28]	• Blanching at 45°C for 2 hours lowered the amount of polyphenols in blanched mango kernel flour compared to untreated mango kernel flour [28]	• Drying at a high temperature contributed to the degradation of phenolic compounds
Antioxidants	• Soaking for 24 hours has lowered the antioxidants in the soaked mango kernel (79.00%) compared to untreated mango kernel flour (83.44%) [28]	• Blanching at 45°C for 2 hours has reduced the antioxidants in blanched mango kernel (68.33%) compared to untreated mango kernel flour (83.44%) [28]	-

Challenges

Removal of tannin from mango seed kernel remains a big challenge in the production of mango kernel flour as it can negatively impact human health and reduce the bioavailability of nutrients. According to Bala et al. [35], soaking the mango seed kernel at 70–80°C removes the tannin significantly and effectively, but this treatment affects the protein content of the mango seed kernel. Besides that, processing activities have a different impact on the nutritional composition of the finished mango kernel product [3]. Thus, an optimum processing parameter for the production of mango kernel flour should be further investigated. On top of that, the palatability of mango kernel flour may be affected by the high tannin content. This is because tannin can impart a bitter taste and reduce the flour quality by discolouration [8]. Incorporating mango kernel flour up to or more than 50% is also undesirable in the food product. It can impart a bitter taste and cause the product to be slightly darker due to the high amount of total phenolic content. The properties of mango kernel flour in terms of nutritional, functional, and bioactive compounds have made it such a great deal, especially in the food industry. Hence, it is recommended to conduct a study on the specifications for safeguarding mango kernel flour against adulteration being commercialised

in the industry. Furthermore, it is suggested for the mango kernel flour to apply the mango kernel flour as a functional food ingredient [19]. In addition, turning mango kernels into a valuable product would also reduce the kernel waste and keep the environment clean.

Conclusion

In conclusion, the steps involved during the processing of mango kernel flour greatly influenced the quality of mango kernel flour in terms of its nutritional composition, functional properties, and bioactive compounds. This is because soaking and blanching lead to leaching loss of certain nutrients, bioactive compounds, and functional properties, but at the same time, they help reduce the anti-nutrients, which refer to tannin. Meanwhile, the drying process reduces the protein, fat, moisture, ash, and fibre but also helps to increase the carbohydrate content, resulting in a high energy value. The presence of bioactive compounds in mango kernel flour, such as polyphenol and ascorbic acid, exhibited therapeutic value, which is high in antioxidants and is beneficial to human health. The functional properties of mango kernel flour make it potentially useful as a functional ingredient in food products, especially in bakery products. Further research on the optimisation of each of the processing steps is required in order to obtain high-quality mango kernel flour.

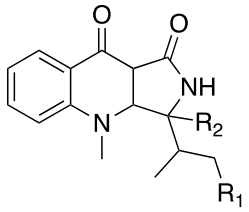
Abstract

Quinolactacins are rare fungal alkaloids extracted from the culture broth of Penicillium species isolated from larvae mulberry pyralis (*Margonia pyloalis Welker*). The synthesis of the natural alkaloids has gained interests among many researchers due to its unique γ-lactam conjugated ring quinolone skeleton. Furthermore, the alkaloids are also proven to exhibited inhibitory activities against tumour necrosis factor (TNF) production. Synthesizing the alkaloids is initiated by forming the key pyrrolidine-2,4-dione intermediates *via* the acid-mediated Meldrum reaction and tetramic acid cyclisation of different amino acids. Subsequently, the diketo intermediates are reduced and eliminated to form hydroxy and enone analogues. The enone analogues are then reacted with an amine-substituted diene by aza Diels-Alder reaction to form the anticipated 4-pyridone-lactam moiety with different substitutions. Nonetheless, the availability of amine-substituted dienes is limited even though aza Diels-Alder reactions shorten the formation of the tricyclic compounds. Consequently, the present study synthesised quinolactacin derivatives through alternative routes, including acylating the key pyrrolidine-2,4-dione with 2-nitrobenzoyl chloride to obtain an acylated tetramic acid and hydrogenated and furnish the final quinolactacin derivatives. The derivatives were also procured through a multicomponent reaction of diethyl oxaloacetate salt with aldehydes and amines. The synthesised compounds were analysed and confirmed with proton and carbon nuclear magnetic resonance (^{1}H- and ^{13}C-NMR) and infrared (IR) spectroscopy.

Keywords: *Penicillium* sp., Diels-Alder, 2,4-pyrrolidinone, quinolactacin

Abstrak

Quinolaktasin adalah kulat alkaloid nadir yang terhasil daripada kultur kaldu Penicillium spesies, di ekstrak daripada larva piralis mulberi (*Marfonia pyloalis Welker*). Sintesis bahan alkaloid yang natural ini telah menarik minat ramai ahli penyelidik oleh kerana keunikan struktur quinolone di mana ianya konjugat bersama gegelang γ-lactam. Alkaloid ini telah dibuktikan bahawa ianya bersikap aktif terhadap aktiviti rencatan melawan penghasilan faktor tumor nekrosis (TNF). Sintesis ini bermula dengan bahantara pirolidina-2,4-dion melalui tindak balas asid Meldrum dan pengitaran asid tetramik dari variasi asid amino. Bahantara diketo pula akan melalui pengurangan berturutan dan tindak balas penyingkiran kumpulan hidroksi dan variasi enon. Variasi enon ini bertindak balas dengan diena amina gantian melalui reaksi aza Diels-Alder bagi menghasilkan sebatian 4-piridona-laktam dengan variasi gantian. Walaupun reaksi kimia aza Diels-Alder dapat membantu menghasilkan sebatian trisiklik dalam langkah yang pendek, tetapi variasi diena amina gentian juga adalah terhad. Oleh itu, sintesis bagi penghasilan variasi quinolaktasin dijalankan melalui cara alternatif di mana pirolidina-2,4-dion menjalani pengasilan dengan 2-nitrobenzoil klorida untuk menghasilkan tetramik asid terasilasi dan penghidrogenan bagi menghasilkan sebatian akhir quinolaktasin. Reaksi pelbagai komponen oleh garam dietil oxaloasetat bersama aldehid dan amina pula adalah alternatif lain bagi penghasilan variasi sebatian quinolaktasin. Semua sebatian di dalam kajian ini dianalisa dan disahkan menggunakan resonans magnet nucleus (^{1}H- dan ^{13}C-NMR) dan spektroskopi infra merah (IR).



Kata kunci: *Penicillium* sp., diels-alder, 2,4-pirolidina, quinolaktasin

Introduction

The first quinolactacin was extracted from the fermented broth of Penicillium sp. EPF-6 extracted from mulberry pyralid larvae (*Margaronia pyloalis Welker*). Solvent extraction and chromatographic purification separated the quinolactacins from the culture medium. The substances were reported to behave as active inhibitors against tumour necrosis factor (TNF) produced by murine macrophages and macrophage-like J774.1 cells stimulated with LPS [1]. Consequently, numerous studies have attempted to synthesise the chemicals in the laboratory. Similarly, the current study described the synthesis of the quinolactacin derivatives.

To date, three different quinolactacins have been discovered by scientists, quinolactacins A, B, and C, differentiated by the alkyl groups at the C-5 position (see Figure 1). The quinolactacins were demonstrated to be weak antifungals against *Aspergillus niger* ATCC 9642 and inactive towards a range of bacteria, filamentous fungi, and yeasts [2]. Nonetheless, the substances are still gaining interest from researchers as they exhibit several biological activities.

The current study found other derivatives types, including quinolactacin H and quinolactacide. The current study also investigated pyrrolidine synthesis, as previous reports demonstrated that numerous pyrrolidine-type molecules were active antibacterial, antifungal, and anti-inflammatory agents [3]. Furthermore, pyrrolidine-2,4-dione or tetramic acid is the essential ring moiety required in the synthesis of quinolactacin.

Quinolactacin A : $R_1 = CH_3$, $R_2 = H$; Quinolactacin B : $R_1 = R_2 = H$; Quinolactacin C : $R_1 = CH_3$, $R_2 = OH$

Materials and Methods

The current study utilized Boc-Val-OH, *D*-valine, 2,2-dimethyl-1,3-dioxane-4,6-dione (Meldrum's acid), 4-dimethylaminopyridine (DMAP), *N,N'*-dicyclohexylcarbodiimide (DCC), 2-nitrobenzoylchloride, tetra-n-butylammonium fluoride (TBAF) in THF, sodium hydride (NaH), sodium borohydride ($NaBH_4$), acetic acid, sodium hydroxide (NaOH), di-*tert*-butyl dicarbonate (BOC_2O), aluminium chloride, *N*-benzylideneaniline, *trans*-1-methoxy-3-trimethylsilyloxy-buta-1,3-diene, 2,4-hexadiene, diphenyl ether, methanol, potassium bisulfate ($KHSO_4$), hexane, diethyl ether, ethyl acetate, tetrahydrofuran (THF), hydrochloric acid (HCl), potassium cyanonitrile

(KCN), *iso*butylraldehyde, formaldehyde, ammonia, aniline, 40% methylamine in water, formic acid diethyl oxaloacetate sodium salt, chloroform, dichloromethane, anhydrous magnesium sulphate, sodium chloride (NaCl), dioxane.

Synthesis of (*tert*-butoxycarbonyl)valine (1)

A solution of *D*-valine, (1.00 g, 8.51 mmol) in dioxane/water (2:1) (40 ml) and 1 M NaOH (8 ml) was stirred. Upon the formation of a homogenous mixture, the reaction mixture was cooled in an iced-water bath before adding the BOC_2O (3.73 g, 17.07 mmol). Then, the reaction mixture was left stirring overnight at room temperature. Progress of the reaction was monitored using TLC analysis. After the reaction completed, the undissolved materials were filtered and the filtrate was partially evaporated. The residue was cooled in an iced-water bath and diluted with ethyl acetate. The mixture was acidified to pH 2-3 with 1 M $KHSO_4$. The aqueous layer was extracted with ethyl acetate and the organic layer was washed with water and brine, dried with anhydrous magnesium sulphate and evaporated under reduced pressure to furnish the compound (*tert*-butoxycarbonyl)valine (**1)** 66 %. White solid, m.p 164-165ºC; 1H-NMR (400 MHz, CD_3OD) δ 3.97 (d, J = 5.5 Hz, 1H), 2.13-2.04 (m, 1H), 1.42 (s, 9H), 0.94 (d, J = 8.9 Hz, 6H); 13C-NMR (100 MHz, CH_3OD) δ 174.26, 157.20, 79.14, 59.02, 30.40, 27.37, 18.26, 16.85.

Synthesis of *tert*-butyl 2-isopropyl-3,5-dioxopyrrolidine-1-carboxylate (2)

To a solution of (*tert*-butoxycarbonyl)valine **(1)** (1.00 g, 4.60 mmol) Meldrum acid (0.66 g, 4.60 mmol), DMAP (0.79 g, 6.44 mmol) in dichloromethane (25 ml), DCC (1.14 g, 5.52 mmol) was added at room temperature. The resulting mixture was stirred for three hours at room temperature. Then the mixture was filtered and washed with ethyl acetate. The combined filtrates were diluted with cold ethyl acetate and were washed with 5% citric acid, water and brine, respectively. The organic layer was dried using anhydrous magnesium sulphate and evaporated under reduced pressure to give a yellow liquid which was dissolved in ethyl acetate and refluxed for one hour. The solvent was removed to furnish *tert*-butyl 2-isopropyl-3,5-dioxopyrrolidine-1-carboxylate, **(2)** 76 %. 1H-NMR (400 MHz, $CDCl_3$) δ 4.26 (d, J= 3.7 Hz, 1H), 3.10 (s, 2H), 2.38-2.28 (m, 1H), 1.52 (s, 9H), 1.09 (d, J= 7.3 Hz, 3H), 0.90 (d, J= 6.9 Hz, 3H); 13C-NMR (100 MHz, $CDCl_3$) δ 203.70, 168.08, 149.08, 84.34, 71.92, 44.2, 31.23, 28.33, 19.14,17.55.

Synthesis of *tert*-butyl-3-hydroxy-2-*iso*propyl-5-oxopyrrolidine-1-carboxylate (3)

In 10 ml chloroform, *tert*-butyl 2-isopropyl-3,5-dioxopyrrolidine-1-carboxylate **(2)** (0.35 g, 1.66 mmol) was dissolved. Then, acetic acid (0.10 ml, 1.66 mmol) and sodium borohydride (0.07 g, 1.82 mmol) were added into the reaction mixture. The resulting mixture was stirred at 0°C for one hour. After one hour, the mixture was continued to stir at room temperature for 8 hours. The progress of the reaction was monitored with TLC analysis. As the reaction completed, the solvent was removed under reduced pressure before being partitioned with ethyl acetate and sodium hydrogen carbonate for extraction. The organic layer was collected and dried over anhydrous magnesium sulphate and evaporated under reduced pressure to furnish the compound, *tert*-butyl-3-hydroxy-2-isopropyl-5-oxopyrrolidine-1-carboxylate, **(3)** 70 %. Yellow oil, 1H-NMR (400 MHz, CH_3OD) δ 4.65 (q, J = 8.5 Hz, 1H, CH), 4.08 (dd, J = 4.8 Hz, 1H), 2.19-2.37 (m, 1H), 1.49 (s, 9H), 1.05 (d, J = 7.3 Hz, 3H), 1.00 (d, J = 7.3 Hz, 3H); 13C-NMR (100 MHz, CH_3OD) δ 172.47, 150.30, 83.28, 66.82, 65.12, 40.66, 28.33, 28.01, 20.64, 18.82.

Synthesis of *tert*-butyl 2-*iso*propyl-5-oxo-2,5-dihydro-1H-pyrrole-1-carboxylate (4)

In a stirred solution of *tert*-butyl-3-hydroxy-2-*iso*propyl-5-oxopyrrolidine-1-carboxylate **(3)** (1.61 g, 6.64 mmol) in anhydrous THF (35 ml), DMAP (2.43 g, 19.91 mmol) and BOC_2O (4.34 g, 19.91 mmol) were added. The resulting mixture was continued to stir for 48 hours at room temperature. After the reaction completed, THF was removed under reduced pressure. Then, the residue was dissolved in 30 ml ethyl acetate. The mixture was then extracted twice with 1 N HCl, twice with $KHCO_3$ and brine. The organic layer was collected and dried over anhydrous magnesium sulphate and the solvent was removed under reduced pressure to furnish compound, *tert*-butyl 2-*iso*propyl-5-oxo-2,5-dihydro-1H-pyrrole-1-carboxylate, **(4)** 9 %. Yellow solid, m. p. 79-82ºC; 1H-NMR (400 MHz, $CDCl_3$) δ

7.20 (td, J = 2.1 Hz, 1H), 6.17 (td, J = 2.1 Hz, 1H), 4.36 (t, J = 1.8 Hz, 2H), 1.57 (s, 9H); 13-C NMR (100 MHz, $CDCl_3$) δ 169.64, 149.63, 147.91, 127.82, 82.90, 67.34, 28.93, 28.17, 19.56, 14.91.

Synthesis of *tert*-butyl 2-*iso*propyl-3-((2-nitrobenzoyl)oxy)-5-oxo-2,5-dihydro-1H-pyrrole-1-carboxylate (9)

To a stirred solution of *tert*-butyl 2-isopropyl-3,5-dioxopyrrolidine-1-carboxylate **(4)** (0.22 g, 0.93 mmol) and sodium hydride (0.08 g, 1.20 mmol) in anhydrous THF (10 ml), 2-nitrobenzoyl chloride (0.23 ml, 1.87 mmol) was added. The reaction mixture was stirred at room temperature for one hour. The solvent was removed, and the crude product was then purified by silica gel column chromatography with ethyl acetate/ petroleum ether, 1/1 to furnish compound *tert*-butyl 2-isopropyl-3-((2-nitrobenzoyl)oxy)-5-oxo-2,5-dihydro-1H-pyrrole-1-carboxylate, **(9)** 26 %. Brown oil, 1H-NMR (400 MHz, $CDCl_3$) δ 8.09-8.07 (m, 1H), 7.87-7.64 (m, 4H), 6.32 (d, J = 0.9 Hz, 1H), 4.53 (q, J = 1.2 Hz, 1H), 2.50-2.43 (m, 1H), 1.57-1.50 (m, 9H), 0.98 (d, J = 7.3 Hz, 3H), 0.87-0.83 (m, 3H); 13C-NMR (100 MHz, $CDCl_3$) δ 168.3, 165.6, 161.0, 149.3, 133.9, 133.1, 132.2, 130.0, 124.7, 109.2, 83.4, 77.4, 77.1, 76.8, 64.8, 29.6, 28.2, 18.6, 16.0.

Synthesis of *tert*-butyl 2-*iso*propyl-4-(2-nitrobenzoyl)-3,5-dioxopyrrolidine-1-carboxylate (10)

To a stirred solution of *tert*-butyl 2-*iso*propyl-3-((2-nitrobenzoyl)oxy)-5-oxo-2,5-dihydro-1H-pyrrole-1-carboxylate **(9)** (0.06 g, 0.17 mmol) and potassium cyanonitrile (0.01 g,0.19 mmol) in anhydrous acetonitrile (10 ml), trimethylamine (0.02 g, 0.19 mmol) was added. The reaction mixture was let to stir for 12 hours at room temperature. Then, the reaction mixture was acidified with 1 N HCl and extracted with diethyl ether. After washing the ether layer with aqueous sodium bicarbonate, the resulting aqueous phase was neutralized to pH 7, extracted with ether, dried, and concentrated to furnish the compound *tert*-butyl 2-*iso*propyl-4-(2-nitrobenzoyl)-3,5-dioxopyrrolidine-1-carboxylate, **(10)** 20%. Yellow oil, 1H-NMR (400 MHz, $CDCl_3$) δ 8.20-8.26 (1H), 7.47-7.83 (4H), 6.91-7.01 (1H), 4.50-4.54 (1H), 2.50-2.59 (1H), 1.48 (s, 9H), 1.13 (d, J = 6.9 Hz, 3H), 0.89 (d, J = 6.9 Hz, 3H); 13C-NMR (100 MHz, $CDCl_3$) δ 207.1, 193.8, 168.9, 149.3, 144.7, 135.4, 134.7, 134.0, 126.3, 123.8, 82.5, 75.2, 68.9, 28.4, 25.9, 19.0.

General synthesis of compounds 11a-c

A mixture of equimolar amount of diethyl oxaloacetate salt (10.00 g, 47.62 mmol), *iso*butyraldehyde (4.34 ml, 47.62 mmol) and 40% methylamine in water (4.12 ml, 47.62 mmol) in ethanol (100 ml) was refluxed for one hour. After cooling, the mixture was poured into ice water and acidified using concentrated hydrochloric acid. The precipitate formed was filtered and washed with water and diethyl ether to furnish compounds **11a-c**.

Ethyl 4-hydroxy-1-methyl-5-oxo-2,5-dihydro-1H-pyrrole-3-carboxylate, **11a**, 20 %. White solid, m.p 152-155ºC; 1H-NMR (400 MHz, $CDCl_3$) δ 8.95 (s, 1H), 4.30 (q, J = 7.2 Hz, 2H), 3.97 (s, 2H), 3.08 (s, 3H), 1.32 (t, J = 7.3 Hz, 3H); 13C-NMR (100 MHz, $CDCl_3$) δ 157.3, 107.6, 77.4, 77.1, 76.8, 61.2, 48.1, 30.1, 14.3.

Ethyl 4-hydroxy-2-isopropyl-1-methyl-5-oxo-2,5-dihydro-1H-pyrrole-3-carboxylate, **11b**, 54 %. Yellow solid, m.p 165-169ºC; 1H-NMR (400 MHz, $CDCl_3$) δ 4.36-4.26 (m, 2H), 4.08 (d, J = 1.8 Hz, 1H), 3.03 (s, 3H), 2.44-2.37 (m, 1H), 1.34-1.30 (m, 3H), 0.97 (d, J = 6.9 Hz, 3H), 0.83 (d, J = 6.9 Hz, 3H); 13C-NMR (100 MHz, $CDCl_3$) δ 165.8, 164.3, 158.6, 110.8, 82.4, 77.5, 77.1, 76.8, 64.1, 62.0, 61.3, 30.2, 30.1, 29.3, 19.6, 18.9, 16.5, 14.3, 13.9.

Ethyl 4-hydroxy-2-isopropyl-5-oxo-2,5-dihydro-1H-pyrrole-3-carboxylate, **11c**, 42 %. Yellow solid, m.p 161-164ºC; 1H-NMR (400 MHz, $CDCl_3$) δ 7.80 (s, 1H), 4.37-4.28 (m, 2H), 4.24 (q, J = 1.4 Hz, 1H), 2.43-2.34 (m, 1H), 1.34 (td, J = 7.3, 4.1 Hz, 3H), 1.10 (d, J = 7.3 Hz, 3H), 0.63 (d, J = 6.9 Hz, 3H); 13C-NMR (100 MHz, $CDCl_3$) δ 166.9, 166.0, 158.3, 113.2, 82.5, 77.4, 77.1, 76.8, 62.0, 61.3, 58.8, 30.2, 29.1, 20.5, 19.6, 14.3, 14.2, 14.1, 13.9

General synthesis of compounds 12a-c

To a solution of ethyl 4-hydroxy-1-methyl-5-oxo-2,5-dihydro-1H-pyrrole-3- carboxylate (2.00 g, 10.80 mmol) in ethanol (10 ml) was added formic acid (0.65 ml, 17.28 mmol) and aniline (1.28 ml, 12.96 mmol). The resulting mixture was heated to reflux for 12 hours. The mixture was cooled to room temperature and the product was separated as solid which was collected by filtration to furnish compounds **12a-c**.

Ethyl 1-methyl-5-oxo-4-(phenylamino)-2,5-dihydro-1H-pyrrole-3-carboxylate, **12a**, 72 %. Yellow solid, m.p 239-242^{o}C; 1H-NMR (400 MHz, $CDCl_3$) δ 8.02 (s, 1H), 7.28-7.07 (m, 5H), 4.15 (q, J = 7.0 Hz, 2H), 4.04 (s, 2H), 3.07 (s, 3H), 1.16 (t, J = 7.1 Hz, 3H); 13C-NMR (100 MHz, $CDCl_3$) δ 165.2, 164.8, 143.3, 138.8, 128.4, 124.4, 122.5, 103.7, 77.5, 77.2, 76.8, 60.2, 49.9, 30.0, 14.3.

Ethyl 2-isopropyl-1-methyl-5-oxo-4-(phenylamino)-2,5-dihydro-1H-pyrrole-3-carboxylate, **12b**, 51 %. Yellow solid, m.p 252-255^{o}C; 1H-NMR (400 MHz, $CDCl_3$) δ 8.06 (s, 1H), 7.28-7.24 (m, 2H), 7.10-7.06 (m, 3H), 4.16 (d, J = 1.8 Hz, 1H), 4.14-4.08 (m, 2H), 3.03 (s, 3H), 2.51-2.45 (m, 1H), 1.13 (t, J = 7.1 Hz, 3H), 1.06 (d, J = 7.3 Hz, 3H), 0.83 (d, J = 6.9 Hz, 3H); 13C-NMR (100 MHz, $CDCl_3$) δ 165.1, 143.5, 139.2, 128.5, 124.3, 122.4, 107.8, 77.4, 77.1, 76.8, 65.5, 60.2, 30.3, 29.8, 19.6, 16.0, 14.1.

Ethyl 2-isopropyl-5-oxo-4-(phenylamino)-2,5-dihydro-1H-pyrrole-3-carboxylate, **12c**, 45 %. Yellow solid, m.p 245-249^{o}C; 1H-NMR (400 MHz, $CDCl_3$) δ 8.11 (s, 0H), 7.28-7.06 (m, 1H), 4.28 (t, J = 1.5 Hz, 0H), 4.15 (qd, J = 7.2, 3.7 Hz, 0H), 2.49 (td, J = 7.0, 2.9 Hz, 0H), 1.57-1.80 (0H), 1.16 (t, J = 7.1 Hz, 1H), 1.07 (d, J = 7.3 Hz, 1H), 0.68 (d, J = 6.9 Hz, 1H); 13C-NMR (100 MHz, $CDCl_3$) δ 167.8, 165.2, 143.4, 139.1, 128.5, 124.2, 122.1, 110.5, 77.4, 77.1, 76.8, 60.3, 59.9, 29.4, 20.6, 14.2, 14.0.

General synthesis of compounds 13a-c

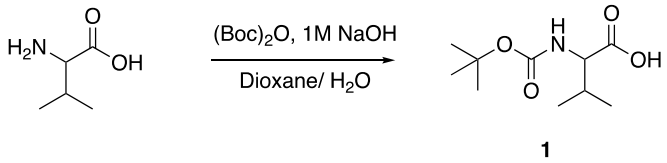
A solution of ethyl 1-methyl-5-oxo-4-(phenylamino)-2,5-dihydro-1H-pyrrole- 3-carboxylate (1.00 g, 3.84 mmol) in diphenyl ether (100 ml) was heated to reflux at 250°C under nitrogen for one hour. The resulting clear solution was cooled at room temperature and the product was separated as solid which was collected by filtration. The solid product was washed with petroleum ether to furnish compounds **13a-c**.

2-Methyl-1,4-dihydro-3H-pyrrolo[3,4-b]quinoline-3,9(2H)-dione, **13a**, 62 %. Yellow solid, m.p >320^{o}c; 1H-NMR (400 MHz, DMSO-D6) δ 8.14 (d, J = 8.2 Hz, 1H), 7.76 (d, J = 8.2 Hz, 1H), 7.67 (t, J = 7.5 Hz, 1H), 7.35 (t, J = 7.5 Hz, 1H), 4.31 (s, 2H), 3.08 (s, 3H); 13C-NMR (100 MHz, DMSO-D6) δ 132.7, 125.5, 124.1, 119.9, 49.1, 40.4, 40.2, 40.0, 39.8, 39.6, 39.4, 30.1.

1-*iso*propyl-2-methyl-1,4-dihydro-3H-pyrrolo[3,4-b]quinoline-3,9(2H)-dione, **13b**, 63 %. Yellow solid, m.p 278-283^{o}C; 1H-NMR (400 MHz, DMSO-D6) δ 8.12 (d, J = 8.2 Hz, 1H), 7.75-7.63 (m, 2H), 7.33 (t, J = 7.3 Hz, 1H), 4.52 (s, 1H), 3.03 (s, 3H), 2.62 (t, J = 6.9 Hz, 1H), 1.01-0.82 (m, 6H); 13C-NMR (100 MHz, DMSO-D6) δ 173.5, 141.6, 140.5, 132.7, 127.1, 125.8, 124.1, 122.3, 119.8, 65.7, 40.6, 40.4, 40.2, 40.0, 39.8, 39.6, 39.4, 29.8, 28.5, 18.7, 17.2.

1-*iso*propyl-1,4-dihydro-3H-pyrrolo[3,4-b]quinoline-3,9(2H)-dione, **13c**, 82 %. Yellow solid, m.p 286-296^{o}C; 1H-NMR (400 MHz, DMSO-D6) δ 9.22 (s, 1H), 8.12 (dd, J = 8.2, 0.9 Hz, 1H), 7.75 (d, J = 7.8 Hz, 1H), 7.68-7.64 (m, 1H), 7.35-7.31 (m, 1H), 4.50 (q, J = 1.4 Hz, 1H), 2.66-2.59 (m, 1H), 1.05 (d, J = 7.3 Hz, 3H), 0.46 (d, J = 6.9 Hz, 3H); 13C-NMR (100 MHz, DMSO-D6) δ 174.1, 166.4, 141.8, 140.7, 132.6, 126.9, 125.6, 124.2, 124.0, 119.9, 60.2, 28.4, 20.7, 14.8.

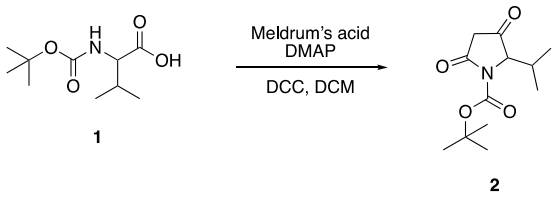
Results and Discussion



In the present study, the nitrogen atoms in amino acids were protected before synthesising the desired quinolactacins derivates. The step was performed as amino acids are good nucleophiles and bases, making the protection of the nitrogen atoms crucial. Moreover, protecting the atoms prevented any possible side reactions from occurring. The current study protected the nitrogen atoms with *tert*-butyloxycarbonyl (Boc), later deprotected by adding an acid or heating. Besides Boc anhydrides, several other protecting groups could also be employed, such as carbobenzyloxy (Cbz) and benzyl (Bn) groups.

The Boc anhydride was chosen as the protecting agent for the nitrogen atoms in the present investigation as it was commercially available. Moreover, Boc anhydride could be easily introduced under basic conditions and is easily removed under acidic conditions. Caplar and co-workers (2003) [4] protected the nitrogen atoms in the amino acid *D*-valine with Boc anhydride to synthesise amino alcohols. The *D*-valine was treated with 1 M NaOH as the base and dioxane/water as the solvent. Subsequently, Boc anhydride was added to produce the *N*-protected amino acid in a moderate yield of 66%. The protected *D*-valine was successfully synthesised following Caplar's procedure in the present study, as illustrated in Scheme 1.

Tetramic acid or 2,4-pyrrolinedione ring was synthesised post-*N*-protected amino acids production as the acid was the key ring moiety in the present study. According to the method reported by Ma, the tetramic acid was synthesised with Meldrum's acid, DMAP as the base, and DCC as the peptide coupling agent, in dichloromethane, the solvent (Scheme 2). The coupling agent, DCC, was added to activate the carbonyl group on the amino acid, making it more electrophilic for nucleophilic attacks that led to the amide bonds formation. Cyclisation occurred upon reflux in ethyl acetate, producing C-5 isopropyl substituted tetramic acid, compound 2.



Spectral studies proved that the tetramic acid, compound 2, could tautomerise to its enol form depending on the solvents used. The observation was supported by the data from the 1H-NMR spectroscopy of the tetramic acid that employed deuterated solvents of different polarities, namely $CDCl_3$ as the less-polar solvent and CH_3OD as the more-polar solvent. The acid existed in both forms, keto and enol tautomers, when analysed with the less-polar solvent, $CDCl_3$. A total of 18 protons from the *tert*-butyloxycarbonyl substituents that belonged to the tautomers of the Boc groups and enol olefin protons were identified. Conversely, the tetramic acid was more stable in its keto form in the more-polar solvent as only one CH_2 at the C-3 position of the tetramic acid was present.

Compound 2 was converted to an enone to obtain the appropriate dienophile for the subsequent Diels-Alder reaction to form the desired quinolactacin derivatives. First, the carbonyl functionality of the pyrrolidine-2,4-dione at the C-4 position was reduced to a hydroxyl group and eliminated (Scheme 3). Subsequently, the pyrrolidine-2,4-dione was treated with $NaBH_4$ as the reducing agent and acetic acid in dichloromethane as the solvent to reduce the carbonyl group at the C-4 position. The $NaBH_4$ was selected as the reducing agent due to its selectivity, thus reducing only carbonyl-keto in the presence of other active functional groups. Finally, the hydroxyl pyrrolidinone was treated with Boc anhydride and NaOH to remove the hydroxyl group. The Boc group was introduced again to make the hydroxyl group a good leaving group during the elimination reaction, deriving enone, compound **4**, at a 9% yield.

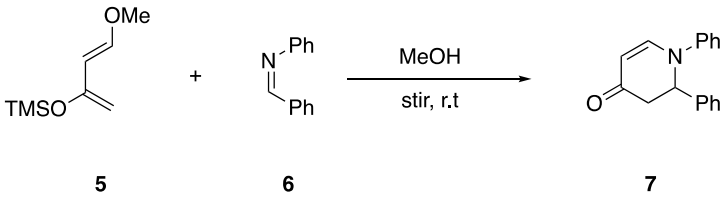
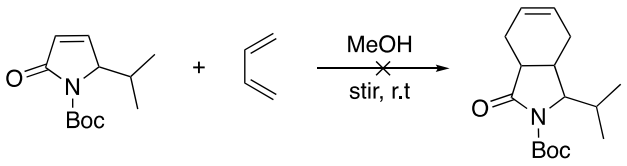
Scheme 1. The amine protection of *D*-valine

Scheme 2. The synthesis of tetramic acid, 2



Scheme 3. The reduction and elimination reaction of the functional group at the C-4 position of compound 2

The Diels-Alder reaction was performed to synthesise the derivatives of quinolactacin. Studies on Diels-Alder reactions by Yuan et al. [5] and Jurcik [6], demonstrated that an aza Diels-Alder reaction was successfully performed between *N*-benzylidiene and Danishefsky's diene, as described in Scheme 4. The present study repeated a similar reaction, but the desired compound 8 was not obtained (Scheme 5). The unsuccessful attempt might be due to the different nature of the functional groups in the starting materials utilised in the current study.



Enone, compound 4, was employed as the dienophile and was reacted with 2,4-hexadiene. Nonetheless, the reaction did not successfully yield the desired final product. The observation was due to the amide group in the enone, an electron-withdrawing group, and 2,4-hexadiene had a methyl group, an electron-donating group. Furthermore, Yuan and Jurcik demonstrated that Danishefsky's diene was rich in electrons with a trimethylsilyl group as the activating group. Consequently, future studies on the configuration, temperature, catalyst, and reaction conditions involving the diene should be done prior to reaction attempts.

Having failed to synthesise the derivatives of quinolactacin via the aza Diels-Alder reactions, an alternative route that involved acylation and hydrogenation reactions was attempted. The key substance, pyrrolidine-2,4-dione, was treated with 2-nitrobenzoyl chloride and sodium hydride as the base in anhydrous THF, as depicted in Scheme 6. The reaction was performed in an inert condition, a nitrogen (N_2) atmosphere, hence producing either the *O*-acylated or the *C*-acylated compounds. The observation could be explained based on the stability of the intermediate enolate formed during the reaction. The *O*-acylation reaction was favoured since the enol was likely to be more stable due to electron conjugation within the ring system.

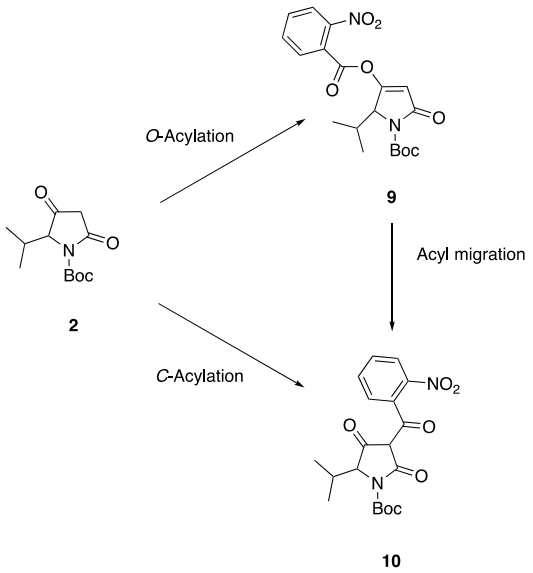
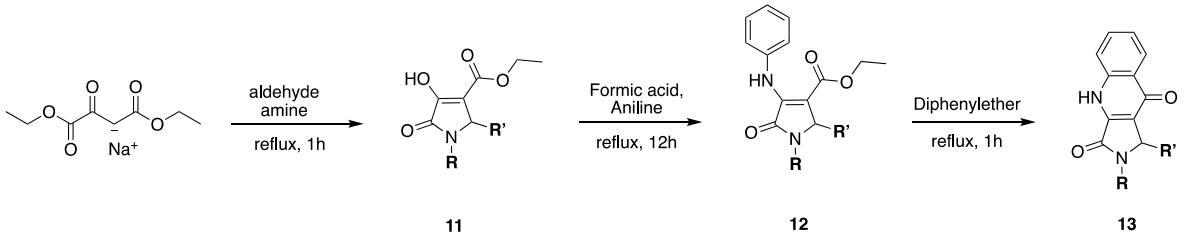
4 **8**



Scheme 5. The Diel-Alder of enone, 4

2 **9**

Scheme 6. The acylation of tetramic acid, 2



During the synthesis of quinolactacin derivatives, a hydrogenation reaction to convert the nitro functionality in the acylated compound to an amine is required to react the nucleophilic amine with the C-4 carbonyl ketone, yielding the quinolone-lactam ring moiety. Nevertheless, the acyl group must be at C-3 to produce the fused tricyclic system. Consequently, repositioning the acyl group from the *O*-enol position to the C-3 position was mandatory in the current study (Scheme 7).

Scheme 7. The *O*- and *C*-acylations of tetramic acid, 2

The *O*-acylated pyrrolidinone, compound 9, was treated with potassium cyanide for almost 12 hours to furnish the *C*-acylated pyrrolidinedione, compound 10, but in a low yield. Consequently, the present study conducted the hydrogenation reaction following the procedure described by Masaki (2006) [7]. Resultantly, the nitro functional group was reduced to an amine that spontaneously attacked the C-4 carbonyl ketone to form the quinolactacin ring moiety.

Studies on the synthesis of such derivatives via alternative ways have allowed the employment of a multicomponent reaction or a one-pot reaction, as illustrated in Scheme 8. The present study synthesised derivatives of quinolactacin through multicomponent reactions of diethyl oxaloacetate sodium salt, aldehydes, and amines in good yields. The C-5 substituted pyrrolidine-2,3-diones were reacted with formic acid and aniline and heated in diphenyl ether to yield derivatives of quinolactacin (Tables 1, 2, and 3). The synthetic route was focused on utilising pyrrolidine-2,3-dione as the key intermediate, which is different from those in Diels-Alder and synthetic acylation routes abovementioned.

Conclusion

The current study explored and attempted synthesising quinolactacin and its derivatives through several synthetic routes. The routes employed during the investigation involved numerous chemistry concepts, including intramolecular cyclisation, acylation, Diels-Alder, and hydrogenation reactions. Currently, the synthesis of quinolactacin via aza Diels-Alder reaction is being further studied. Consequently, the present study might be an essential reference for other researchers in procuring similar target compounds in the future.

Abstract

Muntingia calabura Linn. is one of the roadside trees that can easily be found in Malaysia. The *calabura* is the only species found in the genus Muntingia. The valuable bioactive compounds from this species had been documented, however, those originating from local are still considered scanty. This study was conducted to screen the phytochemicals presented, to identify the total phenolic content (TPC) and total flavonoid content (TFC), and to determine the antibacterial properties of both extracted ripe and unripe fruits. The extraction process was achieved by the successive maceration technique using three different solvents namely *n*-hexane, ethyl acetate, and methanol. The analysis of TPC and TFC was successfully done by Folin-Ciocalteu method and aluminium chloride colorimetric method respectively. A disc diffusion method had been employed to test the antibacterial effect. It was found that the percentage yield of methanol crude extract was the highest with 5.92% for unripe fruit and 8.66% for ripe fruit. Phytochemical screening of *M. calabura* L. extracts indicated the presence of flavonoids, phlobatannins, tannins, and glycosides for unripe fruit, and the ripe fruit extracts show the presence of alkaloids, flavonoids, tannins, and glycosides. The greatest TPC and TFC were observed in the methanol extract with 47.96 mg GAE/g (unripe), 94.43 mg GAE/g (ripe), and 99.74 mg QE/g (unripe), 35.38 mg QE/g (ripe) respectively. The *in vitro* antibacterial study of methanol and ethyl acetate extracts of the unripe fruit were active against all tested bacteria (*B. subtilis*, *S. aureus*, *E. coli*, and *K. pneumonia*). However, the ripe fruit extracts demonstrated no antibacterial activity. Thus, the findings remark the potential of these extracts especially the crude from methanol to obtain unique chemical compounds for drug discovery.

Abstrak

Muntingia calabura Linn. merupakan antara pokok tepi jalan yang mudah didapati di Malaysia. *Calabura* adalah satu-satunya spesies yang terdapat dalam genus Muntingia. Sebatian bioaktif yang berharga daripada spesies ini telah didokumenkan, bagaimanapun, yang berasal dari tempatan masih dianggap sedikit. Kajian ini dijalankan untuk menyaring fitokimia yang dibentangkan, untuk mengenal pasti jumlah kandungan fenolik (TPC) dan jumlah kandungan flavonoid (TFC), dan untuk menentukan sifat antibakteria kedua-dua buah masak dan tidak masak yang diekstrak. Proses pengekstrakan dilakukan dengan teknik pemekatan berturut-turut menggunakan tiga pelarut berbeza iaitu *n*-heksana, etil asetat, dan metanol. Analisis TPC dan TFC

telah berjaya dilakukan dengan kaedah Folin-Ciocalteu dan kaedah kolorimetrik aluminium klorida. Kaedah penyebaran cakera telah digunakan untuk menguji kesan antibakteria. Didapati peratusan hasil ekstrak mentah metanol adalah yang tertinggi iaitu 5.92% bagi buah yang belum masak dan 8.66% bagi buah masak. Pemeriksaan fitokimia bagi ekstrak *M. calabura* L. menunjukkan kehadiran flavonoid, phlobatannin, tanin, dan glikosida untuk buah yang belum masak, dan ekstrak buah masak menunjukkan kehadiran alkaloid, flavonoid, tanin, dan glikosida. Nilai TPC dan TFC terbesar telah diperolehi daripada ekstrak metanol dengan 47.96 mg GAE/g (belum masak), 94.43 mg GAE/g (matang), dan 99.74 mg QE/g (belum masak), 35.38 mg QE/g (matang). Kajian antibakteria *in vitro* bagi ekstrak metanol dan etil asetat buah yang belum masak adalah aktif terhadap semua bakteria yang diuji (*B. subtilis*, *S. aureus*, *E. coli*, dan *K. pneumonia*). Walau bagaimanapun, ekstrak buah masak tidak menunjukkan aktiviti antibakteria. Oleh itu, hasil kajian menunjukkan ekstrak methanol terutamanya, mempunyai potensi yang besar untuk mendapatkan sebatian kimia yang unik bagi hasilan ubat.

Introduction

Nature gives everything to the prosperity of humankind since the ancient times and this includes the keys for the principal endeavour at the therapeutic intervention. In old-fashioned times, humans depend on the natural resources such as plants for the treatment of numerous diseases. Even in the modernized days, plant materials remain a crucial resource to treat illnesses, including infectious diseases [1]. Plant-derived natural products have consistently been an essential source of medicines for the treatment of numerous illnesses and have received extensive attention in the recent years [2]. Therefore, the plant is one of the most important sources for isolating active chemical compounds that contribute to many uses in combating diseases [3]. However, some medicinal plants are still concealed inside the plant and must be carefully analysed.

Muntingia calabura Linn. (*M. calabura* L.) locally known as "buah ceri" or "kerukup siam" is belongs to the family of Muntingiaceae. *M. calabura* L. is native to Central America but has been widely cultivated in many tropical climate countries, such as Brazil, China, India, the Philippines, as well as Malaysia due to its strong tolerance to soil and climate [4, 5]. Extensive literature search shows that *calabura* is the only species found in the genus Muntingia. *Calabura's* fruits (Figure 1) are very sweet and juicy if they are fully ripen. The sweetness of these ripe cherries is due to their high soluble solid content and low total titratable acidity [5]. Traditionally, the fruits of *calabura* are eaten fresh and sometimes cooked in tarts or made into jam [6]. However, this plant was reported to have many health benefits in curing illnesses [7] but the exploration of the fruit's part is very little.

From many reported studies, several compounds were successfully elucidated from each part of this plant including the leaf, root, bark, and fruit [7]. In addition, a few of the reported compounds were found active as antibacterial [9, 10, 11], antitumor [12], anti-inflammatory [13], antipyretic [14], antinociception [15], antiproliferative [16], and also antioxidant [4, 17]. It indicates that *calabura* is one of the potential plants to screen valuable active compounds for drug discovery. However, the study on this species from Malaysia is still limited due to the less reported data from local publications that can be obtained. Thus, this study will present the qualitative phytochemical screening on alkaloids, flavonoids, glycosides, phlobatannins, and tannins, reported the quantitative phytochemical analysis of total phenolic content (TPC), and total flavonoid content (TFC), as well as documented the antibacterial properties from both ripe and unripe of *M. calabura* L. fruit extracts.

Figure 1: The fruits of *M. calabura* L. [8]

Materials and Methods

Fruit samples

The ripe fruits of *M. calabura* L. were collected from Seremban, Negeri Sembilan, and the unripe fruits were collected from Kampung Jembatan Duyong, Melaka, Malaysia in October 2021.

Preparation of fruit extracts

Fresh fruits (ripe and unripe) of *M. calabura* L. were washed with tap water and were directly dried under the sun for one week. The dried fruits were ground into powder form by using a grinder. The extraction process proceeded successively by mixing 100 g of powdered fruits with *n*-hexane, followed by ethyl acetate and methanol (500 mL of each) for 72 hours at room temperature. The extract was filtered by using Whatman no. 1 filter paper and the filtrate was concentrated by using a rotary evaporator. Crude extracts were stored at 4 ℃ prior to phytochemical and *in vitro* antibacterial analyses [18].

Qualitative phytochemical screening

Phytochemical tests were carried out on each extract using the standard procedure [19, 20] to identify the presence of alkaloids [21], flavonoids, glycosides, phlobatannins [22], and tannins [23].

Determination of total phenolic content

Total phenolic content (TPC) in the fruit extracts was determined by using the Folin-Ciocalteu method as described by [24] with minor modifications. An amount of 10 mg of the extract was dissolved in 10 mL of methanol to yield a concentration of 1 mg/mL. To each extract, 0.5 mL of sample was added to 2.5 mL of 10% Folin-Ciocalteu's reagent. After 5 minutes, 2.5 mL of 7.5% Na_2CO_3 was added. The mixture was placed in the dark for 2 hours and the absorbance was measured at 725 nm by using UV-Vis Spectrophotometer. A similar procedure as described was repeated for the standard solution of gallic acid with different concentrations (6.25, 12.5, 25, 50, and 100 µg/mL), and the calibration curve was constructed. The concentration of phenolics (µg/mL) was obtained based on the calibration curve and the content of phenolic in the extract was expressed in terms of gallic acid equivalent (mg of gallic acid/g of extract), and methanol was used as blank.

Determination of total flavonoid content

Total flavonoid content (TFC) in the fruit extracts was determined by using the modified aluminium chloride colorimetric method [25]. An amount of 10 mg of the extract was dissolved in 10 mL of 80% ethanol (1 mg/mL). To each extract, 0.5 mL of sample was mixed with 1.5 mL of 95% ethanol, 0.1 mL of 10% aluminium chloride, 0.1 mL of 1 M potassium acetate, and 2.8 mL of distilled water. The mixture was incubated at room temperature for 30 minutes and the absorbance was measured at 425 nm by using UV-Vis Spectrophotometer. A similar step as described was repeated for the standard solution of quercetin with various concentrations (6.25, 12.5, 25, 50, and 100 µg/mL), and the calibration curve was constructed. The concentration of flavonoids (µg/mL) was obtained based on the calibration curve and the content of flavonoids in the extract was expressed in terms of quercetin equivalent (mg of quercetin/g of extract), and ethanol was used as blank.

Determination of antibacterial properties

Antibacterial assay of *M. calabura* L. fruit extracts was carried out based on the Clinical and Laboratory Standards Institute (CLSI) [26], and the disc diffusion method was used. The overnight bacterial culture (*Escherichia coli*, *Klebsiella pneumonia*, *Staphylococcus aureus*, and *Bacillus subtilis*) from nutrient broth (NB) was adjusted to the turbidity of 0.5 McFarland standard (1.5 X 10^8 CFU/mL). Afterward, 0.1 mL of bacterial culture was pipetted out onto the Muller-Hinton agar (MHA) and spread in a direction and evenly distributed. The dried-loaded extracts (20 µL with a concentration of 10 mg/mL) of disc paper (5.5 mm diameter) were transferred onto the seeded MHA medium and incubated at 37°C for 24 hours. Streptomycin (10 µg) and 10% DMSO were used as positive and negative control. The diameter of zone inhibition was measured and recorded.

Results and Discussion

Qualitative phytochemical screening

M. calabura L. extracts (*n*-hexane, ethyl acetate, and methanol) for both ripe and unripe fruits were first tested for a qualitative phytochemical screening to check the presence and absence of alkaloids, flavonoids, glycosides, tannins, and phlobatannins in which these constituents might be responsible for the antibacterial properties. The data displayed in Table 1 shows that *calabura's* fruit contained various phytochemicals. Flavonoids were detected in all extracts from both ripe and unripe fruits. Meanwhile, alkaloids and phlobatannins were found absent in all extracts from unripe and ripe fruits respectively. However, [21] reported the presence of alkaloids in both ripe and unripe *M. calabura* L. fruit extracts, but the study conducted and the sample collected was from India. For a local sample studied by [4], alkaloids were also reported absent but the sample was from *M. calabura* L. leaf extracts. Thus, abiotic factors such as soil, temperature, air, humidity, light, pH, salinity, minerals, and water may influence the accumulations of secondary metabolites [27, 28, 29].

Table 1. Detected phytochemical constituents in *M.calabura* L. fruit extracts

Constituents	Fruit Extracts					
	Ripe			Unripe		
	***n*-hexane**	**Ethyl Acetate**	**Methanol**	***n*-hexane**	**Ethyl Acetate**	**Methanol**
Alkaloids	-	+	+	-	-	-
Flavonoids	+	+	+	+	+	+
Glycosides	-	-	+	-	-	+
Tannins	-	+	+	-	+	+
Phlobatannins	-	-	-	-	+	+

'-' indicates absence; '+' indicates presence

Quantitative phytochemical analysis

The results of total phenolic content (TPC) and total flavonoid content (TFC) were summarized in Table 2. Among all extracts, methanol extract from both ripe and unripe fruits exhibited the highest TPC with 94.43 and 47.96 mg GAE/g respectively. In general, the more polar solvent influences the amount of TPC which gives a higher value. The 5-hydroxy-3,7,8-trimethoxyflavone compound is reported to contribute as a major phenolic compound [30] and [31, 32] revealed that this compound was elucidated from the fruits of *M. calabura* L. that have polar sites interaction (hydrogen bonds) with the solvent, which increased the solvation of compounds in the solvent.

Similarly, TFC was found highest in methanol extract with 35.38 and 99.74 mg QE/g in ripe and unripe fruits respectively. The TFC content is correlated with the preliminary phytochemical screening to prove that flavonoids are an important constituent in the *calabura* fruits and it is essential for future antioxidant study.

Table 2. The total phenolic and total flavonoid contents of different fruit extracts from *M. calabura* L.

Assay		Solvents Extraction		
		***n*-hexane**	**Ethyl Acetate**	**Methanol**
TPC (mg GAE/g extract)	Ripe	24.11	45.06	94.43
	Unripe	15.43	27.96	47.96
TFC (mg QE/g extract)	Ripe	4.08	22.97	35.38
	Unripe	42.70	61.59	99.74

This study proves that *M. calabura* L. fruit contains phytochemicals as an antibacterial agent. As shown in Table 3, methanolic fruit extract from the unripe sample gave the highest antibacterial effect against all tested bacteria compared to ethyl acetate extract and this is similar to the study reported by [21]. Moreover, the fruit extracts were more active against Gram-positive bacteria with zone inhibition of 14 mm and 12 mm for *S. aureus* and *B. subtilis* respectively. The Gram-negative cell wall is a multilayered structure and quite complex. It consists of an additional lipopolysaccharide layer called the outer membrane to make it more difficult for antibiotics to invade the cell wall [33]. However, none of the ripe sample extracts and extract from *n*-hexane exhibited antibacterial properties. Thus, the active compounds of this extract might have consisted of semi-polar to polar functional groups. Figure 2 displays the disc diffusion assay of *M. calabura* L. fruit extracts against tested bacteria.

Mahmood et al. [7] in their reviewed article had mentioned that various parts of the *M. calabura* L. plant were traditionally used to cure many illnesses. Several reported the antibacterial properties from the local sample used leave part [34, 35, 36]. The fruit part was only mentioned to be used as eaten fresh and cooked to make into jam. Therefore, the antibacterial result from this study can be used as a reference to support that *calabura* fruit also has potential active compounds to combat diseases.

Table 3. The inhibition zone value (mm) of *M. calabura* L. fruit extracts against tested bacteria

Extracts		Zone Inhibition Value (mm)			
		Tested Bacteria			
		Gram-negative		Gram-positive	
		E. coli	***K. pneumonia***	***S. aureus***	***B. subtilis***
n-hexane	Ripe	-	-	-	-

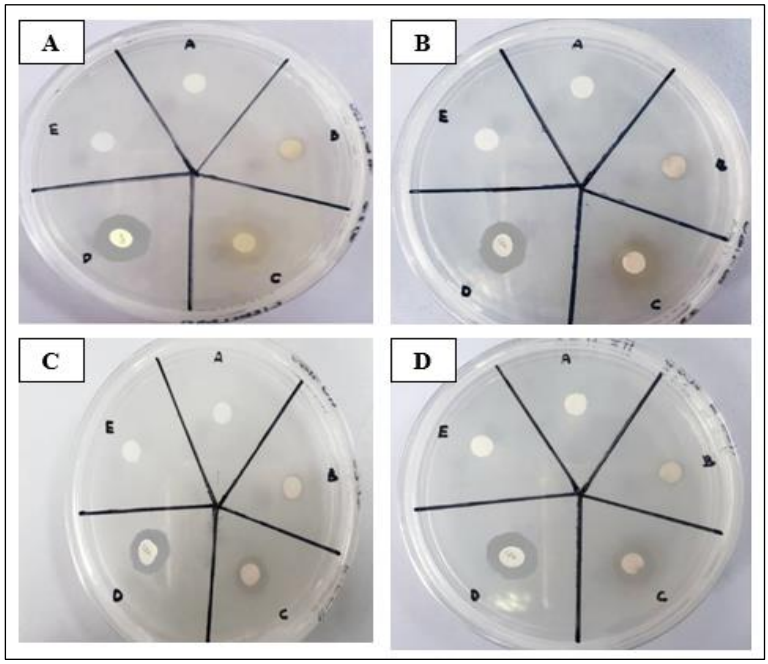

Figure 2. The zone inhibition observation of *M. calabura* L. extracts against *S. aureus* (A), *B. subtilis* (B), *K. pneumonia* (C), and *E. coli* (D) by disc diffusion method

Conclusion

M. calabura L. fruit extracts contain different phytochemical constituents including alkaloids, flavonoids, phlobatannins, tannins, and glycosides. The methanolic fruit extracts showed the highest TPC and TFC values from both ripe and unripe samples, and also exhibited the greatest antibacterial properties against all tested bacteria from the unripe sample. An antioxidant study is required to be performed since antibacterial and antioxidant studies serve as a basis for drug discovery.

Abstract

The utilization of xylazine, a veterinary drug, had recently been reported in drug facilitated crimes (DFC). Victims are incapacitated after consumption of drug-spiked beverages and subsequently exposed to the risk of robbery and sexual assault. In many instances, the suspected drug-spiked beverage samples are available at the scene but the concentration level of xylazine could be very low or restricted by its recoverable amount for forensic testing. To address challenges linked to samples with low or limited recoverable amounts, this study was aimed to establish a laboratory-based gas chromatography method by detecting and quantifying xylazine in drug-spiked beverage samples appearing in liquid, droplet, and dry forms. In this study, a gas chromatography-mass spectroscopy (GC-MS) method was optimized to detect the presence of xylazine, and a gas chromatography-flame ionization detector (GC-FID) method was validated for quantification of the substance. Subsequently, xylazine from four different beverage samples in three different physical forms, simulating the possible forensic settings; were recovered and determined. A validated GC method for the determination and quantification of xylazine within 15 minutes was reported. Limit of detection (LOD) and limit of quantitation (LOQ) were reported at 0.08 µg/mL and 0.26 µg/mL, respectively. Higher recoveries of xylazine were achieved from beverage samples in liquid form (77.2-97.3%) compared to droplet (50.8% – 80.0%) and dry samples (39.8% – 66.9%). This study evidenced that limited volume of leftover beverage samples, and even the dried samples; did not hinder the recovery of the targeted drug. To conclude, a gas chromatographic technique was successfully established for the determination of residual xylazine in drug-spiked beverages that can then provide valuable investigative technique to laboratory analysts and crime scene officers in DFC

investigations.

Keywords: forensic science, drug-facilitated crime, xylazine, gas chromatography, drug spiked beverage

Abstrak

Baru-baru ini, penggunaan xilazin, sejenis ubat haiwan, telah dilaporkan dalam jenayah disebabkan dadah (DFC). Mangsa menjadi lemah selepas meminum minuman yang ditambah dengan dadah dan seterusnya terdedah kepada risiko rompakan dan gangguan seksual. Dalam kebanyakan situasi, sampel minuman yang disyaki telah dimasukkan dadah boleh dijumpai di tempat kejadian tetapi tahap kepekatan xilazin berkemungkinan amat rendah atau dibatasi oleh jumlah yang boleh diperolehi semula untuk pengujian forensik. Untuk mengatasi cabaran dalam mengaitkan sampel yang berisipadu rendah atau mempunyai kebolehpulihan yang terhad, kajian ini bertujuan untuk membangunkan satu kaedah kromatografi gas yang berasaskan makmal dengan mengesan dan menentukan kuantiti xilazin dalam sampel minuman yang dimasukkan dadah yang wujud dalam keadaan cecair, titisan dan kering. Dalam kajian ini, satu kaedah kromatografi gas-spektrometri jisim (GC-MS) telah dioptimumkan untuk mengesan kehadiran xilazin dan satu kromatografi gas-pengesanan pengionan nyalaan (GC-FID) telah ditentu-sahkan untuk pengkuantitian sebatian tersebut. Seterusnya, xilazin daripada empat sampel minuman dalam tiga keadaan fizikal berlainan, menyerupai tetapan forensik yang berkemungkinan, telah diperolehi semula dan ditentukan. Satu kaedah GC yang sah bagi penentuan dan penentuan kuantiti xilazin dalam 15 minit telah dilaporkan. Had pengesanan (LOD) dan had pengkuantitian (LOQ) telah dilaporkan masing-masing pada 0.08 μg/mL and 0.26 μg/mL. Xilazin dapat diperoleh semula daripada sampel minuman dalam keadaan cecair dengan peratusan yang lebih tinggi (77.2-97.3%) berbanding dengan sampel titisan (50.8 – 80.0%) dan sampel kering (39.8 – 66.9%). Kajian ini membuktikan bahawa isipadu sampel minuman tertinggal yang terhad dan dalam keadaan kering tidak menghalang perolehan semula dadah yang disasarkan. Kesimpulannya, satu kaedah kromatografi gas telah berjaya dibangunkan untuk menentukan sisa-sisa xilazin dalam minuman yang dimasukkan dadah. Hal ini dapat membantu teknik penyiasatan kepada juruanalisis makmal dan pegawai tempat kejadian dalam penyiasatan DFC.

Introduction

Xylazine serves as relaxant, sedative, analgesic, and anti-hypertensive agent [1–3]. It is widely used in veterinary practice but is not approved by the Food and Drug Administration (FDA) for human use [3] due to its deleterious side effects such as bradycardia, hypotension, and possibly death [4, 5]. The substance is not scheduled as a controlled substance by the Drug Enforcement Administration (DEA) [6]. In South-East Asian countries, for instance, xylazine is accessible to certain groups of people, such as veterinary personnel and animal trainers under the Poison Act 1952 in Malaysia [7] whereas it is scheduled as a controlled substance in Thailand [8]. According to the FDA, the use of xylazine in "food-producing animals" is specifically not allowable in the United States of America; however, in Canada, United Kingdom, France, Germany, and Switzerland, xylazine can legally be used in food-producing animals [3, 9]. In fact, this substance is still accessible in the market, commonly in injectable solutions, such as Rompun®, Sedazine®, and Anased® [5].

Drug-facilitated crime (DFC) is a serious issue worldwide. It refers to crimes committed whenever victims of the crime are placed under the influence of drugs [10]. More specifically, drug-facilitated sexual assault (DFSA) occurs whenever sexual assault has been committed with a victim has been drugged by the rapist beforehand [11]. The victim had previously unknowingly consumed either a beverage or food that was spiked with drugs and sexual assault occurred without the knowledge, understanding, or consent of the victim due to the drug's affect. In other words, drugs originally designed for medicinal or veterinary use have been illegally used to incapacitate victims by exploiting the pharmacological effects of such drugs [12, 13]. Common examples include benzodiazepine [14-17], ketamine [14, 18] and gamma hydroxybutyrate (GHB) [19-20]. Recently, xylazine was also found in the list [21-25].

One way of DFC modus operandi is via drug-spiked beverages, whereby the beverages are allegedly produced by the unsolicited addition of drugs into them in drug-facilitated crimes, especially in robbery and rape

cases [26]. Recent cases reported drug-spiking incidents through the addition of xylazine into a victim's drink which alleged of sexual assault and robbery utilizing the sedative effects of xylazine [21]. Upon consumption of the spiked drinks, the victims would suffer intoxication with blurred vision, shortness of breath and vomiting before passing out shortly after [3,21]. In view of its potential abuse in DFC and DFSA, the searching of forensic evidence and successful detection of illicit drug contained in drug-spiked beverages is crucial for obtaining justice for victims.

Previous studies have suggested various instrumental techniques in detecting xylazine, for instance gas chromatography (GC) [27, 28], liquid chromatography [21, 28], thin layer chromatography [4] and electrochemical technique [29, 30]. These published articles and technical reports have undoubtedly provided significant contributions, mainly on the toxicology studies in human through the analysis of biological samples. Nonetheless, limited information could be retrieved from published works, particularly from the perspective of forensic related evidence, including the seizure of xylazine as an illicit drug or as an adulterant. The mass spectrometry detector was frequently employed in GC analysis of xylazine as a screening approach [21, 31]. In comparison to gas-chromatography-mass spectrometry (GC-MS), gas chromatography equipped with flame ionization detector (GC-FID) analysis can also serve as a reliable, sensitive, and reproducible method for trace analyses, depending on the structure and behavior of the analyte of interest [32]. When dealing with spiked drink samples, liquid-liquid extraction (LLE) was found to be the most common method applied in forensic drug analyses due to its low cost, comparably rapid and the procedures are easy to implement [33]. A portable electrochemical sensor was recently developed to provide quick, on-scene screening of xylazine in spiked drinks [34]. However, a laboratory-based technique would be crucial in supporting the forensic analysis for drug confirmation.

Additionally, the misuse of xylazine in DFC through the spiking of drug into beverages of victims is particularly serious that needs urgent actions from law enforcement agencies and testing laboratories. In certain cases, a victim claimed that his/her drink has been spiked with drugs, but the obtained sample had tested negative [35]. When dealing with biological samples, a false negative result could be reported due to delayed sample collection and detection [35]. Literature has reported the calculated plasma half-life of xylazine in human plasma was 4.9 hours [36]. As a victim suffers from an altered state of mind or other psychoactive effect upon intoxication, it would further increase the time elapsed between the occurrence of a crime and eventual forensic analysis, as well as pose challenges to rely solely on a witness's statement for legal recourse [37]. In such situation, alternative sample *i.e.,* consumed drinks, could be proposed as evidence to be collected from the glass left at crimes scenes.

Therefore, a study was designed to detect and quantify xylazine from beverages collected directly from drinking containers where the drug residues present might be at trace level. A GC technique was optimized and validated, taking into consideration that such an instrument is routinely used and available in most forensic laboratories. GC-MS was utilized to confirm the presence of xylazine, followed by GC-FID, used to quantitate xylazine that are found in spiked sample. Subsequently, the detection and quantification of xylazine in spiked beverages were investigated with the aid of LLE techniques. Other than appearing in liquid form, a glass or a cup suspected to have contained xylazine could be left with a few residual drops or even have dried off traces. As such, samples present in such states ought to be simulated and explored to maximize potential forms of evidence tracing in alleged DFC. It is hoped that this analytical method would aid in detecting the target drug in suspected spiked beverages to assist forensic investigation and to facilitate the tracing of suspects, while providing some insights to decide crime scene sampling decision by the crime scene officers.

Materials and Methods

Materials and chemicals

Dichloromethane (DCM) of GC grade was obtained from Merck (Whitehouse Station, NJ). Xylazine hydrochloride standard was purchased from U.S. Pharmacopeia (Rockville, MD). 2,2,2-triphenylacetophenone was used as an internal standard (IS), and certified reference material (CRM) standards of heroin, paracetamol, caffeine, codeine, morphine, 6-monoacetylmorphine and ketamine (≥99%); were obtained from the Department of Chemistry Malaysia. Analytical grade sodium hydroxide and anhydrous sodium sulphate were sourced from Merck (Whitehouse Station, NJ).

Ultrapure water (18.2 MΩ) was prepared in-house from a Millipore water purification system (Bedford, NY). Sample beverages (mineral water, carbonated drink, energy drink, and commercial fruit juice) were purchased from the local supermarket. The drinking glasses used in this study were obtained from a nearby kitchenware store.

Instrumentation

An Agilent 7890B GC system equipped with split/splitless injector and a 5977B Mass Spectrometer (MS) (Santa Clara, CA) was utilized to confirm the presence of xylazine. Chromatographic separation was achieved using a (5%-phenyl)-methylpolysiloxane (HP-5) capillary column (30 m × 0.32 μm i.d., 0.25 μm film thickness) purchased from Agilent Technologies (Santa Clara, CA). Purified helium gas (99.9% purity) was used as the carrier gas with a constant flow rate of 1 mL/min. The front inlet was set at 280°C. The oven temperature program began with an initial temperature of 170°C and held for 2 mins. The temperature was gradually increased to reach a temperature of 210°C at 20°C/min and subsequently ramped to 220°C at 3°C/min. It was further increased to 280°C at 50°C/min, and the final temperature was held for 6 mins. Data acquisition rate was set at 1.0 scan/sec and mass spectra were collected in scan mode from m/z 41 to m/z 500. The target compounds were studied, and the resultant peaks were identified using the NIST mass spectral library (Version 2.0) (National Institute of Standards and Technology, Gaithersbury, MD) and literature search.

An Agilent 7890A Gas Chromatographic system equipped with a split/splitless injector and a Flame Ionization Detector (FID) (Agilent Technologies, Santa Clara, CA) was used for quantification of xylazine. HP-5 capillary column with a splitless injection mode was used, and the purified nitrogen gas (99.9% purity) was utilized as the carrier gas at a constant flow rate of 1 mL/min. Liquid injection mode was performed at a constant inlet temperature (280°C). The initial oven temperature was set at 170°C with an equilibration time of 2 min. A temperature ramp of 20°C/min was selected to reach the maximum of 210°C and ramped to 220°C at 3°C/min. It was further increased to 280°C at 50°C/min and held for 6 mins. Hydrogen flow, air flow, and the make-up flow (purified nitrogen gas) were supplied to the detector at 30, 300, and 15 mL/min, respectively. A volume of 1 μL of standard solution or the extract from beverage samples were introduced into the injector port. Chemstation software (Rev. B.04.02, Agilent, Santa Clara, CA) was used for GC automation and data analysis. All standards and IS were identified by comparing the retention time.

Method validation

The xylazine stock solution with a concentration of 1 mg/mL was prepared in DCM. A 5 μg/mL internal standard was also prepared in DCM. Calibration standard solutions ranging from 5 μg/mL to 100 μg/mL were prepared independently by adding in a pre-determined volume of stock solution into volumetric flasks and diluting with DCM. Quality control (QC) solutions at three concentration levels, namely QC_{low}, QC_{medium}, and QC_{high}, were prepared at respective concentration levels of 15, 45, and 75 μg/mL using a separately prepared stock solution.

In this study, GC parameters were adjusted accordingly to establish chromatographic conditions with optimum results and good peak separation. Subsequently, the GC method was validated according to the criteria set by United Nations Office on Drugs and Crime (UNODC) [38]. Selectivity, linearity range, limit of detection and limit of quantitation, repeatability and reproducibility, and the accuracy of the analytical method were evaluated.

Sample extraction

Liquid-liquid extraction (LLE) procedure was performed prior to GC analysis. Briefly, a volume of 1 mL of beverage sample aliquot spiked with xylazine of definite concentration level was carefully transferred into a vial and adjusted to alkaline pH (pH ≈11) using 13% sodium hydroxide solution. The pH of liquid sample was pre-verified using pH litmus paper. Subsequently, the aliquot was extracted with 0.5 mL of DCM twice. Upon extraction, the extracted solution was combined, passed through anhydrous sodium sulphate, and evaporated carefully under a gentle stream of nitrogen gas. Lastly, the residue was reconstituted with 100 µL of 10 µg/mL internal standard solution.

Analysis of xylazine-spiked beverage samples

The recoveries of extraction from the four beverage samples were determined by assaying spiked samples in five replications at concentration levels of 15, 45, and 75 µg/mL. Beverages were chosen based on the range of possible household beverages that would commonly be encountered in drink spiking cases. The selected beverages represented a plain water, an energy drink, a carbonated drink, and a fruit-based drink. To simulate the real case scenario, three different settings of xylazine-spiked beverage samples were prepared.

Firstly, a beverage with remaining at least 2 mL in its volume can be encountered at a scene (spiked liquid samples). To simulate such a setting, the definite amount of xylazine standard was spiked into the respective beverage samples. Following, 1 mL of the spiked liquid beverages were subjected to LLE procedure.

Secondly, leftover of any beverages priorly spiked with xylazine can appear as droplets (spiked droplet samples). To simulate this case, 1 mL of each sample beverage carrying the respective concentration levels was separately sprayed into drinking glass and left for a three-hour duration. Note that such duration did not dry the residues but remained as droplet samples. Then 1 mL of the distilled water was used to rinse the inner surface of the drinking glasses. The rinsates were collected and subjected to LLE procedure.

Thirdly, a beverage sample suspected to have been spiked with drug can exist in completely dry form, either due to the complete consumption by an individual or because of the extended duration of exposure to room conditions (spiked dry samples). To simulate the third scenario, 1 mL of sample beverages with definite concentration of xylazine was sprayed into drinking glass and left overnight to dry undisturbed. Then, 1 mL of distilled water was used to rinse the inner side of the drinking glasses and the rinsate was subjected to LLE procedure.

All prepared samples were analyzed by the validated GC method. Recovery percentages of xylazine from each beverage appearing at three different scenarios were calculated, evaluated, and compared.

Results and Discussion

Through the analysis, it was found that the GC-FID method was selective toward paracetamol, PCM (5.61 min), caffeine, CF (7.02 min), ketamine, KET (7.32 min), xylazine, XYZ (8.23 min), codeine, CD (10.70 min), morphine, MP (11.11 min), 6-monoacetylmorphine, MM (11.74 min), heroin, HR (12.65 min) and 2,2,2-triphenylacetophenone, IS (13.48 min), as shown in Figure 1. The presence of xylazine was also confirmed using the GC-MS, and a mass spectrum which most abundant molecular peak of m/z appeared at 205.1 and 220.1 is demonstrated in Figure 2. Calibration curve of peak area ratio against concentration was plotted with an equation of $y = 0.205x - 0.0583$ with a correlation coefficient of 0.997, suggesting the direct proportional relationship with the concentration of the analyte. For the established method, LOD and LOQ were determined as 0.08 µg/mL and 0.26 µg/mL, respectively, allowing detection and quantification at low microgram levels. This analytical ability of achieving very low LOD and LOQ is important in forensic cases, especially in scenarios where the amount of xylazine available for detection might appear at trace level such as in spiked beverages.

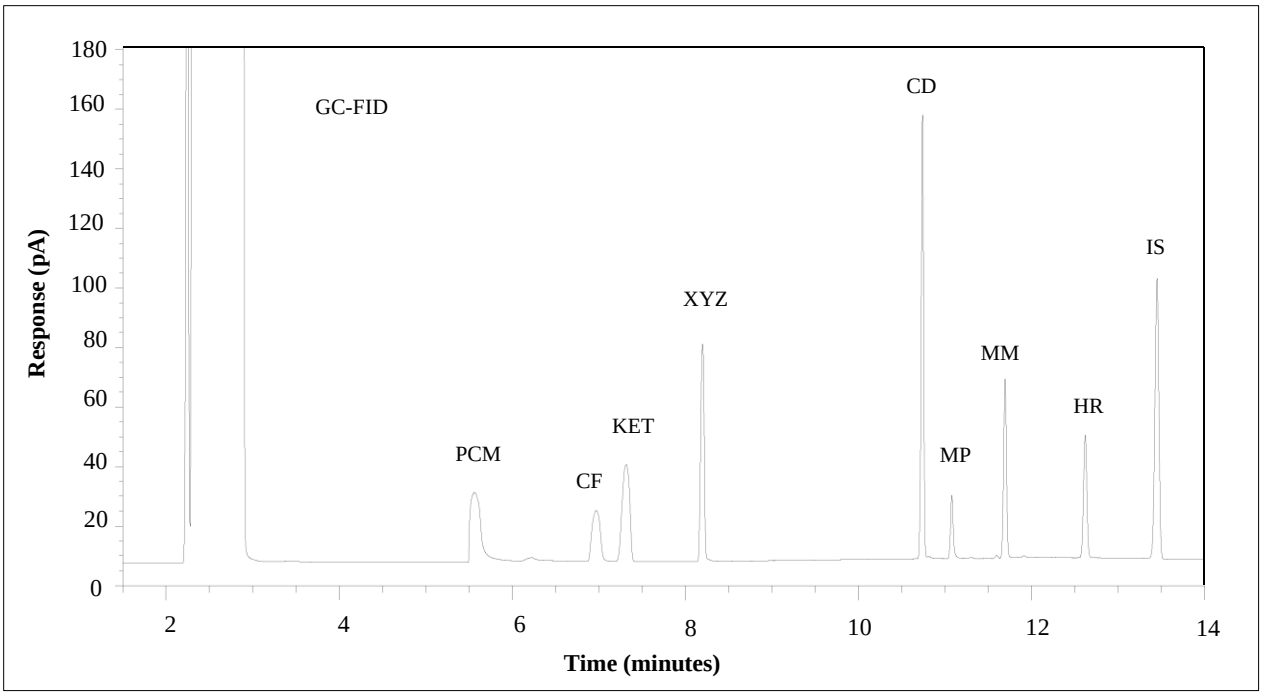

Figure 1. Chromatograms on the selectivity test of the developed method using GC-FID method.

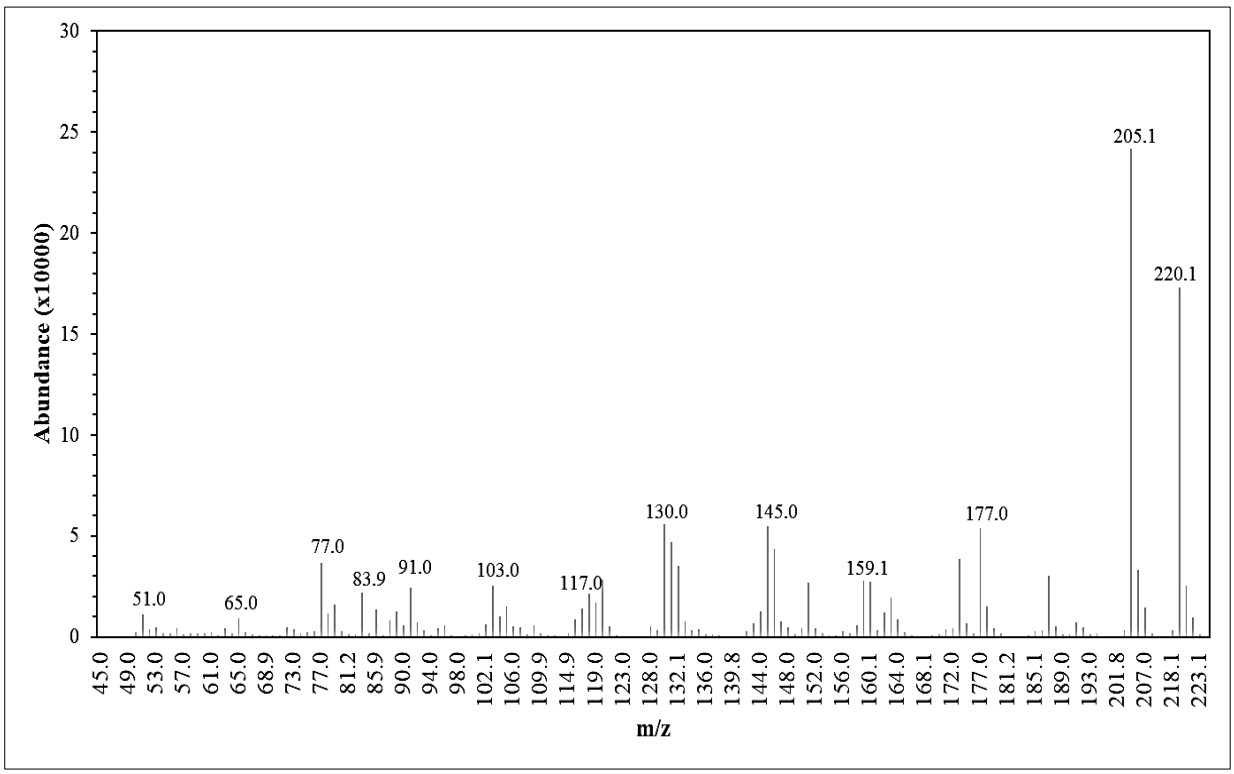

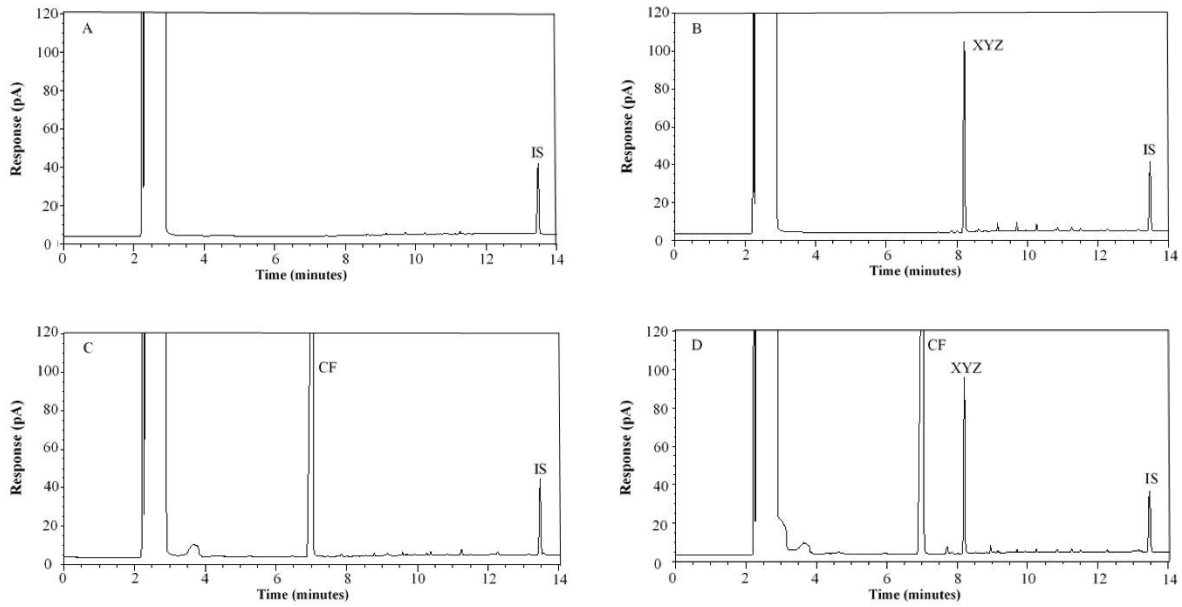

Figure 2. Mass spectrum of xylazine

This study showed good precision, where the intra-day precision reported RSD ranged from 0.5% to 0.7%, while the inter-day precision demonstrated a range of RSD between 1.6% and 3.9%. Repeatable and reproducible data were generated from multiple analyses of the same samples. For accuracy test, recoveries of xylazine from three different QC concentration levels were ranged between 97.3% to 100.7%, i.e., ± 5.0% of the pre-determined concentrations. The GC method proposed here met the intended scope of xylazine analysis, subsequently applied to test the recoveries of the targeted drug from various beverage samples.

Prior to sample analyses, beverage-negative controls, i.e., the extract of beverage-negative without addition of any drug; were run to determine possible matrix interference originating from the beverages. Figure 3 shows the representative chromatograms of beverages-negative controls and xylazine-spiked beverage samples. With the exception of mineral water, it was found that certain substances had been co-extracted, indicated by the presence of extraneous peaks in the chromatograms. Compounds extractable by the LLE procedure were detected, and the presence of caffeine peak was especially evident in both the chromatograms generated from the analyses of beverage-negative carbonated and energy drinks tested in this study. The composition contained in the fruit-based beverage also contributed to extraneous peaks in the chromatogram of beverage-negative control, thus, deserving further identification, perhaps through mass spectrometry, if the identities of these chemical substances are of concern, and they are beyond the scope of this current study.

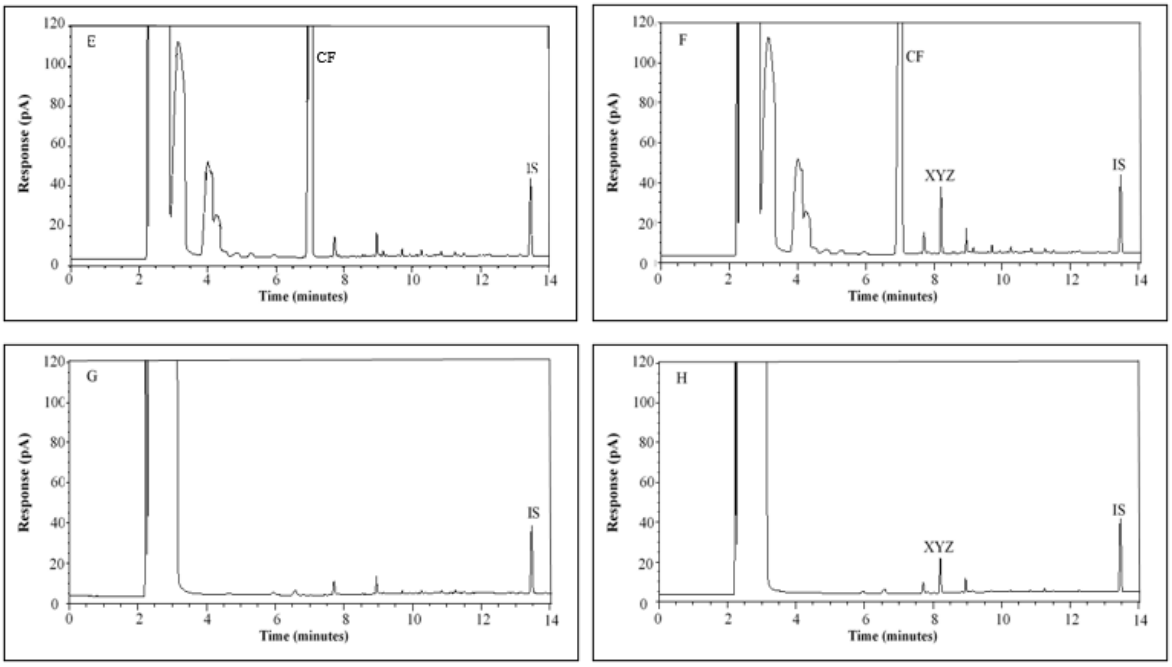

Figure 3. Representative chromatograms of negative control and spiked samples; (A-B) mineral water; (C-D) carbonated drink; (E-F) energy drink; (G-H) fruit-based drink

Although extraneous peaks originated from the beverages were noticed in their respective chromatographic outputs, all these peaks did not interfere the determination and quantification of xylazine as its peak was well-separated from the potential interferences. As a good laboratory practice, it is recommended that a beverage-negative control run is performed in every instance whenever the recovery of a target drug from any beverage is to be determined. This is to avoid obtaining a false positive result, especially in drug-spiked beverage samples.

Under the optimized LLE procedure, DCM was chosen as the extracting solvent due to its relatively good polarity that could increase the recovery efficiency [42]. Apart from that, multiple extraction could potentially increase the distribution coefficient of xylazine [43], while the xylazine was extracted upon basifying the aqueous sample to pH 11 in this study. As a basic drug, alkaline aqueous sample, in this case the beverage sample, allowed greater extraction of the analyte to the DCM layer [43]. It is noted that all drinks except mineral water were appeared acidic in their respective original forms. Therefore, all the solution were made basic for better recovery efficiencies.

Recoveries of xylazine were determined through the evaluation of the extraction efficiency from beverage samples appearing in liquid, droplet, and dry forms. Spiked levels of xylazine with respective mass of 1.5 µg, 4.5 µg and 7.5 µg were utilized, and Table 1 demonstrates the recovery percentages of the drug for each beverage samples.

Table 1. Recoveries (± RSD) of xylazine from the four different beverage

Beverage Sample	1.5 µg	4.5 µg	7.5 µg
Liquid form beverage sample			
Mineral Water	97.3 ± 0.9%	92.1 ± 1.7%	90.1 ± 2.8%
Carbonated drink	90.7 ± 5.7%	90.0 ± 3.2%	85.5 ± 2.1%
Fruit-based drink	87.8 ± 7.0%	82.0 ± 8.6%	77.2 ± 5.3%
Energy drink	89.8 ± 5.3%	84.1 ± 3.5%	82.2 ± 6.4%
Droplet beverage sample			
Mineral Water	71.9 ± 9.0%	80.0 ± 7.9%	75.5 ± 4.4%
Carbonated drink	69.8 ± 14.3%	72.0 ± 7.9%	75.9 ± 3.9%
Fruit-based drink	50.8 ± 5.3%	59.3 ± 9.9%	54.6 ± 11.6%
Energy drink	59.2 ± 16.7%	54.3 ± 15.9%	56.5 ± 12.1%
Dry beverage sample			
Mineral Water	60.8 ± 14.5%	56.1 ± 8.4%	60.5 ± 8.5%
Carbonated drink	57.7 ± 4.3%	58.3 ± 7.7%	66.9 ± 5.3%
Fruit-based drink	51.3 ± 16.2%	49.7 ± 11.6%	45.1 ± 11.3%
Energy drink	50.3 ± 10.2%	42.7 ± 8.9%	39.8 ± 12.4%

In this study, the percentages of xylazine successfully recovered from the liquid beverage samples ranged between 77.2% and 97.3%, depending on the beverages used as the substrates. Meanwhile, percentage recoveries were reported relatively lower in both droplet (50.8-80.0%) and dry samples (39.8-66.9%). In other words, the extraction procedure implemented in this study appeared to be more effective in recovering the target drug from a liquid beverage sample. Unlike liquid sample, both droplet and dry form of samples were highly subjected to variation as they were exposed to the surrounding environment. Perhaps, the variations might be greater in real case scenarios when samples have to be recovered from non-laboratory settings.

Through GC analysis, the amount of xylazine contained in a liquid beverage sample could be quantified with recoveries greater than 82%. It is noted that the recovery and detection of sedative-hypnotics from beverage samples using gas chromatographic method is not a new practice implemented by the forensic communities, especially for the determination of DFC. Research had also been carried out for the detection of various drugs in beverages, including benzodiazepines [14-17], ketamine [14, 18] and GHB [19, 20]. However, to the authors' knowledge, the current study was the first to investigate the determination of xylazine from spiked beverages, with the substance having similar effects as in the above-mentioned drugs on the victim after consumption.

Through the analyses, the composition of beverages could have interfered the extraction efficiencies in recovering the target drug [44, 45], in this case the xylazine. In this study, mineral water with the least matrix interference was found to allow better recoveries of the target drug from liquid samples, reporting at percentages greater than 90%. By comparison, substrates carrying greater matrix within their composition were reported with relatively lower recoveries but remained greater than 82%.

Literatures had suggested a wide range of recovery percentages from 70% and 110% based on the target

illicit drugs and beverages used under different experimental conditions [14, 15, 18, 20]. Whenever beverage samples with complex matrices were used, lower recoveries of the target were achieved as reported by Famiglini et al. [17] with only 47% – 59% of benzodiazepines were successfully recovered from milk-based alcoholic beverages. It is therefore important that a sample of unspiked beverage must be obtained by the crime scene officer and made available for the analyst to use as a control to determine the degree of matrix effect, and extractable percentage.

In real case scenarios, forensic evidence in liquid form might not be always available. There were instances where a few drops of the residual beverages were discovered within a glass or cup, particularly after a victim consumed a drink or after a beverage content was dispensed but has not completely dried up. Additionally, the drinking glass might have totally dried up with no leftover residue being evident due to time elapse, probably due to beyond-control delayed discovery of such forensic evidence. It is mentioned here that the previous published studies mainly focused on the recovery of target drug from liquid beverage samples [14-20]. Droplet and dry evidence should not be overlooked by the forensic investigator as advances in technology which enables the detection of drug traces, as evidenced in this current study, subsequently aiding in DFC investigation.

Nonetheless, the presence of xylazine could still be detected from the droplets and dry form of each beverage. As reported in Table 1, using trace residues of the analyte available for testing, at least 40% of the xylazine can be recovered and detected. It is important to emphasize that the recoveries from droplet and dry beverage samples could vary due to the existence of uncontrolled factors and physical loss in this study, perhaps the variations might be greater in real case scenarios. However, our experimental procedure had successfully allowed for the recovery of xylazine from the drinking glass, at least for positive detection regardless of the volume of its content.

Rinsing is a recommended technique for sampling of traces from a surface [46]. It is useful, particularly in the sampling of large surface area, hollowed area or any area that is hard to access. It was also noted that a sampling method must be comprehensive enough to quantify both soluble and insoluble residuals [46]. A previous study reported the applicability of rinsing procedure to recover illicit ketamine from spiked drinks [47]. Swabbing has also been proposed for sampling of trace surface residues; however, it might yield limited qualitative determination [48-51]. The FDA recommended swabbing procedure to recover the targeted compound from a surface [46] and this shall be further explored in future studies to maximize the recovery and increase the chance for detection, as well as to evidence comparison of suitable sampling strategies in real case scenarios.

This study demonstrated the possibility to detect and quantify trace xylazine from spiked-beverage samples, regardless of its physical forms. Apart from the intention in conducting DFC by criminals, smuggling activities of illicit drugs in adulterated beverages were also reported, deserving screening and testing for the presence of controlled or illegal substances [52]. Therefore, it is important to maximize the likelihood of positive detection, and the method established in this study had allowed the trace detection of 0.08 μg/mL xylazine under experimental parameters. Note that such detection limit was adequately good for the detection of xylazine in real case scenario as the amount of the drug in causing toxicity was reported to be in the range between 40 mg and 2400 mg [3,53]. The outcome of this study provided useful detection technology information and could be beneficial for forensic investigation, sample collection and forensic testing, even in cases with very limited residual samples.

Conclusion

In this study, a gas chromatographic technique was successfully established to determine xylazine in drug-spiked beverages. More than 40% of xylazine can be detected at trace concentration. With the requirement of small amount of beverage samples, the GC method offers valuable investigation clues. As DFC is a serious threat to vulnerable groups, the detection of targeted drug should be performed through an accurate and validated analytical technique. Herein, an appropriate extraction protocol to maximize the recovery of targeted

drugs is presented. The information provided in this study is also beneficial for crime scene investigation and scene sampling practices in cases involving DFC.

Abstract

Magnetite incorporates graphene or its derivatives, graphene oxide, or reduced graphene oxide, has received significant attention for its superior features, such as unique structure and large surface area with great number of active sites. The nanocomposite is priorly used in biosensors and biomedical for drug study. Many researchers currently opt for the nanocomposite in various electrochemistry applications as the first-rate material for said applicative fields due to its environmental-friendly nature and inexpensive production cost. This paper reviews the advantages of magnetic graphene-based material and its applications. The scope of this review is to highlight important justifications of electrochemical applications. A comprehensive discussion of the nanocomposite's physical and electrochemical properties, as well as its stability and reusability, are presented.

Abstract

Magnetit digabungkan dengan grafin atau produk derivasinya, seperti grafin oksida atau grafin oksida terturun mendapat kajian meluas kerana ciri unik komposit tersebut, misalnya kawasan permukaan yang luas dengan bilangan tapak aktif yang amat banyak. Pada asalnya, nanokomposit tersebut digunakan dalam bidang biosensor dan biomedik untuk terutamanya dalam kajian dadah. Kini, ramai penyelidik memilih nanokomposit ini dan mengaplikasikannya sebagai bahan utama dalam pelbagai bidang elektrokimia atas dasar mesra alam dan kos penghasilan yang murah. Dalam kertas kajian ini, kelebihan nanokomposit dan penggunaan dalam bidang elektrokimia diulas. Skop ulasan memberi penghujahan yang penting tentang bidang elektrokimia. Di

samping itu, ciri-ciri fizikal dan elektrokimia nanokomposit tersebut dibincangkan secara mendalam selain daripada kestabilan dan kebolehgunaan semula bahan tersebut.

Keywords: magnetit, grafin, elektrokimia, mesra alam, elektrod

Introduction

Technological advancements in electrochemistry have gained remarkable growth over past decades recently for their constant developed applications. Electrochemical technique is predominantly an efficient and alternative solution to conventional spectroscopic and chromatographic techniques. It offers rapid analysis, low cost, selective sensitivity, and user portability while being environmentally friendly. To further improve the electrochemical technology, electrocatalysis was introduced, which attracted significant attention from researchers globally as an establishment since the new hybrid approach was introduced. Moreover, the typical unmodified electrode such as bare carbon electrode or bare gold electrode has a chemically fouling nature, poor chemical stability, low mechanical strength, and tend to agglomerate on its own [1, 2].

Graphene is known as one of the most interesting materials in the research field for its exclusive characteristics and potential applications in various fields [3]. It is as discrete as one carbon atom in size but still carries a greater surface area, twice larger than ordinary activated carbon [4, 5]. It has a honeycomb lattice arrangement, a primitive building block for other carbon allotropes, such as 0D fullerenes, 1D carbon nanotubes, and 3D graphite. The composite has the capacity to adsorb an assortment of aromatic biomolecules via p–p stacking interaction and electrostatic interaction, making them optimal materials for forming biosensors and loading drugs [6]. Graphene is further refined into graphene oxide for enhanced properties, such as boosted surface area and reactive sites from the addition of oxides functional groups. Hydrophilicity and high dispersibility of graphene make it popular in removing water pollutants; however, it is difficult to be separated from aqueous solutions [7].

Graphene oxide (GO) is a resultant of graphene sheet embellished with oxygen (-OH) functional groups to great negative charge density and hydrophilic character. Typically, GO is a natural insulator, where it has lured sizeable interest for its prospective applications as an electrically insulating material in electronics and can be applied as an adsorbent. Nevertheless, it could be a conductive material through adequate exposure to reducing agents such as hydrazine hydrate or sodium borohydride, reducing and defecting its sites to make it active [8]. It is a prime component in the field of chemistry because of its high surface area with many functional groups around the plane. The high surface area subsequently supports the oxygen reduction reaction [9, 10]. The existence of functional groups on the GO plane produces a high negative charge density, larger surface area, and hydrophilic character.

Diminishing the oxygen-based functional groups in sheets of graphene oxide by in-situ reduction produces reduced graphene oxide (rGO). It is a better choice of using rGO as compared to GO in the aspect of electrochemistry. The reduced oxygen in GO sheets promptly increases Π-Π interaction by increasing sp^2 carbons [11, 12]. With these properties, a study was conducted to foresee the strong interaction between graphene and nanoparticles, especially with magnetic properties, which resulted in a salient potential with exclusive and enhanced functionalities useful in several applications [13].

Magnetic nanoparticle (MNP) utilised in electrochemical activities is known for its decent theoretical value, inexpensive production, and environmentally friendly. Together with magnetic properties, it has metallic properties that can conduct good electricity. Iron oxide nanoparticles, scientifically known as magnetite, are the utmost explored metal-based magnetic nanoparticles up to date. It turns to superparamagnetic once the ferrite particles become smaller than 128 nm. This averts self-agglomeration since they display their magnetic behaviour only when an external magnetic field is implemented [14]. However, inferior cycling stability, vulnerability to air oxidation, and agglomeration caused by imbalanced electron transfer occur easily. Therefore, merging of

magnetite with carbon related materials, especially graphene (for its unique properties) into a nanocomposite was researched [15]. This technically increased the surface area and performed better electrochemical reactions when utilised in applications. With current findings, the nanocomposite can be further utilised for various applications, such as in big energy production plants. This changes the current perspective in the energy production field. More than 51% of global energy production is produced from non-renewable energy resources, to an option of renewable energy source that saves cost [16, 17].

The integration of magnetite-graphene plays a pivotal role in the electrochemical efficiency of a cell, other than to ensure the excellency of characteristics and longevity of nanocomposite while possessing better stability in terms of thermal and conditioning. This is based on the increase of electrical conductivity [18]. Generally, the development of magnetite-graphene nanocomposite begins with the synthesis of graphene oxide via modified Hummers' method [19] followed by the synthesis of MNP using a facile one-pot method or chemical induction method. This combination has been used in various fields such as biosensors, data storage, bioseparation, targeted drug delivery, coating from corrosion, and energy production [20]. The nanocomposite showed a great response in the biomedical field through excellent detection capability in sensor application, which proves to be an optimal substrate for surface immobilisation. This characteristic can be further explored and enhanced in targeted detection apart from the biomedical field, such as water pollution sensors.

Applications of Magnetic Graphene Nanocomposite Batteries

Batteries, the handy energy storage material is a common material in daily life. It can be categorised into three types which are lithium-ion battery (LIB), sodium-ion battery (SIB), and lithium/sulphur-ion battery (LSIB) [21-23]. Among these, LIB is more preferably used for its exclusive features such as high energy density, high voltage, lightweight, and long life-cycle. The first LIB was introduced in 1991 by Sony Inc., and extensively used as handily and portable power source for electric and electronic devices [24]. This type of battery also has attracted attention in aerospace application as well as in military-based devices. As for the working principle of rechargeable batteries, it contains two electrodes, an anode (negative electrode) and a cathode (positive electrode). The cathode, as the lower capacity electrode, determines the overall capacity of a battery. Different types and structures of the separator component have been introduced. It primarily serves to physically separate the electrodes to prevent shorting while providing porosity for lithium-ion flow during charge and discharge [25]. In the discharging process of LIB, lithium-ion moves from the negative electrode to the positive electrode through an electrolyte and vice versa during the charging process. The process of ion movement is illustrated in Figure 1. Generally, the positive electrode in LIB is an intercalated lithium compound, while various materials have been developed for the negative electrode to increase the properties of the lithium-ion battery [26].

Magnetite developed into one of the promising active materials for anode of LIB due to the highest theoretical capacities (926 mAh/g) [27], which shows that Fe_3O_4 can react with eight lithium ions per formula unit compared to the currently used graphite anode with 372 mAh/g of capacity [28]. Apart from that, magnetite also possesses higher conductivity ($\sigma = 2 \times 104\ Sm^{-1}$) than most of other metal oxides [29] due to its magnetic properties [30]. However, a stand-alone magnetite nanoparticle is not significant for the Li-ion batteries' application due to its poor cyclic performance and rate capability, which causes aggregation of the composite and fluctuation of volume during the insertion or the extraction process of Li-ion. Furthermore, this anode exhibits intrinsic large electrochemical polarisation upon cycling, which reduces the system's 'round trip efficiency' and electrochemical reversibility. This is primarily due to poor electronic and ionic conductivities of Fe_3O_4 and slow solid-state diffusion of Li ions in this anode [31]. The low conductivity of composite also may lead to a rapid degradation process.

To add on, the combination of graphene with magnetite boosts the electrical properties and increases surface area, leading to exceptional thermal conductivity (~5000

W/mK). The extremely high values of thermal conductivity suggests that graphene can outperform carbon nanotubes (CNTs) in heat conduction. 2D nanosheets structure of graphene constitutes abundant active sites and accessible surfaces where it enables energy storage materials to achieve high power and energy density [32]. It is supported that the theoretical capacity of graphene (744 mAh/g) is twice as much as that of graphite because graphene can accommodate two Li-ions, instead of one for graphite, in each hexagonal loop of carbon (Li_2C_6). Thus, incorporating magnetite with graphene can overcome the aggregation of magnetite nanoparticles as the high surface area (2620 m^2/g) graphene will help the nanosized magnetite bind to its nanosheets. The large-volume variation of magnetite during the discharge-charge process also can be mitigated through the high surface area graphene [33]. The strategies of coating the magnetite nanoparticles to graphene enhance the electronic conductivity and boost the conversion yield as the metal integration of the magnetite possess an excellent magnetic property. Based on Huang et al. [34] combination of magnetite and graphene leading to the high Fe_3O_4 loading and outstanding cycling stability (83 per cent retention of the initial reversible capacity after 40 cycles) generated by the volume buffering effect of graphene sheets, the discharge capacity was increased to 750.0 mAh/g. This improved Fe_3O_4/graphene composite with improved performance could have a promising future in lithium-ion battery applications [35].

According to Kai Zhu et al. [36], it was observed that there was no capacity loss and better cycling stability of the improved batteries using nanocomposite. The discharge/charge rate of the battery increased while the Coulombic efficiency reached more than 95%. The nanocomposite supported short diffusion between electron transfer which indicated the enhanced conductivity of the battery. Previous works using various magnetite-graphene nanocomposites and their derivatives nanocomposites on lithium-ion batteries are tabulated in Table 1.

Fuel cell

Fuel cell has been a source of energy generation for the past few decades. It has been recognised as the most efficient substitute for fossil fuels [44]. Sir William Robert Grove invented the first fuel cell by developing a wet-cell battery that depended on the electrochemical reaction that split water into hydrogen (H^+) and oxygen (O^-) ions. Since then, many other types of fuel cells have been invented and applied as a source of energy which contributes less pollution compared to other methods. Commonly used fuel cells include alkaline fuel cells, solid oxide fuel cells, microfluidic fuel cell, proton exchange membrane fuel cell, microbial fuel cell, and many more [45, 46]. The concept of fuel cell is the movement of electrons from cathode to anode. In general, hydrogen atoms enter a fuel cell at the anode, stripped of their electrons by a chemical reaction. The hydrogen atoms become "ionised," or electrically charged. Negatively charged electrons carry electricity across wires, allowing work to be done. The DC output of the fuel cell must be channelled via a conversion device called an inverter if alternating current (AC) is required. The cathode is where oxygen enters the fuel cell and then combines with electrons returning from the electrical circuit and hydrogen ions that have gone through the electrolyte from the anode in some cell types (like the one seen above). In other types of cells, oxygen picks up electrons and then travels through the electrolyte to reach the cell membrane. The best part of the fuel cell is that it is a renewable energy resource, easy to be constructed, and environmentally friendly, where no mass land destruction needs to be done to build platforms for other renewable resources such as windmills and hydro turbines. Fuel cell does not stop working as long as fuels (e.g., hydrogen, which is often used) and oxidants are supplied to the anodic chamber and cathodic chamber. The hydrogen oxidises at the anode where the reaction is called hydrogen evolution reaction (HER). At the same time, the oxygen is being reduced at the cathode, and the reaction is known as oxygen reduction reaction (ORR).

ORR at the cathode proceeds proceeds mainly through two pathways: indirect two-electron reduction (equation 1 and 2) and direct four-electron reduction (equation 3). The four-electron reaction is preferable because it does not produce peroxide species in the reaction as the reactivity of H_2O_2 is relatively higher than the stability of H_2O produced in the direct reaction [47]. The direct reaction also has higher operating potential and current efficiency as compared to the indirect reaction. But in general terms, hydrogen atoms enter a fuel cell at the anode, where a chemical reaction strips them off their electrons. The hydrogen atoms are "ionised" and carries a positive electrical charge. The negatively charged electrons provide the current through wires to do work. If alternating current (AC) is needed, the DC output of the fuel cell must be routed through a conversion device called an inverter. Oxygen enters the fuel cell at the cathode. In some cell types (like the one illustrated above), it combines with electrons returning from the electrical circuit and hydrogen ions that have travelled through the electrolyte from the anode. In other cell types, oxygen picks up electrons and then travels through the electrolyte to the anode, where it combines with hydrogen ions. The electrolyte plays a key role. It must permit only the appropriate ions to pass between the anode and cathode. If free electrons or other substances travel through the electrolyte, they will disrupt the chemical reaction whether they combine at anode or cathode, together with hydrogen and oxygen form water, which drains from the cell. As long as a fuel cell is supplied with hydrogen and oxygen, it will generate electricity.

$$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2 \quad (1)$$

$$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O \quad (2)$$

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \quad (3)$$

The overall performance of the fuel cell is mainly dependable on the electrode applied. Therefore, the exceptional material such as graphene is opted as the appropriate electrode for fuel cell. Noticeable high electrical conductivity features of graphene aids to smoothen the flow of ions and charge transportation in the fuel cell. Graphene's sp2 hexagonal lattice structure exhibits a high specific area which contributes to high capacitance value in the fuel cell and can be easily used as electrode for both application of HER and ORR [48, 12]. Graphene also possesses a high carrier mobility

with a value of $2x10^{-5}$ $cm^2/V/s$, high mechanical strength, high transparency (~97.7%), and is also thermochemically stable.

The highly abundant iron oxide is acknowledged as a low-cost material to replace the conventional Pt electrode which make it one of the main reasons of usage in fuel cell application. Iron oxide possess excellent magnetic properties and high selectivity towards the oxygen reduction reaction [49, 50]. However, during the synthesis process of iron oxide, the composite tends to agglomerate due to uncontrollable growth of magnetite ion thus resulting in depleting performance in ORR and HER. In order to prevent such problem, use of carbonised materials as support to magnetite are very convenient. The incorporation of graphene with iron oxide will decrease the agglomeration of iron oxide. The efficient catalytic activity can also be achieved through the positive synergistic coupling effect between graphene and magnetite particles. Table 2 below shown the reaction pathway of composite in ORR.

Table 2. Reaction pathway of composite in ORR

Composites	Reaction Pathway	ORR Potential (V)	Reaction Kinetics	Refs.
α-Fe_2O_3/GO	3.2 to 3.4	-0.3 to -0.5	-	[51,52]
Fe_2O_3/ carbon	3.6	-	-	[53]
$FeO_{1.4}$/N-C	3.1-3.3	-0.056	-0.40 to -0.55	[54]
Fe_3O_4/N-Gas	4	-0.19	-0.19 to -1.2	[55]
Fe_3O_4/N-GSs	2	-0.26	-0.26 to -0.62	[55]
Fe_3O_4/N-CB	2	-0.24	-0.24 to -0.60	[55]
Fe_3O_4-CNx-Lys	3.4-3.6	-0.25	-0.25 to -0.45	[56]

Corrosion

Corrosion is a natural process that converts a refined metal into a more chemically stable form, and the process is well-known for the gradual destruction of materials by chemical and electrochemical reactions with the environment as the corrosive medium. Protection from corrosion is important to prevent structural and material damage. Corrosion also poses a threat towards public health and safety. Many types of organic-based coatings have been used to reduce corrosion of metal surfaces, as such epoxy coatings. However, these coatings only protect the top layer of the metal surface and are permeable to corrosive electrolytes' exposure. Hence, corrosion does occur underneath the epoxy coating [57]. To add on, the epoxy coating was attached to the applied surface through hydrogen bonding, where the stability reduces by time and is vulnerable to wet conditions. Shielding effect of the corrosion coatings is essential as its function is to block the contact between the substrate interface with the corrosive medium such as oxygens or sulfates and impede the diffusion of the corrosive medium to the protected metals through the anti-corrosion coatings [58]. This shielding effect can be increased by a uniform distribution of the anti-corrosive materials [59].

The high dispersibility and ultra-thin two-dimensional structure of graphene formed a barrier and increased the shielding effect. Apart from that, graphene has also become one of the promising corrosion protection due to its characteristics, which is impermeable to almost all molecules and ions [56]. It is believed that graphene is a revolutionary material in the field of corrosion protection because, as corrosion protection pigments, graphene is able to simultaneously improve the wear resistance, barrier properties, thermal conductivity, mechanical properties, and thermal stability of polymeric coatings [60]. The uniform dispersion and

orientation of graphene parallel to the metal surface make it one of the promising materials for anti-corrosion coatings [61]. Graphene also retains a high adhesion force to enhance the bonding strength between the corrosion protecting coatings with the metals as a strong bonding force material able to hinder the accumulation of oxygen and sulphates at the metals interface and disrupt the corrosion process. A remarkable conductivity of graphene also helps to improve the cathodic protection effect of zinc-rich coatings on metal which an active zinc powder was used to formed corrosion couple with the protected metal interface.

The strength of corrosion protective layer against corrosive medium is determined by the angle of anti-corrosion materials with the substrate interface. A narrower angle of the materials with substrate will toughen the barrier of corrosion protective layer [62]. Thus, only graphene parallel to the surface obeys the shielding effect theory; meanwhile, the graphene perpendicular to the substrate interface did not provide the shielding effect. Therefore, a magnetic field-induced orientated alignment of magnetic graphene was introduced by loading magnetite onto the graphene surface. The magnetised graphene was movable under the action of the external magnetic field. It could also be horizontally aligned in the epoxy resin by the magnetic torque applied to the magnetic graphene sheet by the horizontal magnetic field, as shown in Figure 2 [63]. Moreover, the integration of magnetics with graphene is helpful as the magnetic effect increases the stability of the layer on the surface of metal applied [64].

Numerous works on magnetite graphene as a corrosion protective layer have been published in the past few years. One of the works demonstrated by Nayak *et al.,* deployed a graphene coated Ni film with effectiveness up to post annealing of 500 ^{0}C. Another study found that the use of graphene-coated Cu (111) surface, confirms that no corrosion is detected after the annealing process. Meanwhile, Anisur et al., stated a CVD graphene growth on nickel has improved corrosion resistance to 700 kΩcm^2 with the absence of hydrogen during the graphene growth process. Besides that, Fronczak et al., investigated the corrosion resistance of carbon-encapsulated iron nanoparticles with the use of nitric acid as corrosion agent. as it releases a large amount of Fe and exhibits a high corrosion resistance and high effectiveness up to post-annealing of 450-500 ^{0}C [65-67]. In addition, graphene-coated Cu and graphene-coated Cu/Ni alloy foil by CVD under heating for four at 200 °C in laboratory air, and immersing into a solution of 30% hydrogen peroxide, up to 45 minutes showed no changes to the surfaces. In contrast, bare Cu/Ni turned a dark shade of brown onto its surface [68]. It is shown that the presence of graphene in transition metal can act as anti-corrosive and protect the surface from damage. However, there is a challenge in this field, where the existence of defects may ruin all the advantages of graphene films acting as corrosion inhibitor. Table 3 illustrates the corrosion potential among the previous research on magnetite and graphene-based.

Table 3. Corrosion Potential (E_{corr}) Values obtained from potentiodynamic polarisation test

Composite	**Conditions**	**E_{corr} (mv)**	**I_{corr} (μA cm−1)**	**C_R (mm/year)**	**Refs.**

Sensor

Electrochemical sensors work on the basis that an electrical current travels through a sensing electrode as a result of an electrochemical reaction that occurs at the surface of a sensing electrode coated with a catalyst, such as platinum. An electrochemical sensor consists of a metallic anode and a metallic cathode that are submerged in an electrolytic solution (such as H_2SO_4) to allow ion movement between the two electrodes. Electrochemical sensors typically have two or three-electrode designs with a membrane for gas transport. The electrical current is proportional to the hydrogen concentration, which may be monitored to determine the gas concentration [74]. An electrochemical sensor detects and analyses a specific compound by measuring the chemical signals produced from the electrochemical system and converting them into digital signals or well-known as chemical signals. These signals can be measured by analysing the current, potential, and conductance changes being emitted from the system [75]. The response obtained in the electrochemical sensor is due to the interaction between the electron transfer of the analyte in the electrolyte and the electricity being applied to the electrochemical system based on potentiometric, amperometric, voltammetric or conductivity measurements. The two most common electrochemical sensor configurations are amperometric and potentiometric sensors. Amperometric sensors work with a constant applied voltage, and the sensor signal is current. In contrast, potentiometric sensors work with zero current, and the sensor signal is the potential difference between the sensing electrode and a reference electrode [74]. The attraction of applying electrochemical sensors is based on their high sensitivity, good selectivity, cost-effectiveness compared to the conventional method, nature-friendly, simple pre-treatment process and fast analytical period [15].

In the application of electrochemical sensors, it is crucial to have excellent electron transfer properties to promote the ability of some enzymes and exceptional catalytic behaviour towards small biomolecules; and graphene with outstanding electron mobility (200,000 $cm^2V^{-1}s^{-1}$ at electron density ~$2x10^{11}$ cm^{-2}) can fulfil this critical requirement [76]. Graphene also possesses a less weighty graphene chemical sensor that is wearable and operates at normal atmospheric pressure and room temperature, making it cost-effective and low environmental impacts material [79].

Meanwhile, magnetite based-electrochemical sensors have shown to be an excellent choice for highly sensitive sensing with a linear range of several orders of magnitude [79]. Magnetite possesses distinguished properties which one could benefit from. However, it suffers from agglomeration due to its high surface energy and poor conductivity. Therefore, incorporating

magnetite and graphene will enhance the conductivities of magnetite nanoparticles, reduce the agglomeration, improve the effective surface area and accelerate the rate of electron transfer across the electrode surface. This will eventually promote the sensitivity and stability of the analytical response [77, 78]. Table 4 outlines the graphene-magnetite modified electrode in electrochemical sensor application.

Table 4. Graphene-magnetite modified electrode in electrochemical sensor

Electrode	Analyte	Detection Method	Detection Limit	Linear Range	Refs.
C-rGO/Fe_3O_4	Dopamine	CA	7.00 nM	0.01 – 100.55 μM	[80]
Fe_3O_4/r-GO	Dopamine	DPV	0.08 μM	0.40 – 3.50 μM	[81]
Fe_3O_4/r-GO	H_2O_2	CV	6.00 nM	0.02-19.00 μM	[81]
CR-GO	H_2O_2	CV	0.05 μM	0.05 – 1500 μM	[82]
Fe_3O_4-Au/HRP	H_2O_2	CV	12.00 μM	0.02 – 2.50 mM	[83]
Fe_3O_4/GO	Prostate Specific Antigen (PSA)	Amperometric	15 fg/mL	0.1 – 1000 nM	[84]
Fe_3O_4/GO	Prostate Specific Membrane Antigen (PSMA)	Amperometric	4.8 fg/mL	1 – 10000 nM	[84]
Fe_3O_4/r-GO	NADH	CV	0.40 μM	15.00-190.00 μM	[81]
CR-GO	NADH	CV	10.00 μM	40.00-800.00 μM	[82]

Super-capacitor

As a type of electrochemical energy storage device, supercapacitors have received considerable attention because of their high-power density, fast charging/discharging rate, long cycle life, and low equivalent series resistance. A supercapacitor is ideal for numerous applications such as portable devices, electric vehicles, and flexible electronic devices [85]. Many parts make up a supercapacitor, including current collectors, electrodes, electrolytes, and separators. The separator's function is similar to that of the battery's separator. It isolates the two electrodes, allowing ions to travel through while preventing a short circuit between them. The basic principle of supercapacitor energy storage is to store electrical energy via an electric double-layer capacitance generated by charge separation at the electrolyte-bath solution interface [86]. Depending on the charge storage mechanisms, supercapacitors are divided into two main categories, including electrical double-layer capacitors (EDLC), which are based on the charge storage mechanism at the electrode/ electrolyte interface [87] and pseudocapacitance that relies on fast and reversible redox reaction that occurs at the surface of active materials [88, 89]. Electrostatic double-layer capacitors (EDLCs) use carbon electrodes or derivatives electrode-electrolyte (non-faradaic process) [90], while electrochemical pseudocapacitors use metal oxide or conducting polymer electrodes, reversible redox reaction (faradaic process) [91] with a high amount of electrochemical pseudocapacitance additional to the double-layer capacitance. By extending the electrode–electrolyte contact with nanomaterials with large specific area, the EDLC contribution can be boosted even more [92].

The distinctive properties of graphene will enhance the flexibility of the electrode and provide maximum adhesion with minimal distance between the electrode and electrolyte interface; thus, the charge-storage mechanism will eventually be more efficient [93]. However, to further improve the performance of supercapacitor, a nanosized transition metal oxide

incorporated with carbonous material is one of the promising solutions.

The incorporation of magnetite with graphene reduces the aggregation of Fe_3O_4 nanoparticles as the native magnetite is found to be low conductive. Thus the capacity of magnetite-based supercapacitors is easily faded [96]. To overcome this problem, most of the Fe_3O_4 nanoparticles will be attached onto the surface of graphene therefore, the immobilisation of the magnetite particles on the surface of graphene would eventually lower the intensity of the aggregation as graphene had high conductivity and more electrochemical stability. Magnetite-graphene composite considerable as excellent electroactive materials as the composite being composed of 30 Fe_3O_4/r-GO bilayers which reported from Wang *et al.*,., 2014 being synthesised through a layer-by-layer self-assembly method on silicon or indium tin oxide (ITO) substrate and it provides the capacitance, C_s of 151 Fg^{-1} at 0.9 Ag^{-1} [97]. Another work reported by Wang *et al.*,., 2014 provide a capacitance, C_s of 220.1 Fg^{-1} at 0.5 Ag^{-1} by the production of magnetite-graphene via hydrothermal reaction method [98]. Table 5 displays different composites of magnetite graphene used as supercapacitors. Moreover, Table 6 below illustrates advantages, disadvantages and challenges in each application, batteries, fuel cell, corrosion, sensor and supercapacitors

Table 5. Different composites of magnetite graphene used as supercapacitor

Electrode Materials	**Current Collector**	**Electrolyte**	**Highest Specific Capacitance (Fg^{-1})**	**Current Density (Ag^{-1})**	**Refs.**
Multilayer rGO	Au-sputtered	PVA/H_3PO_4	247.3	0.176	[99]
Graphene hydrogel	Au-coated PI	PVA/H_2SO_4	186.0	1.000	[100]
CNT-graphene/Fe_3O_4 nPs	Au-coated PET	Filter paper/Na_2SO_4	200.4	1.000	[101]

Fe_3O_4/C core shell microsphere	-	1M KOH	110.8	0.500	[103]

Table 6. Summary of advantages, disadvantages and challenges between applications

Applications	**Advantages**	**Disadvantages**	**Challenges**	**Ref.**
Batteries	High electrical conductivity, big Li^+ storage capacity, greater reversible capacity, high-rate performance, and cyclic stability.	Large surface area of rGO tends to restack, causing passivated solid electrolyte interface (SEI) film forms and irreversible electrolyte consumptions, resulting in capacity fading and low Coulombic efficiencies	Fabricating three-dimensional (3D) rGO or porous rGO to reduce agglomerations of graphene sheets and increase the active surface area, resulting in fast diffusion	[40-43]
Fuel cell	Surface of the electrocatalyst will not be inactivated prematurely. The catalyst is easy to recycle, which saves money and protects the environment	Graphene sheets tend to restack due to the attractive forces between graphene sheets, leading to a decrease in the availability of active sites	The choice of carrier material is key to the activity, selectivity, durability and cost-effectiveness of a catalyst.	[43]
Corrosion	Preventing the transport of corrosive or oxidative species toward the underlying substrate without notably altering its thermal conductivity and optical properties	Poor adhesion of graphene-based coatings to the most engineering metals	Graphene-based coatings produced directly on metallic surfaces do not improve corrosion protection	[72, 73]
Sensors	High sensitive sensing with a linear range magnitude nanoparticles can be highly dispersed on its surface, and the charge transfer at the interface of these hybrid materials can provide a synergistic effect	Decreasing interfering species' non-specific adsorption, and (3) maintaining the sensor's repeatability and stability in complicated actual matrices	Sensitive to temperature and, therefore, the sensors typically are internally temperature compensated greater the exposure to the target gas, the shorter the life span	[79, 80]

Table 6 (cont'd). Summary of advantages, disadvantages and challenges between applications

Applications	Advantages	Disadvantages	Challenges	Ref.
Super Capacitors	Can be coupled to generate hybrid nanostructures with EDLC and pseudocapacitive capabilities. Adding Fe_3O_4 to the anode boosted both the power output and the anodic capacitance	Poor electrochemical stability and had low conductivity	Limitations in transferring capacitive (F) performance values to bigger scales or commercial devices that retain the desirable properties of EDL SCs that outperform the current supercapacitor generation	[40-43]

Stability and Reusability

The stability and reusability of the magnetite graphene nanocomposite are important aspects to be considered to avoid any loss of cost and energy. The magnetite graphene composite seems to be potential material to supplement the techniques in use due to particular characteristics such as selectivity, low building and storage cost, miniaturising potential, easy automaticity, and simple to build and portable apparatus.

For example, work using batteries application as described by Li et al. revealed that the capacity of the magnetite graphene composite was ~434 $mAhg^{-1}$ after 50 cycles which is still 61% of the initial capacity (709.6 $mAhg^{-1}$) [105]. Another work presented by Zhou et al., uses graphene wrapped Fe_3O_4 nanoparticles for anode materials in applying lithium-ion batteries. The charge capacity of the magnetite graphene remained at 950 $mAhg^{-1}$ from the initial capacity even after the 85^{th} cycle which demonstrates the improvement of cycling stability of the composite. The Coulombic efficiency of the magnetite graphene after the second cycle remained close to 100% until the 30^{th} cycle. The magnetite graphene composite is also reported to exhibit an outstanding cyclic ability where it retains 91% of its initial capacity after 100 cycles when tested at a higher current density of 700 $mAhg^{-1}$ [106].

Based on the work conducted by Guo et al., which used magnetite modified graphene for oxygen reduction reaction (ORR) of fuel cell application, the composites exhibited outstanding stability and a four-electron transfer pathway, suggesting the direct reduction of oxygen to water. The nanocomposite decorated graphene also displayed superior oxygen reduction reaction activity with a half-wave potential of 0.85 V and 0.97 V of the onset potential, where the value is higher than the commercial 20 wt% Pt/C electrode [107].

On top of that, Vinodha et al. also used magnetite graphene as an electrode modifier for detection of hydrazine, The stability of Fe_3O_4-rGO were determined through the stability curves of the composite/GCE between the potential of negative 1 (-1) to positive 1 (+1) at a scan rate of 0.05 Vs^{-1} in 0.1M PBS solution. The composites reached their stable form at 30th cycle after continuous cycle. The redox peak current density decreased evenly before the 30th cycle. Once the magnetite graphene composite reaches its stable form, the stability of the composite remains until the 35^{th} cycle. The reproducibility and reusability properties remained 95.16% from the original detection limit after a gap of 20 days of analysis [108, 109-111].

Long term stability of magnetite graphene composite also has been reported by Ghasemi et al., which used the

composite for supercapacitors application. The composite being tested for 500 cycles by repeating the charge/discharge test, and during the first 100 cycles, it is being observed that it is only a slight increase, and the composite remains 87% of the initial capacitance after 500 cycles and only 3% decay in the capacitance [89,111-113].

Future Perspectives

Magnetite nanoparticles decorated on graphene sheets require comprehensive understanding both theoretically and experimentally. To improve this aspect, researchers are encouraged to use advanced physical characterisation techniques to deeply comprehend the control of the iron oxide nanoparticles' shape, size, crystallinity, distribution, and phase composition onto the graphene sheets. It is recommended to study the electrocatalytic efficiency of the nanocomposite towards ORR that can be further analysed using RDE and RRDE voltammetry techniques, where exposure to hydrodynamic effect and kinetic parameter will be obtained. The synthesis and production of high-quality graphene sheets also need extra attention. The in-situ production may lead to several defects and low purity of product as the core is graphene before magnetite is embedded into the sheets. Small-scale consumption of the nanocomposite in the electrochemical field can be enhanced into big-scale production, which can be used in energy generation plants as a primary source of renewable energy. The appropriate storage of Fe_3O_4/rGO is vital to avoid any contamination towards the sample or oxidation process to maghemite or hematite. The nanocomposite can be used extensively in other fields other than energy production, such as biomedical imaging, wastewater treatment, or water pollution removal. The properties of the nanocomposite might boost and give better-targeted yield throughout applications. Magnetic graphene can be further studied for its usage in human body for bone regeneration surgery treatment. The nanocomposite can be further modified with the addition of different, non-metallic nanoparticles to prolong the lifetime of the nanocomposite and give an increase in surface area and added exceptional properties.

Conclusion

Most of the process to synthesise magnetic graphene oxide is environmentally friendly, obeying the green chemistry rule. Graphene oxide is used as a unique and excellent material in the research field. Magnetic compound integration into GO strengthens the nanocomposite with more active sites and a larger surface area. A various alternative has been found recently to overcome the dependency of fossil fuels that will deplete sooner in the current rate of usage. Fuel cell is the brainchild of scientists who have a more excellent prospect in future; however, not favoured due to high costs due to the requirement of expensive materials such as platinum for generation of energy. Small scale energy production such as batteries improved its efficiency by the usage of magnetite graphene oxide nanocomposite. In corrosion, the nanocomposite layer proved to be better in protecting metal surfaces. Use of magnetite graphene oxide nanocomposite also improvises any gadgets and instruments applied. The simple method of production that obeys the green chemistry rules makes the production of the nanocomposite is safer and can be done at low cost. This is important as it is beneficial to industries and developing countries to cut-cost of energy production mainly. The material would be the most applied compound in wider fields in the future.

Abstract

A simple, convenient, economical and especially environmentally friendly method for ethanol analysis in gasohol was developed. The ethanol was extracted from gasohol by water based on 'like dissolved like' principle and then determined by simply weighing the water ethanol mixture using an analytical balance as a detector. The parameters that effect on the extraction such as extraction device, extraction ratio and sample volume were investigated. The results showed the correlation coefficient was 0.9976 for linear ranges 3-100% (v/v). Since this correlation coefficient was nearly 1 the relationship between ethanol content in gasohol and weigh of extracted water was linear. The limit of detection (LOD) and the limit of quantitation (LOQ) were 1.4% (v/v) and 4.6% (v/v), respectively. The percentage recovery (%Recovery) was 88-111%. The proposed method was successfully applied for determination of ethanol content in some gasohol products produced in Thailand and validated by gas chromatographic method (GC). The results obtained from the developed method was not significantly different from the GC at 95% confidence level (t_{stat} = 2.41, t_{crit} = 2.78).

Keywords: a reagent-less method, ethanol analysis, gasohol, analytical balance, green analytical method

Abstrak

Kaedah mudah, meyakinkan, ekonomik dan mesra alam bagi analisis etanol di dalam gasohol telah dibangunkan. Etanol yang diekstrak dari gasohol oleh pelarut air berasaskan prinsip larutan suka pelarut dan kemudian ditentukan melalui timbangan campuran air dan methanol menggunakan penimbang analitikal sebagai pengesan. Parameter yang memberi kesan terhadap pengekstrakan seperti alat pengesktrakan, nisbah pengekstrakan dan isipadu sampel telah dikaji. Keputusan menunjukkan pekali korelasi ialah 0.9976 untuk julat kelinearan 3-100% (v/v). Nilai pekali korelasi yang menghampiri 1 menjelaskan hubungan linear antara kandungan etanol dalam gasohol dan berat pelarut air yang diekstrak. Had pengesanan (LOD) dan had pengkuantitian (LOQ) masing -masing ialah 1.4% (v/v) dan 4.6% (v/v). Peratus perolehan semula ialah 88-111%. Kaedah yang dicadang telah Berjaya digunapakai bagi penentuan kandungan etanol di dalam beberapa produk gasohol di Thailand dan ditentusahkan melalui kaedah gas kromatografi (GC). Keputusan yang diperolehi tidak menghasilkan perbezaan secara signifikan pada aras keyakinan (t_{stat} = 2.41, t_{crit} = 2.78).

Kata kunci: kaedah tanpa reagen, analisis etanol, gasohol, penimbang analitikal, kaedah analisis hijau

Introduction

Today gasohol is used as an alternative energy source and is very popular in many countries around the world, for example America, Canada, Brazil, Kenya, Paraguay, Spain, Sweden, Australia and China. In Thailand there are attempts bring to use gasohol as a supplement or replacement fuel instead of crude oil because of several advantages including being more environmentally friendly [1-3]. Gasohol usually consists of a mixture of gasoline (fossil fuel) and purified ethanol (99.0-99.5% purity) in various proportions. Generally, ethanol or ethyl alcohol can be produced from natural raw materials such as sugar cane and cassava. Inferences can supply and growing up in a short time [4-7]. Then the gasohol is not only used as a green fuel for people around the world, but it can help agriculturalists' revenue around the world also. Especially Thailand, it is an agricultural land. Due to foreseeing of the Royal Majesty the King Rama 9, the gasohol was occurred in 1985 by the Royal Development project. Then, the gasohol in Thailand has started at that time and has developed continuously to this day [8-10]

The different percentages of ethanol which are added into gasoline, are by the E-number, for instance E10 contains 10% (v/v) purified ethanol and 90% (v/v) gasoline. The advantages of ethanol blending with gasoline base-fuel include decreasing toxic combustion products, reduced price, increasing agriculture and boosting the octane number of the fuel. It is important that the ethanol content be monitored to control the quality of the fuel [11, 12].

Since, the quality of gasohol depends on the amount of ethanol added to the gasoline, the determination of ethanol in fuel ethanol is important to the oil and petroleum industry. There are many methods available to investigate the ethanol content in fuel including those based on chromatography, spectroscopy and electrochemistry. For example, chromatographic methods; gas chromatography (GC) is used as a standard method for determination of ether and alcohols in gasoline (ASTMD 4815-03) [13] and a liquid chromatography method was reported by Zinbo in 1984 [14] for the determination of C1-C3 alcohols in gasoline and alcohol blends using a mixed mode of size-exclusion and adsorption liquid chromatography (LC). In 2018, Morine et al., described the determination of ethanol in gasoline by high performance liquid chromatography (HPLC) [15]. In addition, GC was also used for determination of alcohols in other samples such as groundwater and surface water [16]. Spectroscopic methods; one of spectroscopy for ethanol analysis in fuel gas was infra-red spectroscopy (IR) [17, 18]. In 1981, Battiste et al. presented the measurement of ethanol concentration in a series of gasohol using IR-reflectance detection [17]. In 2003, Mendes et al. exhibited Fourier Transforms (FT)-near infra-red and FT-Raman spectrometry to analyze the ethanol content in fuels and beverages [18]. Flow based methods have also been used for analysis of ethanol in fuel [1, 19, 20]. Electrochemical method such as voltammetry [21, 22] and amperometry [23, 24] are often chosen for ethanol analysis. However, all the above methods require chemical reagents, sophisticated instruments and operators with special expertise. At the present time "green analytical methods" have become widely popular.

The main objectives of these methods are reduction of environmentally harmful chemicals and the harm caused using chemicals. The reagent-less method is one of the green analytical method. It is widely popular in various fields. The ultimate aim is to develop reagentless analytical strategies in this case for determination of the ethanol content in gasohol. The method is based on ethanol extraction from gasohol into distilled water and simply weighting the extract using an analytical balance .

Materials and Methods

Reagents and chemicals

An analytical balance Model RC 250 S (Scientific Promotion CO., LTD) and 10 mL syringe with metal lure lock (Mira) were used in the "reagent-free" analytical method. A UV-Visible Spectrophotometer model HP 8453 (Hewlett Packard CO., LTD) was used for the extraction efficiency study. A gas chromatograph (GC) model HP 6890 (Hewlett Packard CO., LTD) was used as the standard calibration method for ethanol.

Analytical procedure

The "reagent-free" method for analysis of ethanol in

gasohol fuels was as follows: 3 mL of distilled water and then 1 mL of gasohol or based fuel was withdrawn into a 10 mL graduated syringe. The needle of syringe was inverted with the needle up and the solution was mixed well by pulling the plunger in and out for 2 min. The syringe was placed with the needle down and left united the water and oil layers separated. The extracted bottom water/ethanol layer was transferred into a vial for weighing using an analytical balance. Finally, the weight was analyzed to determine the amount of ethanol in gasohol. The schematic diagram of this extraction is shown in Figure 1 Additionally, the ethanol content analyzed by the proposed method were compared to that obtained by the standard GC method [25], [26].

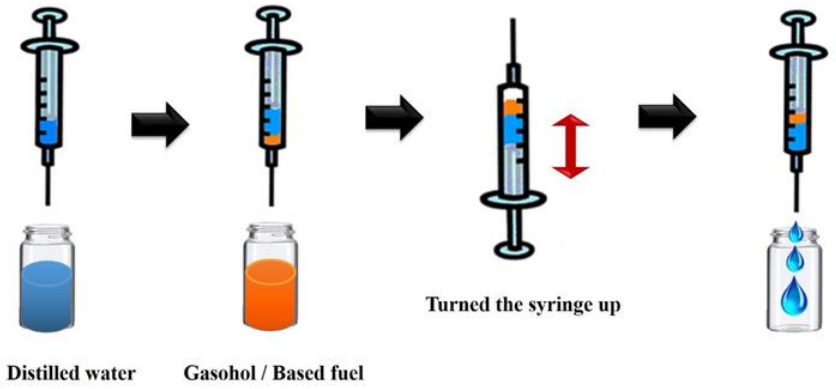

Figure 1. The schematic diagram of the 1st method that proposed for ethanol extraction from gasohol.

Optimization of the extraction device

The devices for extraction of the ethanol from gasohol studied here were burette, glass vial, modified burette and syringe with metal lure lock as shown in the Figure 2. These were used for extraction of standard gasohol fuel with various concentrations of ethanol content of 0, 10, 20, 40 and 60*%v/v.* The extraction procedure using these various devices was done according to topic 2.3. The extraction ratio used in this study was 1:2 (gasohol: distilled water) for plotting the calibration. The calibrations were plotted between the extracted water weight (y-axis) and concentrations of standard gasohol (x-axis) using different extraction devices.

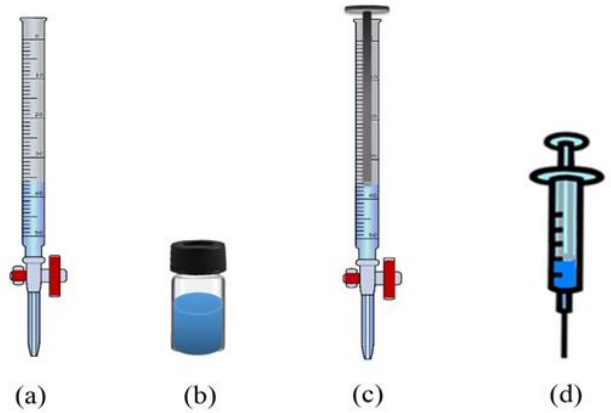

Figure 2. The devices used for the study of ethanol extraction from gasohol (a) commercial burette (b) glass vial (c) modified burette and (d) syringe.

Extraction ratio and sample volume

According to the experiment procedure (Analytical procedure), the ratio of gasohol fuel and distilled water was varied among 1:1, 1:2 and 1:3. In this study, the sample volume of 1 mL was used for varying these ratios. For sample volume study, the optimum ratio was used in this investigation varying the sample volumes of 0.6, 1.0 and 2.0 mL, respectively. Both studies, the comparisons of absorbance between the extracted ethanol and standard ethanol in water were studied using the regression line method as criterion.

Results and Discussion

Extraction device

These devices: burette, glass vial, modified burette and syringe with metal lure lock were used for the optimized extraction device study. The linearity, sensitivity and correlation coefficient (r^2) were considered as criterion for the suitability of the extraction device. As shown in the Table 1, the sensitivities, which were slopes of the linear equations, were almost identical (0.0143-0.0149). However, the correlation coefficient (r^2) created from the syringe was the closet to 1 (0.9896), while r^2 for the glass vial was slightly lower (0.9619) probably because of the many transfers step involved. Thus, the vial method was found to be less suitable as an ethanol extraction device. Considering the relative standard deviation (%RSD), the results illustrated that the highest value and subordinate values were burette, vial, modified burette and syringe, respectively (Table 1). This indicated that both the modified burette and syringe exhibited good precision. Nevertheless, considering convenience, controlling the volume of distilled water or gasohol using the modified burette was more difficult than the syringe. Consequently, the syringe with a metal lure lock was chosen as the most appropriate extraction device for extraction of ethanol.

Table 1. Linear equation, correlation coefficient, relative standard deviation (%RSD) of all studied extraction devices: burette, glass vial, modified burette and syringe

Extraction device	Linear equation	Correlation coefficient (r^2)	%RSD (n= 3)
Burette	y = 0.0145x - 0.0144	0.9778	1.8
Glass vial	y = 0.0149x - 0.0285	0.9619	0.9
Modified burette	y = 0.0147x + 0.0650	0.9823	0.7
Syringe	y = 0.0143x + 0.1336	0.9896	0.6

Optimization of the extraction condition: Extraction sequence

The extraction sequence was studied by different series of gasohol and distilled water. Here, the sequence of extraction was divided to 3 sets: (i) suction of 4.0 mL distilled water and then 2.0 mL standard gasohol (ii) suction of 2.0 mL standard gasohol and then 4.0 mL distilled water (iii) the series of 2.0 distilled water, 1.0 mL standard gasohol, 2.0 distilled water and finally 1.0 mL standard. The criteria sensitivity and relative standard deviation (%RSD) were used to compare the methods. The results shown in Table 1, found that the 3rd method gave the highest sensitivity due to the higher surface contact between the gasohol and water. However, it was found that this method also gave a poor method precision (the highest %RSD). It may because of difficult control of the capacitance of these solutions. The 2nd method gave the lowest slope of linearity range (sensitivity) compared to other methods, perhaps due to the easier evaporation of ethanol in gasohol. In the 1st method, the distilled water was pulled first and the gasohol was sucked later. Ethanol in the gasohol could be more easily trapped in the distilled water than in the 2nd set. It may be reason of the sensitivity of the 2nd one showed the higher value (slope of linearity). In addition, the precision in the 1st set was greater than the 2nd method (%RSD = 0.7467 and 1.0237 for the 1st and the 2nd sets, respectively). Consequently, the 1st method was selected for the extraction of ethanol content in gasohol for further work.

The ratio of gasohol and distilled water

In this study, the ratio of gasohol fuel and distilled water was varied among 1:1, 1:2 and 1:3. The absorbance of extracted ethanol results was compared to these of standard ethanol in water using the regression line method is shown in Figure 3. As a compromise between the correlation coefficient (r^2) and extraction percentage for these ratios (Table 2), a ratio of 1:3 was chosen for further work (Figure 3).

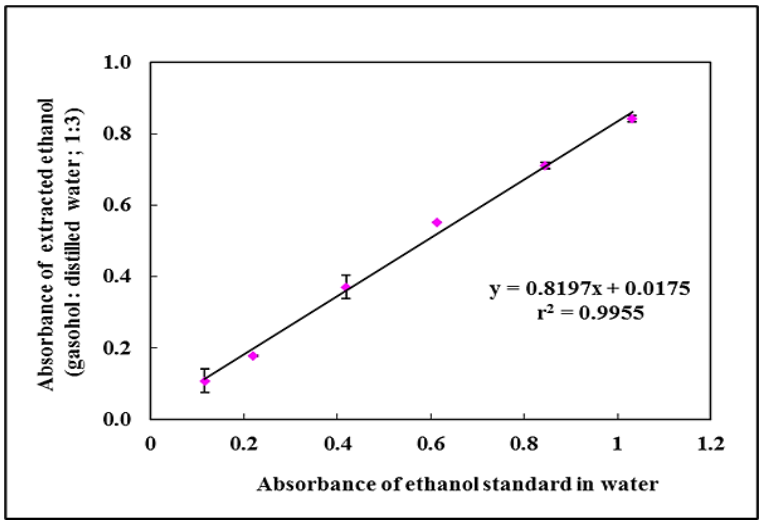

Figure 3. The plot of absorbance of extracted ethanol in water (from gasohol) and standard ethanol (the regression line method)

Table 2. Linear equations, correlation coefficient (r^2) and extraction percentage of standard ethanol for the extraction at various ratios of samples (gasohol) and distilled water

Ratio of extraction	Linear equation	Correlation coefficient (r^2)	Percentage extraction of extracted ethanol at various concentrations (%*v/v*)					
			10	20	40	60	80	100
1 : 1	y = 0.0177x + 0.0264	0.9964	71	72	62	53	52	50
1 : 2	y = 0.0178x - 0.0612	0.9976	85	86	60	76	76	72
1 : 3	y = 0.0175x - 0.0273	0.9958	94	82	89	90	84	82

Volume of gasohol and distilled water for 1:3 ratio extraction

The volume of standard gasohol and extractant (distilled water) at 1:3 extraction ratio was studied. The volume (mL) of gasohol : distilled water was 0.6: 1.8; 1.0: 3.0; 2.0: 6.0 mL, respectively. The standard gasohol concentrations of ethanol content of 0, 10, 20, 40, 60 and 100 %*v/v* were studied for construction of calibration plots. The results (Figure 4) showed that the ratio of 2.0 mL gasohol : 6.0 mL distilled water gave the highest

sensitivity and r^2. Thus, the volume of standard gasohol fuel and distilled water of 2.0 : 6.0 mL was selected for all subsequent experiments. Finally, the optimized extraction conditions for the 'reagent-free' method were in Table 3.

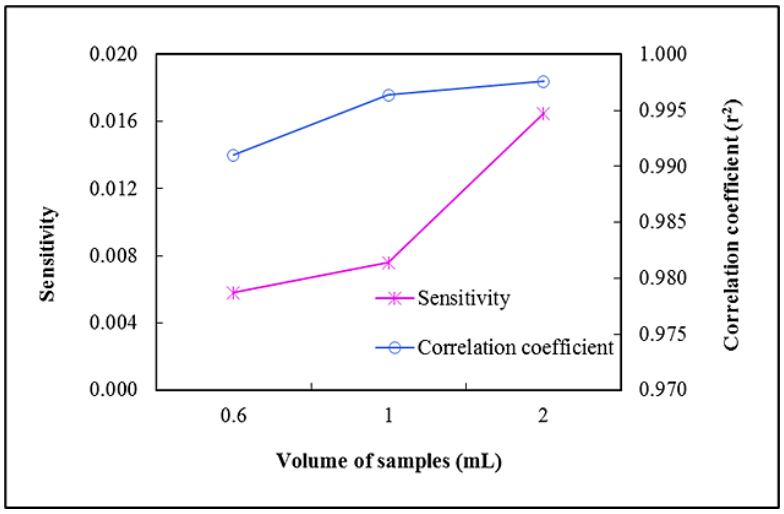

Figure 4. The relation plots of sensitivities (pink line) and correlation coefficient (r^2) (blue line) of the extraction method with ratio of sample or gasohol : distilled water of 1:3 with sample volumes

Table 3. Optimization of experimental parameters for extraction of ethanol in gasohol

Parameter	**Studied Condition**	**Selected Condition**
Extraction sequence	1st method (the distilled water was pulled first, and the gasohol was sucked later). 2nd method (the gasohol was pulled first, and the distilled water was sucked later). 3rd method (switching the distilled water and gasohol).	1st method
The ratio of gasohol and distilled water	1 : 1 1 : 2 1 : 3	1 : 3
Volume of gasohol and distilled water for 1:3 ratio extraction (mL)	0.6 : 1.8 1.0 : 3.0 2.0 : 6.0	2.0 : 6.0

Analytical performance: Linearity range

The capability of the proposed method for ethanol analysis was investigated using 'reagent-free' method. This method showed the two linearity ranges of 3-100 %*v/v* with r^2 of 0.9976 as shown in Figure 5.

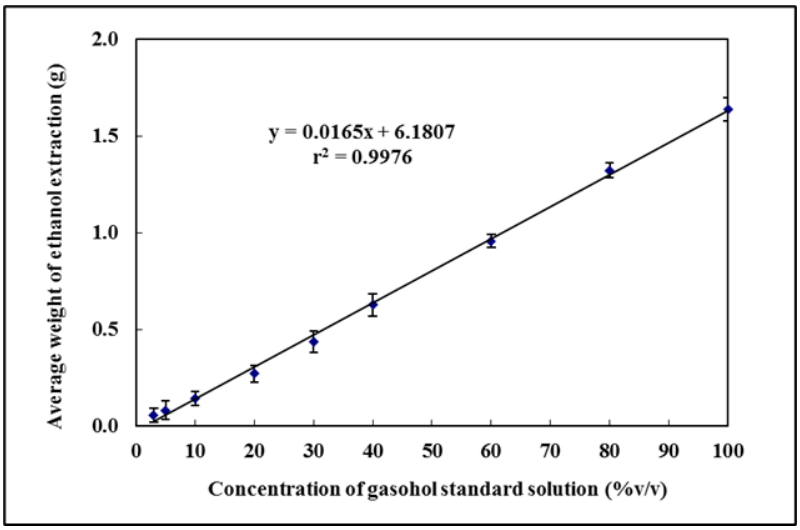

Figure 5. The calibration plots from the 'reagent-free' method corresponding to different concentrations of ethanol in the range of 3 to 100 %*v/v*

Limit of detection (LOD) and limit of quantitation (LOQ)

The LOD was 1.4 %*v/v* while the LOQ was 4.6 %*v/v* (Table 4), these were calculated by 3SD/slope and 10SD/slope, respectively. SD is the standard deviation of a series of replicate analyses and the slope is the gradient of the calibration curve.

Table 4. Analytical parameters for determination of ethanol in gasohol using 'reagent-free' method

Parameter	Optimized Value
Linearity range (%*v/v*)	3 - 100
Linear equations:	y = 0.0165x + 6.1807 (r^2= 0.9976)
LOD (%*v/v*)	1.4
LOQ (%*v/v*)	4.6
% RSD (n=10)	<1
% Recovery	88.0 -111

Repeatability

The precision of the method or repeatability is represented by the relative standard deviation (%RSD). For concentrations of standard gasohol were 10 and 20%*v/v*, the %RSD of the weight were less than 1% for 10 replicate analyses (Table 5). This indicated that the proposed 'reagent-free' method provided a good precision for determination of ethanol in gasohol fuel.

Table 5. Relative standard deviation (%RSD) for precision study of the proposed method

Ethanol Concentration (%*v/v*)	**Average Weight of Extracted Ethanol (g)***	**Relative Standard Deviation (%RSD)**
10	6.3688 ± 0.0466	0.73
20	6.4977 ± 0.0610	0.94

Note * n = 10

Recovery percentage

To test the accuracy of the ethanol analysis in gasohol fuel the standard addition method with the reagent-free method was used to evaluate as the recovery percentage. Normally gasohol fuel (10% *v/v*) called E10, is found at fuel service stations in Thailand. Thus, different brands of E10 were used in this study. The recoveries achieved for the samples spiked with various concentrations of ethanol were in the range of 88 -111% as shown in Table 6. This indicated that the proposed method was reliable for determination of ethanol in real samples.

Table 6. Recovery percentage for determination of ethanol in gasohol samples using the developed method

Sample	**Concentration of Ethanol (%*v/v*)**				**Recovery (%)**
	Added	**Found (mean ± SD; n = 3)**			
A	-	9.1	±	0.0106	
	5	13.6	±	0.0173	89.8
B	-	9.8	±	0.0091	
	5	15.3	±	0.0116	111
C	-	8.9	±	0.0093	
	5	14.3	±	0.0076	108
D	-	9.3	±	0.0214	
	5	13.7	±	0.0138	87.6
E	-	19.8	±	0.0084	
	5	25.7	±	0.0168	117

Sample analysis

The determination of the ethanol content in gasohol fuel (real samples) was achieved using the external standard method. The results obtained using this method agreed with the data from gas-chromatography (GC) for all samples as shown in Table 7. The paired *t*-test [27] showed that the ethanol contents in real samples determined by the reagent-free methods were not significantly different from the contents given by gas-chromatography the at the 95% confidence level (t_{stat} = 2.41, t_{crit} = 2.78). This showed that the developed method was accurate and reliable for determination of ethanol in gasohol

Table 7. Validation of the 'reagent-free method' by comparison the results with the standard gas chromatography

Sample	Type Of Gasohol	The Proposed Method	Standard Method (Gas-Chromatography: GC)
A	E10	9.3 ± 0.1	10.7 ± 0.1
B	E10	10.7 ± 0.6	10.2 ± 0.1
C	E10	10.0 ± 0.6	11.3 ± 0.2
D	E10	9.2 ± 1.5	10.0 ± 0.1
E	E20	19.5 ± 0.6	20.8 ± 0.3

Note: E10 is 10% *v/v* and E20 is 10% *v/v* of ethanol added in based fuel. Sample A-E were purchased from the gas stations in Chonburi province of Thailand

Conclusion

A reagent-free method was developed and applied to the analysis of ethanol content in gasohol fuel. The proposed experimental process uses no chemicals including using syringes in the experimental procedure that are commonly available is easy. Especially, other experimental devices are simple and economical. The responses of the method were found to be linear in the range of 3-100 %*v/v* of ethanol, Additionally, a comparison of the accurate values given by the gas chromatographic method and the proposed method revealed that there is no significant difference between the two methods. This suggests that the proposed method is valid alternative for determination of ethanol in fuel. Additionally, another application of the proposed method is in education especially quantitative analysis. Due to simple equipment non-toxicity and easy to operation.

Abstract

This study highlighted preliminary studies on photodegradation of 2-chlorophenol using MoS_2/rGO photocatalyst with different weight ratios under sunlight irradiation. The 2-chlorophenol is known as one of the most dangerous pollutant due to its hazardous properties of mutagenicity, carcinogenicity and eco-pollutant. The MoS_2/rGO photocatalysts were synthesized using the hydrothermal method and used for the degradation of 2-chlorophenol under solar light irradiation. Three different compositions of MoS_2/rGO (1%, 5% and 15%) were synthesized with different weight ratio of MoS_2. The composites material of MoS_2, GO and MoS_2/rGO was characterized by FTIR and XRD indicating successful formation of MoS_2/rGO composites. The photodegradation of the 10 ppm of 2-chlorophenol were observed under the exposure of sunlight for 180 minutes and analyzed using UV-VIS to measure percent degradation of 2-chlorophenol. 1% MoS_2/rGO has been chosen as the composite to degrade 2-chlorophenol due to having the highest percent degradation of 51.41% among other photocatalysts.

Keywords: graphene oxide, molybdenum disulfide, photocatalytic degradation, semiconductor photocatalyst, solar irradiation

Abstrak

Kajian in menekankan kajian awal mengenai fotodegradasi 2-klorofenol dengan menggunakan berat ratio pemangkin cahaya MoS_2/rGO yang berlainan dibawah radiasi matahari. 2-klorofenol dikenali sebagai salah satu bahan pencemar yang mempunyai ciri-ciri merbahaya seperti mutagenisiti, karsinogenik dan eko-pencemar. Komposit MoS2/rGO telah disintesis menggunakan kaedah hidroterma. Kaedah fotokatalisis yang menggunakan MoS_2/rGO sebagai pemangkin cahaya untuk merosotkan 2-klorofenol dibawah sinaran matahari. Tiga komposisi MoS_2/rGO yang berlainan (1%, 5% and 15%) telah disintesis menggunakan nisbah berat MoS_2 yang berbeza. Bahan komposit MoS_2, GO dan MoS_2/rGO yang dicirikan menggunakan FTIR dan XRD telah menunjukkan hasil jaya pembentukan komposit MoS_2/rGO dengan jayanya. Penyusutan sinaran oleh 10 ppm 2-klorofenol telah diperhatikan dibawah sinaran matahari selama 180 minit telah dianalisiskan dengan UV-VIS untuk mengukur peratus penyusutan sinaran 2-klorofenol. 1% MoS2/rGO telah dipilih untuk merosotkan 2-klorofenol kerana mempunyai peratusan penyosotan yang tinggi iaitu 51.41%.

Kata kunci: grafena oksida, molibdenum disulfida, degradasi fotokatalitik, pemangkin cahaya semikonduktor, penyinaran suria

Introduction

2-chlorophenol is one of the chemical groups derives from chlorophenol that were made by electrophilic halogenation of phenol with chlorine. It is widely known as one of the most priority pollutants by the US Environmental Protection Agency and World Health Organization (WHO) based on its properties of strong odor, mutagenicity, carcinogenicity and eco-persistent [1]. It is highly toxic and difficult to degrade due to its high thermal and chemical stability [2]. Even with its hazardous characteristics, it is largely used in industrial and commercial scales such as plastic, pesticide, textile, steel, pharmaceutical, iron, paper and wood preserving that were reported to be a major source of chlorophenol compound found in the wastewater [3]. It can affect organisms when it released to the environment. Thus, many studies have been made to eliminate it such as biodegradation, adsorption and Fenton-like advanced oxidation processes. However, due to utilization of extra oxidants, vigorous conditions and intensive energy input, studies are made to search for sustainable technology to degrade 2-chlorophenol. Hence, to overcome the environment issues, solar-driven photocatalysis method is being used to eliminate the contaminant in the wastewater, ground water and rivers.

Photocatalysis is known as one of the advanced oxidation processes which is a method of removing contaminants concerning wastewater effluents. Photocatalysis is a technique to degrade pollutant by using photocatalyst to utilize photogenerated carriers such as electrons and holes in order to start the redox reaction for the conversion of solar to chemical energy [4]. Photocatalysis is one of the advanced treatment technologies to degrade contaminant by using radicals produced from transition-metal oxide photocatalysts involving UV irradiation. To promote indirect hole oxidation, the electron-hole pairs are generated on the photocatalyst surface and the valence band edge of photocatalysts must be better of the oxidation potential of hydroxyl radical, •OH [5].

Table 1 examines the different types of photocatalyst materials for degradation of 2-chlorophenol.

Table 1. Degradation of 2-chlorophenol using photocatalytic degradation

Photocatalyst	Source of Light	Degradation Time	Percentage Degradation	References
Ru/TiO_2	UV light	180 minutes	50%	[6]
Cu doped $BiFeO_3$ and Ba-Cu co-doped $BiFeO_3$	Visible light	70 minutes	98% and 100%	[7]
C_3N_4/TiO_2-NTs in pH of 9 and 12	UV/ Visible light	180 minutes	25.02% and 70.25%	[8]
ZnO-ZnS@PANI	Visible light	240 minutes	89%	[9]
5% Ag-TiO_2	UV light	150 minutes	74%	[10]

Meanwhile, photocatalyst is material that absorbs light energy to facilitate chemical reaction. Semiconductor photocatalyst uses light energy to get desirable chemical transformation through reduction-oxidation (redox) reaction. The photocatalytic semiconductors are commonly used for wastewater treatment, surfaces with self-cleaning and antifogging properties, purification of outdoor air, indoor air deodorization and cancer therapy [11]. It uses suitable band gap to produce strong visible light response with a high photocatalytic presentation, non-toxicity, good thermal, inexpensive and have chemical stability [12].

Graphene is a 2-D structure of hexagonal carbon atom in the sp^2 hybrid orbital that is widely used in electrochemical energy storage, optical and optoelectronics bioengineering due to its outstanding electrical, optical, thermal and mechanical properties. Graphene and its derivatives consist of large surface area, thermal conductivity and carrier mobility. Thus, it has the high potential in energy sensors and microelectronic devices. Integration of GO with other semiconductor can effectively improve the structural stability of the composites and enhance the photocatalytic activity by hindering the recombination of photo-generated carrier. Moreover, GO-based composite can alleviate the serious agglomeration of nanoparticles to a certain extent [13, 14] . Graphene is also known as electron cocatalyst that can improve hydrogen performance of photocatalysts due to its excellent of conductivity [15]. It also has capacity for adsorption of organic pollutants and potential mechanical strength and electrical conductivity [16]. GO can give productive route for highly dispersive, band tunable and few-layer structured of graphene-based materials thus it acts as supportive material for photocatalyst semiconductor [17].

MoS_2 is a 2-D layered n-type semiconductor and has narrow bandgap of 1.20 eV for its few layers where each layers have gap value of 1.90 eV. Thus, it has large specific surface area complex edge structure and abundant unsaturated active sites. It has high thermal stability and strong absorption in visible spectrum region. MoS_2 have limitations as it has limit in energy storage and photocatalytic properties due to high recombination rate of photo-generated electron hole pairs, low energy density and poor electronic conductivity. Combining with other metal oxide nanostructures, it can improve the disadvantages of MoS_2 such as GO can enhance its photocatalytic performances [18, 19]. This can be explained by transfer of photo-generated electrons from MoS_2 conduction band to the graphene [20]. When the band gap of MoS_2 increases due to quantum confinement effects of MoS_2, it will change the redox potential of MoS_2 thus photo-generated electron can be easily migrate [21]. Therefore, this research focusses on preliminary studies on the ability of MoS_2-GO photocatalyst to degrade 2-chlorophenol from aqueous solution under sunlight.

Materials and Methods

Materials

2-chlorophenol, sulphuric acid (H_2SO_4), sodium nitrate ($NaNO_3$), graphite powder, hydrogen peroxide (H_2O_2), hydrochloric acid (HCl), sodium molybdate dihydrate ($Na_2MoO_4.2H_2O$), thiourea (H_2NCSNH_2) were purchased from Merck Sdn. Bhd. Finally, deionized water was supplied from Purite machine model Fusion system (United Kingdom) that has ultrapure water 18.2 M Ω at a flow rate of 48 L/hr.

Synthesis of GO

Graphene oxide was prepared by using modified Hummers method from pure graphite powder. Solution of 23 mL sulphuric acid, H_2SO_4, 0.5 g of sodium nitrate, $NaNO_3$ and 1.0 g of graphite powder were mixed. The solution was stirred for an hour in ice bath until it becomes dark green solution. The solution was stirred for another 4 hours after being removed from the ice bath where the solution turned into dark grey solution. The solution was transferred into a water bath and the temperature was raised to 35˚C and stirred for 30 minutes. The solution was added 250 mL of deionized water and was stirred for another 15 minutes while heated up to 70˚C then added dropwise of 10 mL of hydrogen peroxide, H_2O_2. Cool the solution as there will be exothermic reaction occurs. The solution was centrifuged three times at 3000rpm for 10 minutes and the supernatant drained, and the residual was washed HCl to obtain GO solution. The GO solution was dried

the using the oven at ˚C for 24 hours to gain powdered form of GO [22].

Synthesis of MoS_2

Molybdenum disulfide, MoS_2 was synthesized by using hydrothermal method. Firstly, 3.0 g sodium molybdate dihydrate, $Na_2MoO_4.2H_2O$, 3.8 g of thiourea, H_2NCSNH_2, 80 mL of deionized water were mixed and stirred for 30 minutes. 10 mL of 1M HCl was added to the solution and transferred into 100 mL Teflon stainless steel autoclave and heated in the oven at 120˚C for 24 hours. The solution was kept in the room temperature to let it cooled before centrifuged three times and washed with deionized water. The solution was dried in the oven at 70˚C for 24 hours [23].

Synthesis of MoS_2/GO

The solution was prepared by using ex-situ and hydrothermal method by adding 0.001 g of molybdenum disulfide, MoS_2 and 20 mL of deionized water were mixed and sonicated for 30 minutes. Another solution was prepared of 0.1 g of graphene oxide, GO and added with 20 mL of deionized water before sonicated for 30 minutes. Both solutions were added together and sonicate for another 30 minutes before transferred into the Teflon stainless steel and dry in the oven overnight at 120˚C. Centrifuged and washed the solution with deionized water three times after cooling at room temperature and dried the product at 80˚C for 24 hours [24].

Characterisations

Perkin Elmer Fourier Transform model 100 was used to identify the functional group of the sample by producing infrared absorption spectrum in the range 600-4000 cm^{-1}. Ultraviolet-visible spectroscopy solid Perkin Elmer model was used to measure light absorbance of the sample at the wavelength range of 200 to 500 nm. The model Oxford Instruments of X-ray Diffractometer (XRD) was used to determine the crystallographic structure of composites.

Degradation of 2-Chlorophenol by using MoS_2/ GO

The composites undergo screening process to determine the optimum sorbent for the extraction of 2-chlorophenol by exposing under the sunlight for 3 hours. 20 mL of 10 ppm of 2-chlorophenol was added to 10 mg photocatalyst. The degradation of 2-chlorophenol was measured using UV-visible in wavelength between 230 nm to 500 nm. Degradation percentage of 2-chlorophenol was determined by using the formula:

Degradation of 2-chlorophenol(%)

$$= \frac{Ao - A}{Ao} \times 100 \qquad (1)$$

where A_o is an initial absorption of 2-chlorophenol and A is an absorption of 2-chlorophenol at sampling time after the degradation process [25]. The natural sunlight photocatalysis was measured from April to May 2021 (Wednesday to Friday) at (2° 47' 20.3892" N, 102° 13' 4.6992" E) in Kuala Pilah, Negeri Sembilan Malaysia, (10AM- 1PM). The daily solar irradiance could reach 4.21–5.56 $kWhm^{-2}$ [26].

Results and Discussion

Figure 1 below show IR spectra of the representative composites within the range of 650 to 4000 cm^{-1}. The broad peak at 3353.94 cm^{-1} in Figure 1 represented the hydroxyl group stretching vibration of graphene oxide composite. Besides, there is also C=O stretch of carboxylic acid at 1737.46 cm^{-1}. The peak at 1163.52 cm^{-1} and 1042.35 cm^{-1} assigned to C-O-C, epoxy and C-O stretch. Next, the peak at 1588.21 cm^{-1} were corresponding to the C=C aromatic stretch group. The peaks at 862.28 cm^{-1} that were observed at the MoS2 composite corresponds to the Mo-O bond. [24]. FTIR spectroscopy in Figure 1 confirms the presence of MoS_2 and GO which indicates successful preparation of MoS_2/GO in the experiment. Moreover, there are band shifts and intensified of the spectra for different concentration of the 1%, 5% and 15% MoS_2/GO composites.

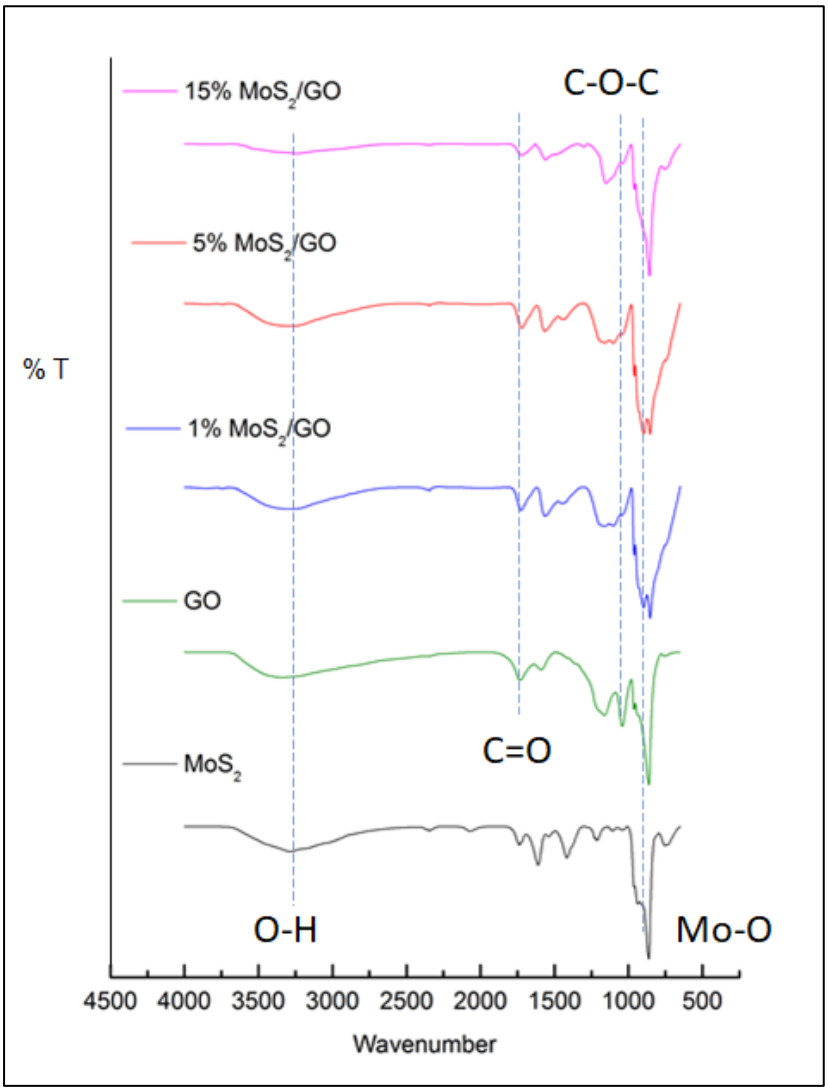

Figure 1. FTIR spectrum of MoS_2, GO and MoS_2/GO composites (1%, 5% and 15%)

Figure 2 shows diffractogram of MoS_2, GO and MoS_2/GO composites (1%, 5% and 15%). Based on the figure, the diffraction peak of GO can be seen at 2^{θ} = 24.92˚ indicating interplanar space of the GO sheet (001) [25]. MoS_2 also showed peak corresponding to (100) plane at 2^{θ} = 32.65˚ which successfully appeared at all of the mass ratio of MoS_2/GO (1%, 5% and 15%)[27][28]. Thus, it confirmed that GO and MoS_2 composites were successfully integrated.

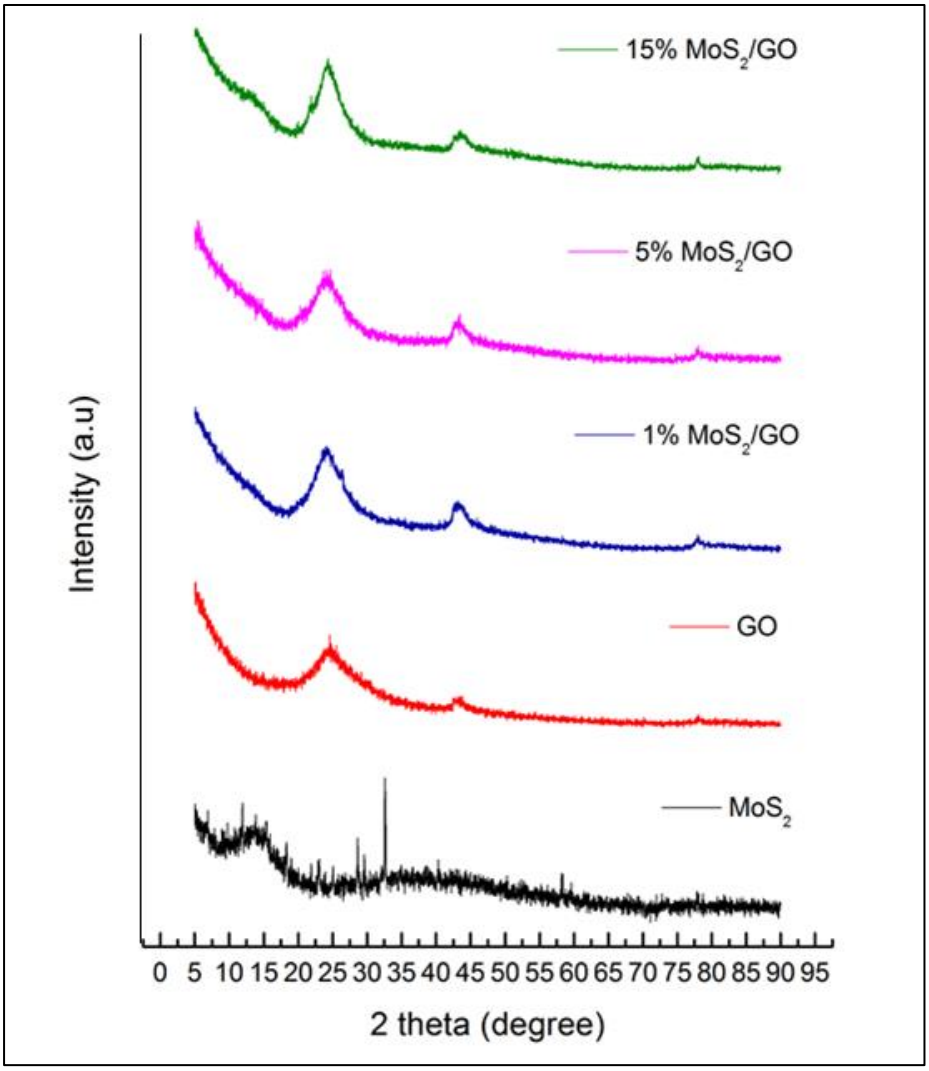

Figure 2. XRD patterns of MoS_2, GO, MoS_2/GO composite (1%, 5% and 15%)

Figure 3 reveals the photodegradation of 2-chlorophenol under sunlight using MoS_2, GO, MoS_2/GO composite (1%, 5% and 15%) photocatalyst. Successful photodegradation was monitored by decreasing in the intensity of absorbance with time irradiation. Hence, 1% MoS_2/GO proved for having lowest absorbance of 0.086 Abs. Based on the Figure 3, the MoS_2 showed an increase in absorption at 0.198 Abs of the visible light in the range of ~275 nm due to the absorption of MoS_2 in the 2-chlorophenol pollutant as it hinders complete usage of sunlight for charge carrier generation due to having wider band gap and have low mobility preventing charge transfer [29]. Moreover, rapid recombination of photogenerated electron hole pairs can decline its photocatalytic activities and poor dispersion happened when the nanomaterials are accumulated [30]. Meanwhile, Figure 4 presents the degradation percentage of all composites where the highest percent degradation is 51.41% for 1% MoS_2/GO composite due to the compatibility between graphene and MoS_2 as it enhanced the catalytic activities of amorphous producing highly efficient hydrogen production under visible light irradiation [31].

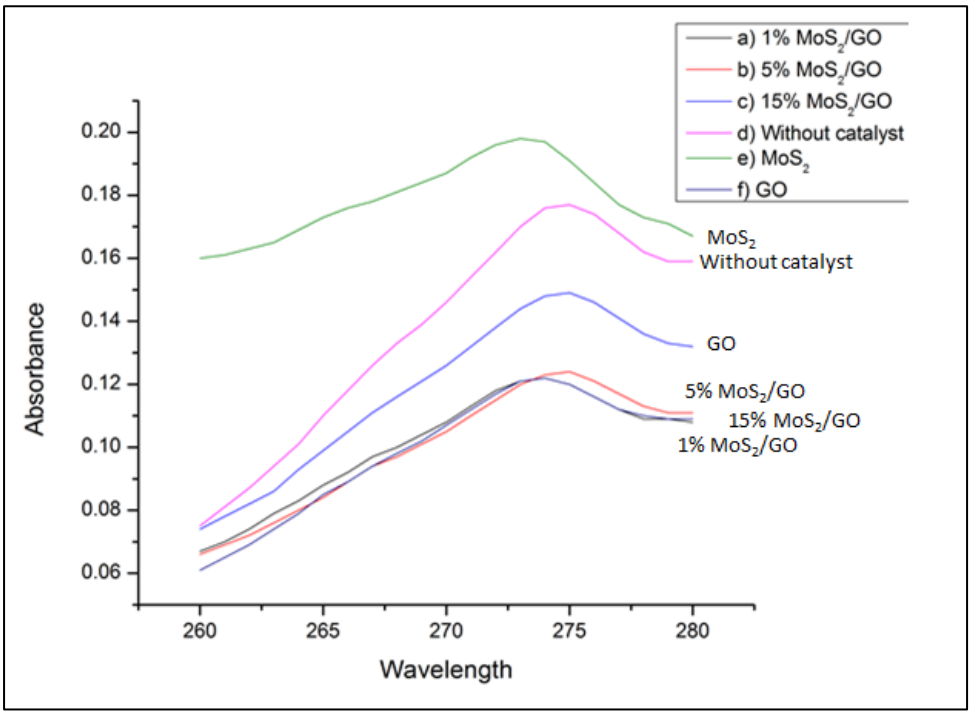

Figure 3. Different absorbance for different catalyst for 3 hours

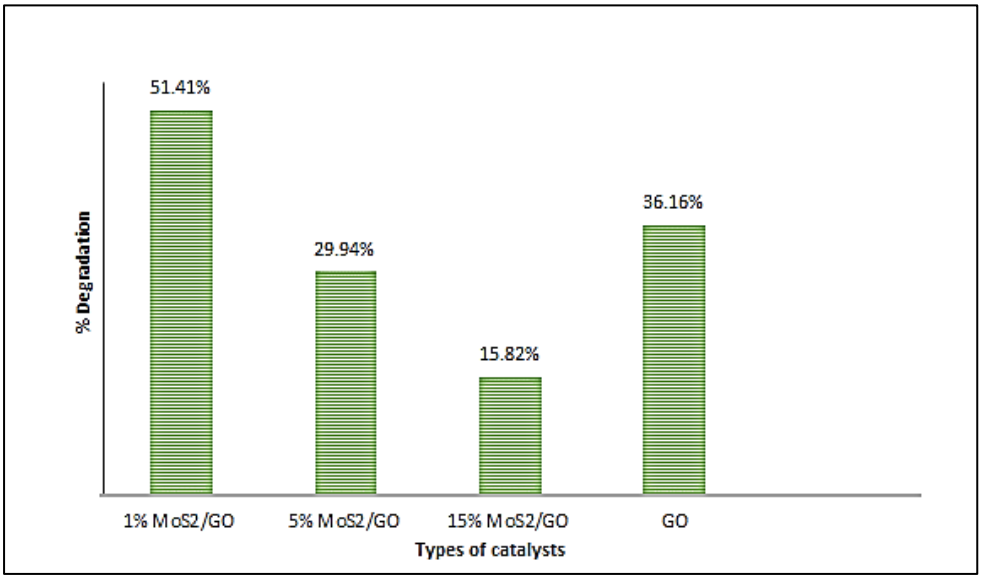

Figure 4. Degradation percentage of 2-chlorophenol for different catalysts under sunlight

Conclusion

MoS_2/GO composites were successfully prepared using ex-situ and hydrothermal method. This can be seen from the analyses of the FTIR, UV-Vis and XRD which confirmed the functional group and incorporated of MoS_2 and GO composites. From the findings, all of the

composites prepared have the potential in degrading 2-chlorophenol under sunlight assisted degradation. 1% MoS_2/GO was revealed as the best composite to degrade 2-chlorophenol with the percentage degradation of 51.41%. Further optimization and controlled experiments can be done to tackle the most prominent condition for 2-chlorophenol to degrade with sunlight as the main source of light to achieve highest degradation percentage within a short time.

Abstract

Biopolymer electrolytes have a lot of potential for future electrochemical device developments because of their environmentally-friendly features. In general, the structural characteristics of the biopolymer host play the most crucial impact in determining electrolyte conductivity. However, the semi crystallinity structure of biopolymer hosts caused the reduction of electrolyte conductivity. As a result, in this study, the structural characteristics of the biomaterial have been modified by blending jackfruit seed starch (JSS) and polyvinyl alcohol (PVA) to obtain the optimal composition of the blend that is compatible to be employed as a biopolymer electrolyte host. The jackfruit seed starch and polyvinyl alcohol were blended with various compositions using th e solution casting technique. The purpose of this study is to look into the amorphousness, functional groups, and morphology of J SS with PVA blend and determine the compatibility of JSS with PVA blend as a polymer electrolyte host. The best compatible bl end composition is JSS-PVA with a 1:1 ratio, which has the highest degree of amorphosity and the highest percentage of hydroge n bonding contact, C=O stretching, and C-O vibrations. Scanning electron microscopy investigation confirms the results, indicati ng that the blend is evenly dispersed.

Abstrak

Elektrolit biopolimer mempunyai banyak potensi untuk perkembangan peranti elektrokimia masa depan kerana ciri-ciri mesra alamnya. Secara umumnya, ciri-ciri struktur hos biopolimer memainkan peranan yang paling penting dalam menentukan kekonduksian elektrolit. Walau bagaimanapun, struktur separa kristal perumah biopolimer menyebabkan pengurangan dalam kekonduksian elektrolit. Hasilnya, dalam kajian ini, ciri-ciri struktur biomaterial telah diubahsuai dengan mencampurkan kanji biji nangka (JSS) dan polivinil alkohol (PVA) untuk mendapatkan komposisi optimum campuran yang serasi untuk digunakan sebagai hos elektrolit biopolimer. Kanji biji nangka dan polivinil alkohol diadun dengan pelbagai komposisi menggunakan teknik 'solution casting'. Ia bertujuan untuk melihat sifat amorfousness, kumpulan berfungsi, dan morfologi JSS dengan campuran PVA dan menentukan keserasian JSS dengan campuran PVA sebagai hos elektrolit polimer. Komposisi campuran serasi terbaik ialah JSS-PVA dengan nisbah 1:1, yang mempunyai tahap amorphositi tertinggi dan peratusan tertinggi hubungan ikatan hidrogen, regangan

C=O, dan getaran C-O. Mengimbas penyiasatan mikroskopi elektron mengesahkan hasilnya, menunjukkan bahawa campuran itu tersebar sama rata.

Kata kunci: kanji biji nangka, polivinil alkohol, perumah elektrolit biopolimer, amorphous

Introduction

Polymer electrolytes (PEs) are generally described as linear macromolecular chains containing a large charge. It is also utilized in solar cells, batteries, and supercapacitors, among other electrochemical devices [1, 2]. PE has recently piqued researchers' interest because of its promising features, which can be employed as a powerful platform for achieving high efficiency in the energy storage device. Recently, most of commercialized PE was prepared with non-biodegradable materials that are harmful to the environment and humans. This is due to most of the PE using petroleum-based polymers in the production of PEs. Petroleum-based polymer have limitations such as being expensive, depleting petroleum supplies, and causing environmental issues.

Biopolymer is a polymer host that has advantages since it eliminates the need for petroleum as a material source. In general, the choice of polymer host is an essential issue in the development of PEs [2]. Based on the previous studies, the choice of polymer host depends on two factors. Firstly, the presence of polar (functional) groups with adequate electron donor power to establish coordination with cations. For example, by having high concentration of polar groups (containing electron donors: O, NH, CN, F). Secondly, a low impediment to bond rotation [2]. Aside from that, the polymer host must be highly amorphous. It may occur due to increase in ionic diffusivity, as ions can move freely due to the low energy barrier. Furthermore, an amorphous polymer has a flexible backbone, which can increase local chain mobility. As a result, the segmental motion of a polymer can improve the electrolyte's transportation property [2]. Other researchers also found that selection of a polymer host is determined by factors such as the presence of atoms or groups of atoms with sufficient electron donor capacity to form coordination bonds with cations, a low barrier to bond rotations, allowing for easy segmental motion of the polymer chain, and a suitable distance between coordinating centers, which allows for the formation of multiple intra-polymer ion bonds [3].

To replace the petroleum-based material, the structural properties of jackfruit seed starch were investigated to determine its compatibility as a polymer electrolyte host. In Malaysia, the average weight of a jackfruit ranges from 3.5 kg to 10 kg, with the largest edible fruit weighing up to 35 kg, and the source is abundant [4]. Seeds can account for up to 10% to 15% of the total weight of the fruit [5]. Jackfruit seed starch has a high amylose content (24-32%) and a high polar group [6]. Previous studies indicate that the functional properties of jackfruit seed starch, which have C=O and C-O-C bonding which suggest that they can be used as a polymer electrolyte host [7, 8, 9]. It demonstrates that jackfruit seed starch contained an electron donor and met one of the requirements of the polymer host. However, no research has been conducted on the percentage of C=O and C-O-C bonding functional groups. As a result, the percentage of these functional groups was measured in this study.

Semi-crystalline properties are found in some of the native starch polymers. The previous researchers discovered that the sample's ionic conductivity is low due to its crystalline structure after synthesizing PEs by reacting poly(ethylene oxide) (PEO) with a salt such as lithium iodide (LiI) [10]. PVA also has semi-crystallinity structure, by blending PVA with another polymer, it might reduce the crystallinity properties. The previous researchers found that blending PVA with pure cornstarch and chitosan can reduce the crystallinity peak [11, 12]. The chain structure promotes the formation of interchain "tunnels" through which the desired ion can bounce between coordination sites while the counterion travels down the polymer chain [13]. These tunnels constrain the movement of anion and cation in crystalline PEs due to their highly ordered crystalline domains that are selective for an ion and exclude its counterion, allowing for separation [10]. The conductivity of amorphous polymers is higher due to

their amorphous properties, which allow for significant chain movement because ion coordination is transitory, enhancing ion mobility [14]. Ion transport is triggered in the amorphous phase by local mobility of polymer chain segments, which creates new coordination sites into which the ions can then travel [10]. While the crystallinity can restrict the movement of ions. It has been well reported that the ion transport occurs mainly in the amorphous region rather than the crystalline region, but the polymers host materials that used in PEs are often semi-crystalline. To summarize, the movements of ions in the amorphous phase allow ionic conductivity.

Thus, in this research, synthetic polymers such as PVA were blended with jackfruit seed starch to modify the polymer's structural properties and achieve the optimal state of amorphosity [15]. According to previous study, PVA is used because it has excellent charge storage properties, optical properties, and high dielectric strength. Fahmy et al. stated that PVA has a carbon chain backbone that is connected with hydroxyl groups [16]. Due to hydroxyl groups, or OH groups, are a source of hydrogen bonding, they aid in the formation of polymer blends or polymer complexes. Chen et al. investigated varied features of PVA/chitosan blends at different ratios and discovered that chitosan, as a natural polymer which can reduce the PVA crystallinity [17].

As a result, the primary goal of this study is to investigate the amorphousness, functional groups, and morphology of JSS with PVA blend to ensure that these properties are compatible as potential polymer electrolyte hosts.

Materials and Methods

Materials

JSS used in this experiment was purchased from the jackfruit merchant in Bandar Pusat Jengka, Pahang. The chemicals used were PVA and glycerol from R & M Chemicals, UK. 0.1 M sodium hydroxide (NaOH) and 0.1 M hydrochloric acid (HCl) were also used and were purchased from Sigma-Aldrich, USA.

Preparation of jackfruit seed starch and polyvinyl alcohol blend

The samples were prepared by using solution casting method. Different compositions of JSS and PVA were used as represented in Table 1. Firstly, the PVA solution was prepared by dissolving PVA into distilled water. The solution was heated at 100 ℃ for 30 minutes. While the PVA was being diluted, the JSS mixture were prepared by using double boiled method. JSS was mixed with distilled water before adding 1.5 mL of glycerol, HCl and NaOH. The mixture was stirred at 90 ℃ for 20 minutes. Then, the PVA solution was added into the mixture and it was stirred continuously for 30 minutes at 100 ℃ until the homogenous gel-like mixture was formed. After being homogenous, it was poured into a petri dish and dried for 48 hours at room temperature. Next, the dried films were peeled from the petri dish and was cut according to the characterization method used.

Table 1. Composition of JSS and PVA

Sample	JSS (%)	PVA (%)
S1	0	100
S2	30	70
S3	50	50
S4	70	30
S5	100	0

Characterization

The Fourier-transform infrared spectral analysis of functional groups for the bioplastic films was carried out by Perkin Elmer FTIR Model 2000 spectrometer in a range of 500-4000 cm^{-1} at a resolution of 4 cm^{-1}. The surface analysis of the bioplastic films was carried out

by using Scanning Electron Microscopy (SEM, Vega 3, Tescan Analytics, France). The morphological structure of the bioplastic films was obtained at a voltage of 20 kV (magnification of 1000x). The X-ray diffraction patterns of the films was characterized by X'Pert PRO MPD diffractometer (PANalytical, UK). It operated at 36 kV (20 mA) and the scanning range was 5°-90° in the scale of the angle 2θ.

Results and Discussion

Fourier-transform infrared spectral analysis

The FTIR spectra for JSS and PVA blend are shown in Figure 1. The strong and wide absorption band at 3300 cm^{-1} indicates that the blend has the stretching vibration of OH groups [18]. The possible functional groups for this peak are the hydroxyl group and H-bonded OH stretch. The available hydroxyl groups on the starch chains cause the formation of the peak at 3300 cm^{-1} [19]. The absorption band is also present in the PVA film, indicating that there are many water hydroxyl groups in the film, which are the same as those studied by El-Sawy and his colleagues [20]. The major OH groups that appear in all samples at 3300 cm^{-1}, indicate that there is an interaction between different –OH groups in the JSS and PVA blends for the other four samples. The intensity of S1 becomes lower with additional JSS into the blend due to the intensity of pure JSS, which is S5 that is the lowest. In other words, the FTIR spectra pattern for JSS and PVA blends seems to overlap compared to a single polymer component.

The peaks that occurred at 2900 to 2950 cm^{-1} were attributed to C=H asymmetric stretching vibration [21]. Then, the peak at 1650 cm^{-1} was caused by C=O stretch [22]. This peak belongs to PVA. Next, the peak at 1040 cm^{-1} was attributed to C-O vibration of C-O-C groups [18]. The bands at 1000–1200 cm^{-1} were ascribed to the C-O stretching vibration. The changes occurred of the peak intensity of C-O in C-O-C groups by blending JSS and PVA. The highest intensity was obtained at S3. It shows that the S3 has the highest C-O in C-O-C groups. Then, the peak for S3 slightly shifted to the left, from 1040 cm^{-1} to 1029 cm^{-1}, indicating that strong hydrogen bonding interactions occurred between starch and PVA components. Both JSS and PVA have a lot of OH and C-O groups, which might help them establish hydrogen bonds and increase their compatibility [18]. The absorption peaks have also changed and shifted at 1400 cm^{-1} to 1450 cm^{-1}. The peak for PVA appeared at 1400 cm^{-1}, but when there was the presence of JSS, the peak shifted to 1450 cm^{-1}. The shift indicates that there is a weak interaction caused by C-O bonds that occurred during the solution blending and casting process [8]. The FTIR spectra for the JSS and PVA blend films showed the same pattern with the FTIR spectra for PVA film which is S1. From Figure 1, there is no major change that occurred in the functional group due to the JSS and PVA that is homogenously blended. Changes in the characteristic spectra peaks alter the physical blends versus chemical interactions when two components are blended [23]. Based on the previous studies, if the shape and location of the characteristic peak for the blend films is similar to PVA, the interaction among the PVA molecules is dominant and stronger compared to the JSS-PVA molecules and JSS-JSS molecules [20].

The percentage area under the graph for each stretch was summarized in Table 2. The peak at 1040 cm^{-1} for S3 has the highest percentage area under the graph. Having a higher percentage area under the graph for the C=O and C-O-C region is important in PEs because it is related to the conductivity of the PEs. Having a higher percentage area in those regions means that it has higher conductivity compared to the other blend films [24].

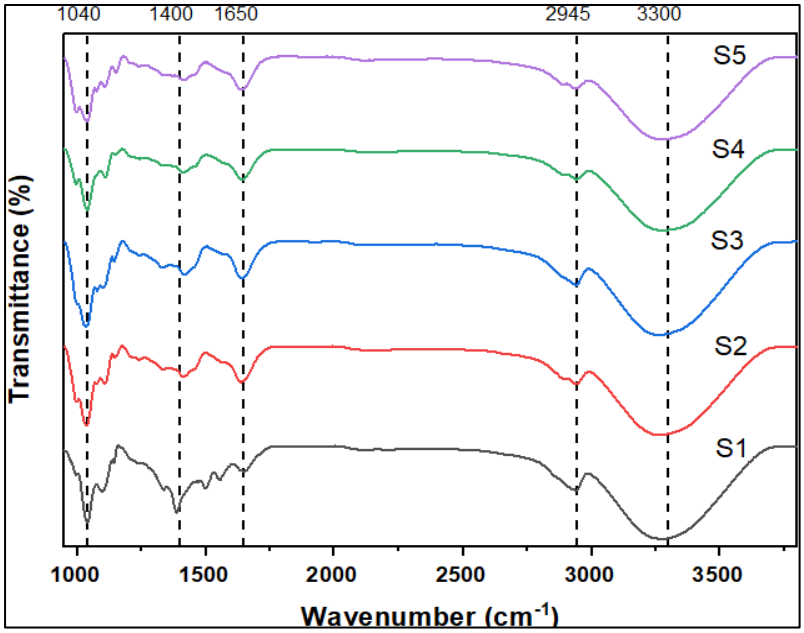

Figure 1. FTIR spectra of polymer blend with different composition of JSS and PVA blend

Table 2. Percentage area under the graph for each stretch

Sample	Percentage Area Under the Graph (%)				
	1040 (cm^{-1})	1400 (cm^{-1})	1650 (cm^{-1})	2945 (cm^{-1})	3300 (cm^{-1})
S1	9.99	14.27	6.30	6.98	62.45
S2	10.55	16.52	5.44	5.96	61.52
S3	14.26	8.00	4.47	7.09	66.18
S4	9.66	6.05	4.99	5.69	73.61
S5	12.25	6.05	5.25	5.90	70.60

Scanning electron microscope testing

The morphological structure of JSS and PVA blend films was analysed by SEM at magnification of 1000x (Figure 2). A homogenous structure was analysed for all of the samples. The surface of S1, which is an unfilled PVA film, had a smooth and clear surface as shown in Figure 2a. JSS is present in semi-round shaped granules and PVA is completely dissolved in the blend. The previous researchers also observed the semi-round shaped granules at a magnification of 1000x [25]. Then, a few other researchers also found that the presence of granules belong to the starch which is JSS [6, 11, 26]. Figure 2b, 2c, and 2d show that the JSS and PVA is evenly distributed and there is no formation of voids. The interface between those two materials in the blend was indistinct, which indicates the strong interaction between starch and PVA components. As indicated in the FTIR section, there is a strong hydrogen bonding formed between JSS and PVA, and it could improve the compatibility effectively [18]. The surface of S2 in Figure 2b shows a clear, semi-round shaped granules of JSS due to the fact that the amount of JSS in the blend is less than PVA. The JSS is evenly blended in the PVA matrix. As the amount of JSS added into the blend increases, the shape of the JSS in the blend can barely

be seen as the JSS becomes more compact and the blend films become smoother and homogenous.

The smoothness of the blend films represents the amorphous phase of the electrolyte films [27]. As the amorphous surface in PEs increases, the conductivity will also increase. This is because the ions can move freely when a smooth surface PE is formed [28]. As a result, the conductivity is improved. For S5 with only JSS in the blend film, the surface of the blend film looks a little rough without the presence of PVA. Based on the previous research, blend films with the presence of PVA will appear a lot smoother compared to those without it [29]. The previous research also indicates that a rough surface morphology in the electrolyte film reflects a semi-crystalline phase, which reduces the film's ionic conductivity [28]. From the morphological structure obtained, S3 with 50:50 of JSS and PVA demonstrated the optimum interaction between JSS and PVA compared to the other films with different compositions of JSS and PVA. Figure 2c reveals that the starch granules are well dispersed, homogenous, and have a smoother surface compared to other blend films. It can be concluded that S3 has the best conductivity based on the smoothness of the blend film.

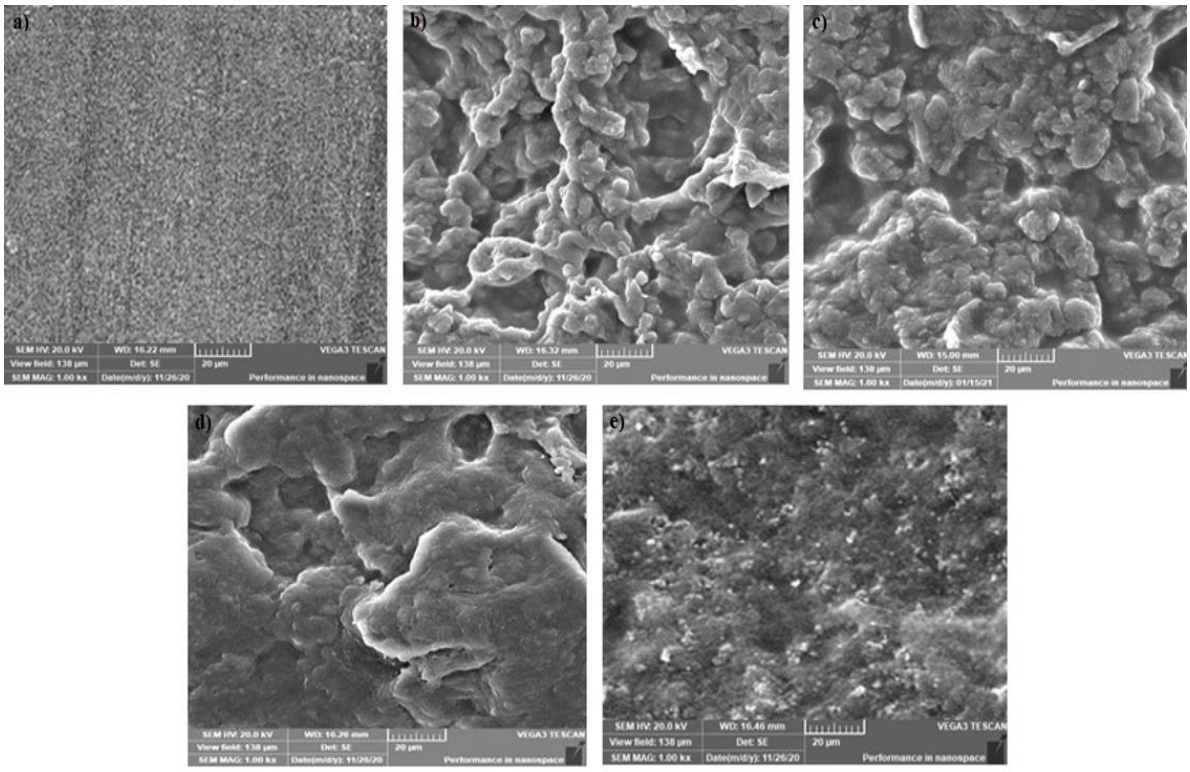

Figure 2. Surface morphology of different composition of JSS: (a) S1; (b) S2; (c) S3; (d) S4; (e) S5

X-ray powder diffraction testing

The XRD pattern for five samples with different compositions of JSS and PVA was presented in Figure 3 in the range 13° to 30°. Based on the figure, broad peak has been observed at 19.7° for all samples. This peak is related to the PVA phase where it is in a partially crystalline structure. The broad diffraction peak indicates that the crystallite is very small [4]. The position of the broad peaks for amorphous is normally within the range of 15° to 30°, implying that the broad peaks at 19.7° exhibit amorphous properties [30]. In Figure 3, the broadness for S2 and S3 increased while the intensity decreased. However, the intensity for S4 increased as the broadness increased. The increase in the broadness of the peak portrays the amorphous nature in the samples [31]. The previous researchers reported that

the amorphousness in the system is related to the height of the peak and the degree of crystallinity of the system [31]. Thus, S3 is the sample that has the highest amorphous nature compared to the other samples as it has a broad diffraction peak with low intensity. It can be proven based on the value of percent crystallinity in Table 3, where S3 has the lowest percent crystallinity compared to other samples. This is compatible with the SEM analysis where S3 has the optimum interaction between JSS and PVA compared to other films.

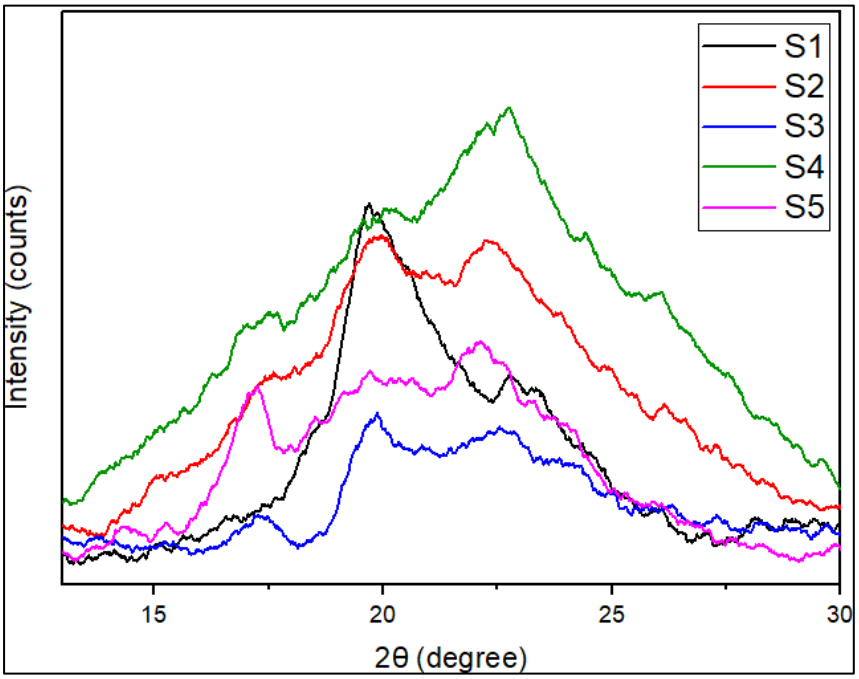

Figure 3. XRD analysis at 20° for polymer blend with different composition of JSS

Table 3. Percent crystallinity for each sample

Sample	Percent Crystallinity (%)
S1	84.04
S2	88.35
S3	41.82
S4	81.87
S5	74.55

Conclusion

The blend of JSS and PVA with different compositions was prepared via the solution casting method and their properties were investigated. From this study, it shows that the JSS and PVA have good compatibility and can be effectively reinforced together. Based on the FTIR analysis, the blend has a hydrogen bonding interaction and also have C=O stretching and C-O vibrations. Then, from SEM and XRD analysis, S3 has the most amorphous structure which then leads to high ionic conductivity. Thus, this study suggests that JSS and PVA are suitable to be used as PEs.

Abstract

This study investigated the composite cathode of $LaSrCoFeO_3$-$BaCeZrYO_3$ (LSCF-BCZY) in a ratio of 7 : 3. A 13-mm symmetrical half-cell was fabricated using the dry pressing and spin-coating techniques to yield the configuration of LSCF-BCZY|BCZY|LSCF-BCZY. The phase of the sample was verified using the X-Ray Diffraction (XRD) spectroscopy. The electrochemical and microstructure of the half-cell were characterized using the Electrochemical Impedance Spectroscopy and Scanning Electron Microscopy (SEM), respectively. The XRD analysis showed that the single-phase structure of LSCF and BCZY was still preserved at the calcination temperature of 900 ºC. The half-cell demonstrated a thermally activated trend in a humidified atmosphere with area-specific resistance values of 0.25, 0.33, 1.02, 1.64, and 5.75 Ω.cm^2 at temperatures of 800, 750, 700, 650, and 600 ºC, respectively. The SEM image revealed that the 10-µm LSCF-BCZY layer was well-adhered on the dense BCZY electrolyte surface. This synthesised LSCF-BCZY in the ratio of 7 : 3 demonstrated excellent characteristics as a composite cathode for PCFCs.

Keywords: composite cathode, single phase, spin coating, proton ceramic fuel cells

Abstrak

Dalam kajian ini, komposit katod daripada $LaSrCoFeO_3$-$BaCeZrYO_3$ (LSCF-BCZY) dengan nisbah 7 : 3 dipilih disebabkan kelebihanya berbanding dengan LSCF tulen. Teknik penekanan kering dan saduran berpusing telah digunakan untuk menghasilkan 13-mm sel separa simetri dengan konfigurasi iaitu LSCF-BCZY|BCZY|LSCF-BCZY. Pembentukan fasa sampel telah disahkan oleh pembelauan sinar-X (XRD). Sifat elektrokimia dan struktur mikro daripada sel separa simetri masing-masing telah diciri menggunakan spektroskopi impedans elektrokimia (EIS) dan pengimbasan mikroskop elektron (SEM). Pada suhu kalsinan 900 ^oC, komponen LSCF dan BCZY tidak menunjukkan sebarang perubahan dan berfasa tunggal seperti dibuktikan melalui analisis XRD. Sel ini menunjukkan kecenderungan aktif secara terma, yang disahkan melalui pengukuran EIS dalam atmosfera lembap dengan kawasan rintangan khusus (ASR) masing-masing iaitu 0.25, 0.33, 1.02 , 1.64, dan 5.75 $\Omega.cm^2$ pada suhu 800, 750, 700, 650 dan 600 ^oC. Gambar SEM menunjukkan bahawa lapisan 10 μm LSCF-BCZY melekat dengan baik pada permukaan elektrolit padat BCZY. Maka, penghasilan LSCF-BCZY dengan nisbah 7 : 3 menunjukkan ciri-ciri yang terbaik sebagai katod komposit bagi aplikasi PCFC.

Introduction

A Proton Ceramic Fuel Cell (PCFC) is a green device that converts chemical energy to electrical energy with heat and water as by-products for a high-power generation system. However, a high cathode polarisation resistance (R_p) reduces the overall cell system performance substantially, particularly at the intermediate temperature range of 500 to 800 ^oC [1]. The rising trend in R_p is related to the lack of a surface-active site for the oxygen reduction process (ORR) at the triple-phase boundary (TPB) that connects the electrolyte, cathode, and gas phase. Thus, selecting the best materials for the cathode component is crucial for the PCFC system because materials will exhibit different characteristics when coupled with other materials or operating at elevated temperatures. In this respect, pure $LaSrCoFeO_3$ (LSCF) is a well-known cathode material for PCFCs because it contains more excellent ionic and electronic charge carrier species than traditional cathodes [2]. However, because LSCF has a limited number of TPB sites, various methods or materials have been suggested to increase the TPB length [3, 4]. One of the suggested methods is the use of a composite cathode for integrating proton conductors, mixed electronic-ionic conductors, or a catalytic layer [5].

For PCFCs, a composite cathode is produced by mixing materials of the cathode and proton conductor electrolyte for high-kinetic ORR. The electrical conductivity of the composite cathode increased about two times higher than the pure cathode [6 - 8]. However, an excessive amount (> 50%) of protonic species in the mixed ionic-electronic conductor MIEC cathodes caused water loading across the bulk cathode, reducing the overall performance of the fuel cell [9, 10]. Meanwhile, protonic species based on cerate-zirconate oxides exhibited high conductivity; they were chemically stable and compatible with LSCF cathodes [11]. Recently, adding some protonic species, for example, doped-barium cerate zirconate oxide, into the LSCF cathode using chemical approaches lengthened the TPB [12].

In general, a symmetrical half-cell is fabricated for electrochemical studies to evaluate the behaviour of the composite cathode. The half-cell requires the optimised electrolyte substrate and cathode thin-film design. The electrolyte substrate is dry-pressed at the desired pressure and sintered at high temperatures to obtain the dense pellet. The cell is subjected to electrochemical impedance spectroscopy (EIS) measurement to study the material behaviour and performance. A suitable equivalent circuit for EIS spectra is introduced to fit the EIS spectrum via a fitting procedure. Information or data gained is used to calculate capacitance, arc summit frequency, and area-specific resistance (ASR) of the half-cell as a function of temperature. The Adler Lane Steel (ALS) model is used to extract the associated response in the EIS spectrum.

In this study, $BaCeZrYO_3$(BCZY) was chosen as a proton-conducting medium to form the composite cathode of LSCF-BCZY. The structural and electrochemical properties of the prepared cathode were further analysed and characterised.

Materials and Methods

The $LaSrCoFeO_3$ cathode powder was produced using a modified sol-gel process in which all the metal nitrate salts in the universal solvent were dissolved, followed by adding citric acid and ethylenediaminetetraacetic acid (EDTA). Upon alkalinising the mixture to pH 9 with ammonium hydroxide, ethylene glycol was added, and the brownish gel produced was calcined for five hours at 900 ºC. The single-phased BCZY powder and the high relative density pellet (97.1%) were prepared as previously described [13]. The LSCF and BCZY powders were mixed in the ratio of 7: 3 weight percent (wt%) to form the LSCF-BCZY composite cathode. The composite powder was transformed into cathode slurry and spin-coated on both sites of the BCZY pellet under optimised conditions (2,000 rpm for 30 s). The half-cell with the configuration of LSCF-BCZY|BCZY|LSCF-BCZY was sintered at 600 ºC for one hour and 900 ºC for three hours.

The prepared powder and half-cell were characterised using X-ray diffraction (XRD) spectroscopy, EIS, and scanning electron microscopy (SEM). For XRD, the LSCF-BCZY powder was radiated with Cu-K_α at the ambient temperature at the wavelength of 1.5406 Å using 8.04 keV (PANalytical X'Pert PRO MRD PW 3040). The scanning was set at the rate of 0.02 s^{-1} to collect the two thetas from 20º to 80º. The XRD data was analyzed with X'Pert HighScore Plus software (version 5.1, Malvern Panalytical) and compared to the Joint Committee on Powder Diffraction Standard (JCPDS) card number 089-1268 for LCSF and 01-089-2485 for BCZY. The perovskite phases were calculated using the Swarts and Shrout equation. Meanwhile, the symmetrical half-cell was passed through wet air at the flow rate of 90 mL/min, and the electrochemical parameter was measured between 1 MHz and 10 MHz with amplitude voltages ranging from 3 to 5 mV at 600 – 800 ºC using the electrochemical workstation ZIVE SP2 (ZIVE LAB WonATech). An equivalent circuit of L_s-R_s(R1Q1)-(R2Q2) was used for the impedance spectrum analysis using the test station (ZIVE ZMAN™ 2.4). Values of capacitance, arc summit frequency, and polarisation resistance were calculated for each temperature using the equations reported in another study [14]. The raw and fitted data were re-plotted using the software Origin 2019b. After electrochemical testing, the morphology of pellets was evaluated using SEM with energy dispersive X-ray (EDX). The software ImageJ was used to measure the porosity of the SEM image.

Results and Discussion

Figure 1 shows the XRD pattern of LSCF-BCZY composite cathode powder upon calcination at 900 ºC. All diffraction peaks agreed with JCPDS-card no. (LSCF ID: 01-089-1268) and (BCZY ID: 01-089-2485) with orthorhombic and cubic structures, respectively. More than 90% of the single perovskite phase was formed for both LSCF and BCZY, indicating that these materials maintained their phases after the heat treatment at 900 °C. The prominent peaks were indexed using Miller Indices (hkl) reflected plane as follows: (110), (020), (202), (220), (132), (224), and (332) for LSCF, and (110), (200), (211), (220), and (222) for BCZY. The lattice constants of LSCF and BCZY were calculated using the software Mathcad 14.0 (Mathsoft). Table 1 shows the lattice constants of LSCF and BCZY, and they agreed with the reference data. These values were consistent with the finding of another study [15] for LSCF-BCZY treated at 1,000 ºC.

Figure 2 shows the Nyquist impedance plot of the fabricated half-cell in humidified air at temperatures ranging from 600 to 800 ºC. As the temperature increased, the impedance spectrum became smaller in size, obeying the thermally activated behaviour, as expected by Arrhenius's Law [16]. The arcs were resolved using an equivalent circuit (the inset of Figure 2). The first arc, represented by R_1Q_1, was referred to as an electronic charge transfer that occurred at the cathode surface. The second arc, R_2Q_2, was associated with the ionic charge transfer reaction at the cathode-electrolyte interphase. The calculated capacitance ranged from 10^{-2} - 10^{-4} for the R_1Q_1 circuit and 4 x 10^{-5} - 10^{-7} for the R_2Q_2 circuit [5], denoting the respective cathode process. Also, the arc summit frequency confirmed the presence of these two arcs in the middle and low-frequency regions. ASR values of 0.25, 0.33, 1.02, 1.64, and 5.75 Ω.cm^2 were obtained between 800 and 600 ºC at intervals of 50 ºC. ASR values of the pure LSCF increased by about one time

higher than modified samples (800 – 600 ºC: 1.06, 1.13, 3.13, and 6.50 Ω.cm^2). Compared to the pure LSCF, the reduction of ASR values for LSCF-BCZY suggested that the use of composite cathode could potentially enhance the performance of PCFC.

Figure 3 shows the SEM images of the fractured cross-section and cathode surface of the LSCF-BCZY|BCZY|LSCF-BCZY symmetrical half-cell after the electrochemical measurement. There was no sign of crack and delamination in the cell, indicating a good adhesion between a 10-µm LSCF layer and a dense electrolyte that promoted a low contact resistance [15]. The cathode surface showed a well dispersed and homogenised microstructure with a porosity of 32%. This amount was sufficient to allow better oxygen diffusion through the cathode material as the required porosity ranged from 20% to 40% [16]. Good adhesion between LSCF-BCZY cathode and BCZY electrolyte as well as the homogenised microstructure of the LSCF layer reduced the resistance of cathode bulk, leading to fast surface oxygen ion diffusion [5, 17].

Conclusion

The LSCF and BCZY powders were prepared by the sol-gel method using metals nitrate salts. Both compounds maintained their respective phase even after they were simultaneously calcined at 900 °C. ASR values at the intermediate temperatures of 800 to 600 °C with the composite cathode half-cell were 0.25, 0.33, 1.02, 1.64, and 5.75 Ω.cm^2. After the electrochemical testing, the morphology of the well-distributed cells remained unchanged, i.e., with no delamination and porosity optimised. The use of the LSCF-BCZY composite cathode reduced the polarization resistance of the fabricated cell substantially, suggesting that it might have great potential for PCFC application.

Abstract

Fluctuation levels of geochemical elements, sediment texture and nutrients were analysed from five surface sediments taken from the northern Malacca Straits. These samples were obtained during the RV Discovery Scientific cruises in September 2017 and April 2018, to assess pollution sources during monsoonal events. The results show a high output of clay and silt, revealing that the monsoonal season and cross-shelf inputs affect textural sediment. On the other hand, fluctuations in geochemical concentrations are due to industrialisation and urbanisation along the Malacca Straits, contributed by the local drainage basin. The presence of the monsoon also affects the diffusivity and absorption between the water-sediment interfaces, leading to constant fluctuation along the straits. Principal Component Analysis (PCA) of the association between the geochemical elements, sediment texture and nutrients reveal hydrological factors, mobility and accumulation through the sediment interface.

Keywords: weathering, pollution, monsoon, sediment, Malacca Strait

Abstrak

Tahap kepekatan unsur geokimia, tekstur sedimen dan nutrien telah dianalisis daripada lima sedimen permukaan yang diambil dari kawasan utara Selat Melaka. Sampel ini diperoleh semasa pelayaran RV Discovery Scientific pada September 2017 dan April 2018 untuk menilai sumber pencemaran semasa peristiwa monsun. Keputusan menunjukkan keluaran lempung dan kelodak yang lebih tinggi, menunjukkan bahawa musim monsun dan input rentas pelantar mempengaruhi sedimen tekstur. Sebaliknya, fluktuasi kepekatan geokimia adalah disebabkan oleh kawasan perindustrian dan pembandaran di sepanjang Selat Melaka, disumbangkan oleh lembangan saliran tempatan. Kehadiran monsun juga menjejaskan resapan dan penyerapan antara antara muka air-mendapan, yang membawa kepada fluktuasi yang berterusan di sepanjang selat. Analisis Komponen Utama (PCA) perkaitan antara unsur geokimia tekstur sedimen dan nutrien mendedahkan faktor hidrologi, mobiliti dan pengumpulan melalui antara muka sedimen.

Introduction

The Malacca Strait is located between the west coast of the Malaysian Peninsular and the east coast of Sumatra Island, and is connected with the Strait of Singapore at its south-eastern end. There are also smaller straits, such as the Johor Strait, Bengkali Strait and Rupat Strait. Together, these straits play an important role in international shipping routes linking the Indian Ocean to the Pacific Ocean [1]. The tropical climate in the Malacca Strait results in an annual precipitation of 3000 mm yr^{-1} [2], leading to severe weathering on the adjacent peninsular. The tides and currents present in the Malacca Straits are mainly semi-diurnal, following the monsoonal current as the main force around the surrounding coast [3]. Low to medium high turbidity has been recorded, with transparency ranging from 10 to 30 m. Primary productivity is influenced geographically but is constant throughout the whole year. Shallower water along the coastlines leads to vertical mixing and nutrient inputs from drainage basins adjacent to the Malacca Straits [4].

A high volume of annual precipitation (3000 mm yr^{-1}) also leads to severe terrestrial weathering towards the straits, resulting in elevated sediment discharge [5]. On the west coast of the Malaysian Peninsular, a number of discharged sediment sources are the result of physical and chemical weathering [6], with most of the weathered material originating from igneous rock. The granitic rock present in the Malaysian Peninsular originates from the Central and Western Belts, for which the primary source are the Titiwangsa Ranges [7, 8]. According to Shoieb et al. [9], the Sibumasu Terrane, which comprises the Malaysian Peninsula's Western Belt, was derived from the North West Australian Gondwana margin within the late Cambrian-Early Permian period. Therefore, the discharged weathered sedimentary rock material is Palaeozoic shale. An earlier study by Zakariah et al. [10] on the sustainability of the Kuala Muda basin located in the Kedah River, revealed a large quantity of granitic-bearing rocks, most of it originating from the Bintang Range granites. In Penang and Langkawi Island, the formation of the bedrock surrounding both islands originated from the Quaternary deposits, where most of the discharge was feldspar and plagioclase [11, 12]. This has resulted in the constant supply of igneous rock towards the Malacca Straits. In term of temporal influences, the Malacca Strait is affected by monsoonal seasons, where the northeast monsoon prevails from November to March and the southwest monsoon runs from May to September. In essence, the energy generated by the monsoonal season leads to corresponding changes in sea currents through eddies and cyclonic and anti-cyclonic events, thus altering the sinking processes in the Malacca Strait [13]. These monsoonal seasons also affect hydrological processes in the straits, leading to the distribution of weathered material around the coast.

The Malacca Strait is abundant in natural resources and many socio-economic activities related to metal processes and consumption, such as industrial and residential activities which are concentrated in this area, resulting in an increased contaminants load, due to rapid urbanisation and increased population density [14]. Urban development and industrialisation over the previous decade have raised major environmental issues. Pollutants in rivers are a severe problem in many rapidly growing cities, owing to the fact that water quality and sanitary infrastructure do not keep up with population and city expansion, particularly in developing countries. Human activities such as sand mining, land reclamation, deforestation, landfill leachate and urban water runoff are common anthropogenic problems of environmental concern [15]. Contaminants are deposited in aquatic environments as a result of physical erosion, chemical weathering and soil leaching [16]. Furthermore, monsoon-induced events (i.e., storms, flash floods and landslides) can be devastating in mountainous tropical environments, causing severe soil erosion with both on-site and downstream repercussions. When combined with anthropogenic inputs, these result in severe damage to the local population. These hazards also elevate geochemical concentrations and sedimentation.

Sediment is a major source of concern when it comes to environmental quality because of its importance in monitoring the health of both humans and the ecosystem. The importance of sediment is evidenced by its constant deposition of many sources of contamination, leading to bioaccumulation and

bioassimilation in aquatic life, through source and sink processes. In theory, the high level of pollution surrounding the Malacca Straits is the result of natural and anthropogenic inputs, backed with monsoonal seasons, enhancing its concentration under physical and hydrological processes. The objective of this study is to identify the source of geochemical elements within the Malacca Straits, while assessing several factors influencing these geochemical elements. This paper examines pollution concentrations in the Malacca Strait and the prominent factors affecting geochemical elements along the straits.

Materials and Methods

During the UKM-FIO Scientific cruise in August 2017 and May 2018, five surface sediment samples were collected using a Veen Van Grab, at locations on the western coast of the Malaysia Peninsular (Figure 1 and Figure 2). Water depth in the study area ranged from 15.5 m to 67.8 m (Table 1). The sediment samples in this study were taken using a plastic scoop, rather than a metal scoop, to prevent cross contamination. They were stored in zipped polyethylene bags and frozen below 15°C on-board, before being shipped back to National University of Malaysia (UKM).

Sediment textural analysis was carried out, according to the method by Miller and Miller [17, 18]. Calgon solution was used, as proposed by Kaur and Fanourakis [19]. The 4 g bulk sample was mixed in a 50 ml centrifuge tube with 4.2% Calgon solution for better separation into clay, sand and silt layers. The sample was then mixed and sonicated for 15 to 30 minutes, for dispersion. The sample was centrifuged at 770 rpm for 3.3 minutes, for the clay to settle. The clay was then removed at 2.5 cm below the centrifuge tube meniscus level. Silt was obtained via wet sieving at 45 μm and the total amount of sand was calculated via the subtraction of total clay and silt [20].

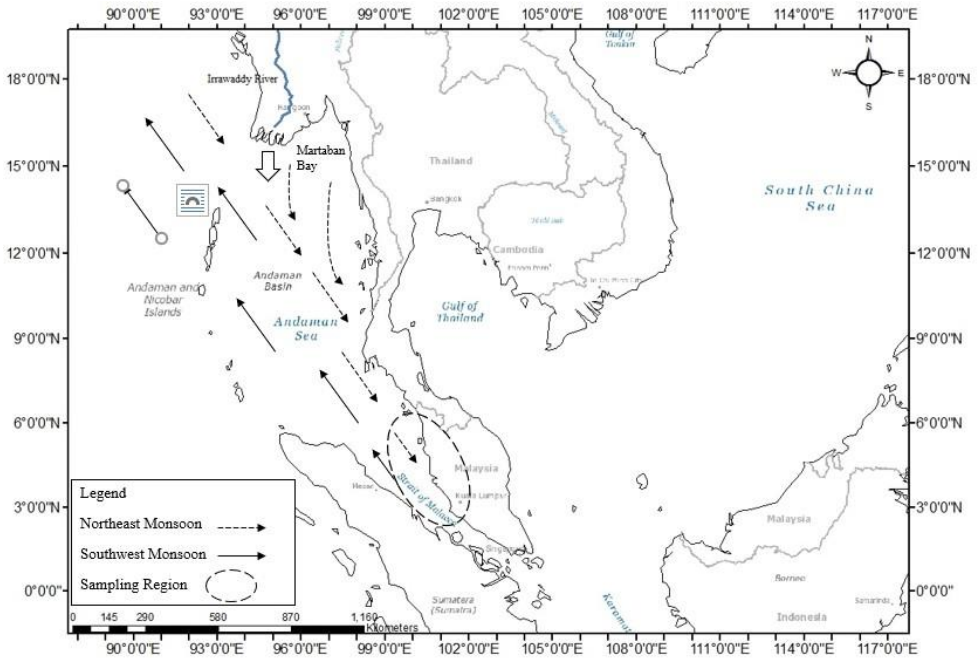

Figure 1. The area of sampling in Northern Malacca Straits affected by monsoonal season (Data source: [23])

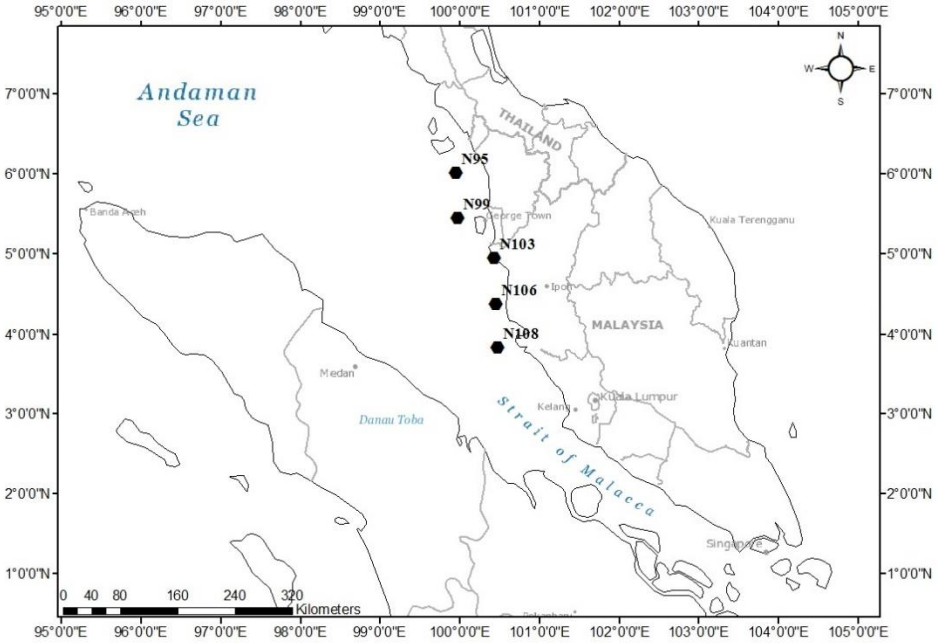

Figure 2. Sampling station in the Malacca Straits

Table 1. Sampling stations along the Malacca Straits

Station	Longitude	Latitude	Sampling Date	Depth (m)
N95	99.9606	6.0069	1/5/2018	39.5
N99	99.9811	5.4428	2/5/2018	40.8
N103	100.44	4.9433	2/5/2018	15.5
N106	100.4561	4.3733	2/5/2018	22.0
N108	100.4828	3.8247	2/5/2018	67.8

Geochemical element analysis was conducted, following the methods in Rahim et al. [16]. In summary, the dry and homogenised sediment was used and mixed with a mixture of 10 mL nitric acid (HNO_3), 5 mL perchloric acid ($HClO_4$) and 1 mL hydrofluoric acid (HF) for 2 h in a Teflon beaker at 120°C. With the acquisition of three replicates for each sample, the concentration of Al, Fe, Ti, Mn, Mg and Cr were determined using Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Standard reference material (NIST 1633b) was used for the five replicates, to assess the yield and effectiveness of the established methods. The yield obtained was between 88% and 92%, with an average result of 13.54 ± 0.1% for Al, 7.00 ± 0.03% for Fe, 0.71 ± 0.02% for Ti, 0.43 ± 0.04% for Mg,118.55 ± 1.1 µg/g for Mn and 174.41 ± 1.3 µg/g for Cr.

For organic matter (OM) and calcium carbonate ($CaCO_3$) content, the loss of ignition (LOI) method was used, as suggested by Santisteban et al. [21]. The dried, finely ground and homogenised sediment was weighed accordingly and treated with high combustion heat for 4 hours at 550°C in a furnace. After heating, the sample was cooled down in the desiccator and weighed again.

The same sample was then treated for 2 hours at 950°C, for $CaCO_3$ determination.

Results and Discussion

The data in Table 2 shows that the average percentage was 10.93% for clay, 37.99% for silt and 51.08% for sand, while OM and $CaCO_3$ averaged 5.87% and 9.51%, respectively, along the Malacca Strait. There was an average difference of OM (5.41%) and $CaCO_3$ (9.51%) between stations N95 and N108, where station N95 dominated with a higher value for OM and $CaCO_3$. In the meantime, the difference between N95 and N108 was apparent in the sediment, where a higher value of silt was present in N95, while N108 secured a higher value for clay and sand content in its sediment. This suggests that constant remobilisation acts on surface sediments and that this occurred at station N108. The constant discharge of particulates due to anthropogenic inputs and frequent precipitation from the nearby drainage basin, lead to the dominance of clay and sand at station N108 [22]. According to Ramaswamy et al. [23], sediment discharge from the Irrawaddy River, due to the continuous weathering of igneous rock, leads to accumulation within the Irrawaddy Delta. In addition, the severity of the monsoonal seasons has an effect on the Andaman Sea, extending to the Gulf of Martaban. Hence, the tides, waves and the Ekman transport generates a net motion via the monsoonal season, causing mass migration of suspended particulates towards station N95, before sinking to the bottom.

In nutrient distribution along the Malacca Strait, the average OM and $CaCO_3$ acquired was 5.87 ± 0.12% and 9.51 ± 0.28%, respectively. There is a difference in OM (5.41%) and $CaCO_3$ (8.24%) content between stations N95 and N108, due to the exposure of the neighbouring shelf, where hydrological changes affect the total distribution along the Malacca Strait. There are higher OM and $CaCO_3$ contents at N95, compared to N108, due to hydrological factors taking place within the Malacca Straits. According to [24], the general circulation of the Malacca Strait was affected by monsoonal seasons, producing ebb tides which, in turn, affected the sediment composition present in the Malacca Straits. The presence of the monsoonal season affects seabed sediment as the major sink, where the rate of removal is higher, in accordance with diffusion rates in the seabed sediment [25]. Similar to composition differences in textural sediments, the monsoonal season affects the coast where the reworking process on the seabed sediment is present, leading to the constant production of nutrients along the station.

Table 2. Physio-chemical characteristics of sediment in the Malacca Straits

Station	Clay (%)	Silt (%)	Sand (%)	OM (%)	$CaCO_3$ (%)
N95	7.23	21.98	70.79	8.53 ± 0.11	14.42 ± 0.34
N99	11.30	15.09	73.61	6.73 ± 0.02	10.02 ± 0.19
N103	13.24	65.70	21.06	4.24 ± 0.2	3.9 ± 0.47
N106	11.44	83.43	5.12	7.63 ± 0.2	6.68 ± 0.13
N108	11.41	3.77	84.81	3.12 ± 0.19	6.18 ± 0.45

The geochemical elements shown in Table 3 reveal that the average concentration for each element is 5.00 ± 0.5 % (Al), 2.88 ± 0.34 %(Fe), 0.23 ± 0.03 % (Ti), 51.41 ± 0.9 µg/g (Zn), 94.56 ± 6.4 µg/g (Cr), 526.08 ± 41.95 µg/g (Mn), and 1.92 ± 0.18 % (Mg). Following the acquired concentrations above, several elements show a difference in concentration compared to the paper by Shaari et al. [26], where higher levels of Fe and Zn were apparent, with respective differences of 44% and 10% on the east coast, compared to the west coast of the Malaysian Peninsular. This suggests continuous inputs from several sources, i.e., the Gulf of Thailand, the Western Pacific and the Natuna Straits. The weathering rate is more apparent as the monsoonal season elevates the precipitation rate, leading to a higher discharge rate. Furthermore, the industrialisation occurring along both river channels also contributes to the increase in geochemical elements. Low geochemical element

concentrations, compared to Shaari et al. [26], are due to the bathymetry of the Malacca Straits, which promotes the diurnal prevailing tides within its semi-enclosed straits, which, in turn, contributes to the mobilisation and dilution of geochemical elements [24,27]. Cross-shelf inputs towards the semi-enclosed coast also affects the total geochemical elements being supplied to the east coast of the Malaysian Peninsular [28]. The cross-shelf input via the Western Pacific, which mobilises via the longshore currents of the Vietnamese coast through the Luzon Strait and through the southern South China Sea (sSCS), coupled with periodic monsoonal seasons, lead to the fluctuations of geochemical elements on the east coast of the Malaysian Peninsular [29].

Table 3. Concentration of geochemical elements in the Malacca Straits

Station	Al (%)	Fe (%)	Ti (%)	Zn (µg/g)	Cr (µg/g)	Mn (µg/g)	Mg (%)
N95	6.09 ± 0.29	3.01 ± 0.31	0.19 ± 0.02	55.09 ± 1.09	121.46 ± 6.25	371.62 ± 20.18	3.01 ± 0.12
N99	5.51 ± 0.24	2.68 ± 0.19	0.23 ± 0.02	46.05 ± 0.6	85.08 ± 5.07	319.86 ± 26.62	2.10 ± 0.10
N103	6.40 ± 0.96	3.00 ± 0.58	0.28 ± 0.05	59.78 ± 1.05	91.78 ± 9.77	564.96 ± 89.81	1.81 ± 0.32
N106	8.11 ± 1.56	3.75 ± 0.95	0.27 ± 0.06	73.09 ± 1.11	128.35 ± 5.97	598.15 ± 91.47	2.44 ± 0.46
N108	3.31 ± 0.09	1.48 ± 0.03	0.13 ± 0.01	52.57 ± 1.26	39.42 ± 2.07	505.40 ± 2.52	1.59 ± 0.06

On the west coast, the prominent contributor is the Andaman Sea, with its origins in the Bay of Bengal and Martaban Bay. Martaban Bay is the drainage basin for the Irrawaddy River and the Bay of Bengal is the drainage basin for the Ganges River, contributing most of the geochemical elements into the sea. Depth differences on the west coast may affect the bottom current trajectory, leading to a difference in the up-welling and down-welling dynamics. This results in less transport in deeper water, leading to a lower rate of remobilisation of seabed sediment. According to Väli et al. [30], the difference in dynamic uplift due to water depth suggests a larger difference in nutrient transport, leading to lower nutrient content in shallower coastal waters due to constant remobilisation. Furthermore, the difference in topography may lead to a lower current output, due to convergence at the northern Malacca Strait. Haditiar et al. [31] stated that the Malacca Strait facilitates a small water mass exchange between the Andaman Sea and the Malacca Strait, compared to the east coast of the Malaysian Peninsular, under the influence of monsoon, resulting in a smaller transport dynamic between the coasts.

To assess environment quality at the sampling stations, principal component analysis (PCA) was used to assess the significance of sediment contamination levels to aquatic ecosystem and environmental management. It also provides more quantification of dataset regarding geochemical elements in sediments and its controlling factors. The results of the PCA are presented in Table 4 for two principal components. The analysis shows that about 54 % of the total variation is explained by the first principal component, followed by 38% for the second principal component.

The first PCA is defined by the hydrological process that results in the accumulation preserved in silts, which, in turn, becomes a depository for Al, Fe, Ti, Cr, Mn and Zn (Table 4). Constant remobilisation of surficial sediment in the Malacca Strait may occur due to difference in the depths of the straits, leading to severe fluctuations in coastal transport dynamics, thus affecting the silt fraction and geochemical content in the sediment [30]. The absorbent nature of Fe-Mn oxyhydroxides combined with silt, would lead to sorption of most of the geochemical elements into the silt, leading to higher affinity, as well as through oxidation and reduction [32]. Fe-Mn acts as a scavenger in coastal environments where the co-precipitation process occurs, leading to the strong enrichment of geochemical elements [33]. On the other hand, the presence of Al, with respect to the silt fraction in seabed sediment, suggests the presence of feldspar and plagioclase, since both of the minerals are

the main constituents in the sediment surrounding the Malaysian Peninsular due to weathering [34,35]. Furthermore, weathering effects in the natural environment lead to the conversion of common zinc species into a soluble form, which is then discharged into the aquatic environment and supplies the sediment in the Malacca Straits [36].

Table 4. Principal component loadings against variables in the Malacca Straits

	Component	
	1	2
Clay	0.265	-0.893
Silt	0.985	-0.166
Sand	-0.976	0.218
Al	0.941	0.316
Fe	0.897	0.412
Ti	0.868	-0.063
Mg	0.285	0.943
Cr	0.759	0.649
Mn	0.619	-0.635
Zn	0.873	-0.101
OM	0.374	0.91
$CaCO_3$	-0.307	0.952

Extraction Method: Principal Component Analysis
Rotation Method: Varimax with Kaiser Normalisation

The second PCA is defined by mobility, where clay acts as a carrier for geochemical elements and OM. A high negative value for clay represents the removal of the clay as the main carrier for nutrients and geochemical elements. This can be seen in Table 4, where a lower clay gradient is apparent with respect to nutrients (i.e., OM and $CaCO_3$). According to Pitt et al. [37], lower clay content represents the elevated infiltration of nutrients in the sediments, hence increasing the availability of nutrients within the sediments. Furthermore, Bobrowsky and Marker [38] also suggest that the association of Mg, Cr and Zn (Table 4) forms a dispersive clay, rather than ordinary clay; dispersive clay is easily flocculated in water and very erodible [39]. This characteristic explains why there is elevated Mg and Cr but less Mn, as the dispersity process prohibits clay from forming into fine-sized clumps. Furthermore, Mg and Cr are known pollutants within the marine ecosystem, where higher levels of water hardness are contributed by Mg, while toxicity and persistent Cr could bioaccumulate in aquatic environments. According to Ismail et al. [40], a medium to high level of chromium was detected due to various industrialisation and shipping activities adjacent to the coast. Similar connections were present when Idriss [41] stated that the Juru River contributed to elevated Cr levels, due to frequent land reclamation surrounding its deltaic region and deforestation within Penang Island, leading to mobilisation along the Juru River.

Conclusion

Sediment in the Malacca Strait faces elevated geochemical elements from natural and anthropogenic inputs. Cross-shelf inputs contribute towards the distribution and differences in concentrations along the Malacca Strait. Furthermore, the Malacca Strait is subject to physical and hydrological factors which lead to fluctuations in geochemical element distribution. In

addition, local drainage basins channel pollutants from natural sources (via weathering) and through anthropogenic sources (via deforestation and land reclamation).

Acknowledgements

The authors would like to thank the First Institute of Oceanography (FIO) and the People's Republic of China, for providing the research grant (ST-2016-005) through the Universiti Kebangsaan Malaysia (UKM). We also thank the Ministry of Science Technology & Innovation (MOSTI) of Malaysia and the Universiti Malaysia Terengganu and Universiti Kebangsaan Malaysia, for their support during sampling. Lastly, we thank the laboratory members, for being an excellent research group, and the staff of the Department of Earth Sciences & Environment, Faculty of Science and Technology, Universiti Kebangsaan Malaysia, for their help during sampling.

Abstract

A rapid, accurate, and sensitive spectrophotometric method for the determination of micro amounts of hydroxylamine and hydrazine is described. The proposed method is based on the interaction of ninhydrin with the amino group of hydroxylamine and hydrazine. Hydroxylamine reacted with ninhydrin as a chromogenic reagent in phosphate buffer at pH 9.14, forming a violet complex with a maximum absorbance at 375 nm after heating for 10 min at 70 °C. Hydrazine reacted with ninhydrin upon heating for 10 min at 85 °C in the presence of phosphate buffer (pH 9), giving a red-brown complex with a maximum absorbance at 425 nm. The optimum conditions affecting the method, such as pH and buffer, sequence of addition, time, temperature, organic solvent, and surfactant, were studied. The complexes of ninhydrin with hydroxylamine and hydrazine were formed in a molar ratio of 1:2. The hydroxylamine–ninhydrin and hydrazine–ninhydrin complexes obeyed Beer's law in a concentration range of 0.033-3.3 and 0.130-3.25 µg mL^{-1}, respectively. Molar absorptivity and Sandell's sensitivity were 0.21508×10^2 L mol^{-1} cm^{-1} and 1.53 µg cm^{-2}, respectively, for hydroxylamine and 0.8583×10^2 L mol^{-1} cm^{-1} and 1.51 µg cm^{-2}, respectively, for hydrazine. The limit of detection and quantification was calculated. The interference effect of various foreign ions and substances was also studied. The proposed method was applied for the determination of micro amounts of hydroxylamine in urine and tap water and hydrazine in tap water.

Keywords: spectrophotometric method, ninhydrin, hydroxylamine, hydrazine, urine

Abstrak

Kaedah spektrofotometri yang cepat, tepat dan sensitif untuk penentuan jumlah mikro hidroksilamin dan hidrazin diterangkan. Kaedah yang dicadangkan adalah berdasarkan interaksi ninhidrin dengan kumpulan amino yang terdapat dalam hidroksilamin dan hidrazin. Hidroksilamin bertindak balas dengan ninhidrin sebagai reagen kromogenik dalam medium beralkali pada pH = 9.14 menggunakan penimbal fosfat membentuk kompleks ungu dengan penyerapan maksimum pada 375 nm selepas dipanaskan selama 10 minit pada 70 °C. Hidrazin bertindak balas dengan ninhidrin apabila dipanaskan selama 10 minit pada 85 °C dengan kehadiran penimbal fosfat (pH = 9) memberikan kompleks merah-coklat dengan penyerapan maksimum pada 425 nm. Keadaan optimum yang mempengaruhi kaedah dikaji seperti pH dan penimbal, jujukan penambahan, masa, suhu, pelarut organik, dan surfaktan. Dua kompleks yang terbentuk bagi ninhidrin dengan hidroksilamin dan hidrazin terbentuk dengan nisbah molar (1:2). Kompleks hidroksilamin–ninhidrin dan hidrazin–ninhidrin mematuhi hukum Beer dalam julat kepekatan 0.033-3.3 dan 0.130-3.25 µg mL^{-1}, masing-masing. Penyerapan molar dan kepekaan Sandell masing-masing ialah 0.21508×10^2 L mol^{-1} cm^{-1} dan 1.53 µg cm^{-2}, untuk hidroksilamin dan 0.8583×10^2 L mol^{-1} cm^{-1} dan 1.51 µg cm^{-2} masing-masing, untuk hidrazin. Had

pengesanan dan kuantifikasi telah dikira. Kesan gangguan pelbagai ion dan bahan asing turut dikaji. Kaedah yang dicadangkan digunakan untuk penentuan jumlah mikro hidroksilamin dalam air kencing dan air paip dan hidrazin dalam air paip

Kata kunci: kaedah spektrofotometri, ninhidrin, hidroksilamin, hidrazin, urin

Introduction

Ninhydrin (2,2-dihydroxyindane-1, 3-dione), a white solid soluble in ethanol and acetone, is generally used to determine ammonia or primary and secondary amines via the formation of Ruhemann's purple as a result of the interaction ninhydrin with these free amines. Ninhydrin has been applied in various spectrophotometric methods for the determination of famotidine in drug formulations [1], cobalt [2], amino acids, peptides, and proteins in agricultural and biomedical fields [3], trace cyanide [4], neomycin sulfate [5], gabapentin [6], and amlodipine besylate [7] in pharmaceutical forms, and glyphosate [8] and ammonia [9].

Hydroxylamine is produced during nitrification and anaerobic ammonium oxidation, which are both essential microbial processes in the nitrogen cycle [10-11]. Hydroxylamine is frequently used as a starting material for the production of pharmaceutical intermediates and drugs [12]; however, hydroxylamine is a well-known mutagen that is toxic to humans, animals, and plants [13], even at low concentration [12]. Many methods have been developed for the determination of hydroxylamine, including spectrophotometry, gas chromatography (GC), and voltammetry methods. For instance, a spectrophotometric method for the determination of hydroxylamine involves its oxidation to nitrite by using sodium arsenate in alkaline conditions. Then the diazo coupling reaction between *p*-nitroaniline and *N*-(1-naphthyl) ethylenediamine dihydrochloride is used to determine the amount of nitrite produced [14]. The use of ferric ammonium sulfate as an oxidant and 1,10-phenanthroline as a chromogenic agent was reported for the determination of the concentration of hydroxylamine in biological wastewater treatment processes [15]. Meanwhile, an indirect spectrophotometric determination of hydroxylamine based on its reaction with iodate was also reported [16]. Another hydroxylamine determination method based on its oxidation to nitrite uses *N, N*-dimethyl aniline and *p*-nitroaniline accompanied by micelle-mediated extraction of the produced azo dye for nitrite determination [17]. As examples of GC and voltammetry methods, the conversion of hydroxylamine to nitrous oxide (N_2O) allows for the GC indirect determination of hydroxylamine [18], and a carbon-paste electrode modified with TiO_2 nanoparticles and quinizarine was reported for the voltammetric determination of hydroxylamine [19].

Hydrazine is an important inorganic base of formula N_2H_4, which is a colorless and flammable liquid highly toxic and dangerously unstable in solution [20]. There are a variety of spectrophotometric methods for the determination of hydrazine such as the condensation of veratraldehyde with hydrazine in acidic medium [21]. Hydrazine can be also determined by reducing ferric ion to ferrous ion, which then reacts with 2,2'-bipyridyl at 60 °C to form a stable red-pink complex [22]. Other method for detecting hydrazine is based on its inhibitory effect on the oxidation of Victoria Blue 4- R by $KBrO_3$ [23]. Moreover, hydrazine can be detected using the Firordt method, which consists in its preliminary derivatization with 5-nitro-2-furaldehyde [24]. A flow injection spectrometric method for the determination of hydrazine consists of its reaction with *p*-dimethylamino-benzaldehyde to produce aldazine [25]. The chemical structures of hydroxylamine, hydrazine, and ninhydrin are shown in Figure 1(a, b), respectively.

Materials and Methods

Reagents and solutions

All the chemicals and solvents utilized were of analytical grade and were used without further purification. The materials used were of the highest quality. Ninhydrin (purity 99.00%) was obtained from BDH Company. Hydroxylamine (purity 99.00%) and hydrazine sulfate (purity 99.00%) were obtained from Sigma-Aldrich. Ethanol (purity 99.99%) was obtained from Elnaser Company, Egypt. Ninhydrin stock solutions (1×10^{-2} M) were prepared by dissolving 0.20 g of ninhydrin in 100 mL ethanol 96%. Hydroxylamine stock solutions (1×10^{-2} M) were prepared by dissolving 0.033 g hydroxylamine in appropriate quantities of distilled water, followed by dilution to 100 mL in a measuring flask. A hydrazine sulfate (1×10^{-2} M) solution was prepared by adding 0.13 g in a 100 mL measuring flask and diluting up to the mark with distilled water.

Instrumentation

A UV/VIS double beam spectrophotometer (T80 Spectrophotometer, PG instruments Ltd. Company, United Kingdom) was used to measure the absorbance using matched quartz cells with a path length of 10 mm and a width of 2 mm. An Adwa pH meter, model AD 1030, from Romania was used to determine the pH change.

Buffers

Different types of buffers were prepared according to standard methods, including acetate buffer (pH 3.5-6) universal buffer (pH 1.81-11.98) [26], borate buffer (pH 7.6-10) [27], citrate buffer (pH 3-6), phosphate buffer (pH 7-11) and acetate buffer (pH 3.5-6) [28].

Surfactant solutions

Different surfactants such as anionic sodium laurate sulfate (SLS), nonionic Triton-X 100, and cationic cetyl trimethyl ammonium bromide (CTAB) were prepared at a concentration of 1×10^{-2} M by dissolving the appropriate amounts in 100 mL of deionized water and used without further purification.

General procedure

In a 10 mL measuring flask, 2.00 mL of hydroxylamine (1×10^{-2} M) or 1.00 mL hydrazine (1×10^{-2} M) was added, followed by 2.00 mL of ninhydrin (1×10^{-2} M), and 2.00 mL of phosphate buffer at pH 9.14 for hydroxylamine and at pH 9 for hydrazine. The measuring flask was heated in a water bath for 10 min at 70 °C for hydroxylamine but at 85 °C for hydrazine, and the absorbance was then measured by scanning the wavelength from 200 to 700 nm against a blank reagent containing 2.00 mL of both ninhydrin and phosphate buffer and 6.00 mL of distilled water.

Beer's law

Aliquots of hydroxylamine in a concentration range of 0.033-3.3 μg mL^{-1} and hydrazine in a concentration range of 0.0130-3.25 μg mL^{-1} hydrazine were transferred into a series of 10 mL measuring flasks containing 2.00 mL of phosphate buffer at pH 9.14 and 9 for hydroxylamine and hydrazine, respectively, and 2.00 mL of ninhydrin was then added. The absorbance was recorded at 375 and 425 nm for hydroxylamine and hydrazine, respectively. The calibration graph was obtained by plotting the absorbance against the concentration of the studied materials in μg mL^{-1}.

Applications of hydroxylamine and hydrazine: Spectrophotometric determination of hydroxylamine and hydrazine in tap water

Tap water (250 mL) was heated gently until the volume was reduced to 25 mL. In two 10 mL volumetric flasks, 2.00 mL of concentrated tap water was added, followed by 2.00 mL of ninhydrin (1×10^{-2} M) and 2.00 mL of phosphate buffer at pH 9.14 for hydroxylamine and pH 9 for hydrazine, and the mixture was heated in a water bath for 10 min at 70 °C for hydroxylamine and at 85 °C for hydrazine. The absorbance was measured against the blank solution.

Spectrophotometric determination of hydroxylamine in urine

A urine sample was obtained from two patients, i.e., an adult man (32 years old) and a woman (24 years old), who did not suffer from kidney problems. 50 mL of urine sample was concentrated to 7 mL by gentle heating and then filtrated. The filtrate (0.5 mL), 2.00 mL of ninhydrin (1×10^{-2} M) and 2.00 mL of phosphate buffer (pH 9.14) were placed in a 10 mL measuring flask using a microburette. The measuring flask was heated in a water bath for 10 min at 70 °C, and the absorbance was measured against the blank at 375 nm.

Results and Discussion

Absorption curve

Ninhydrin was used as a new spectrophotometric reagent for the determination of hydroxylamine and hydrazine sulfate on the basis of the reaction of ninhydrin with the amino group of the studied compounds, which produced a violet complex with hydroxylamine and a red-brown complex with hydrazine showing maximum absorbance at 375 and 425 nm, respectively, as shown in the absorption curve depicted in Figure 2**.**

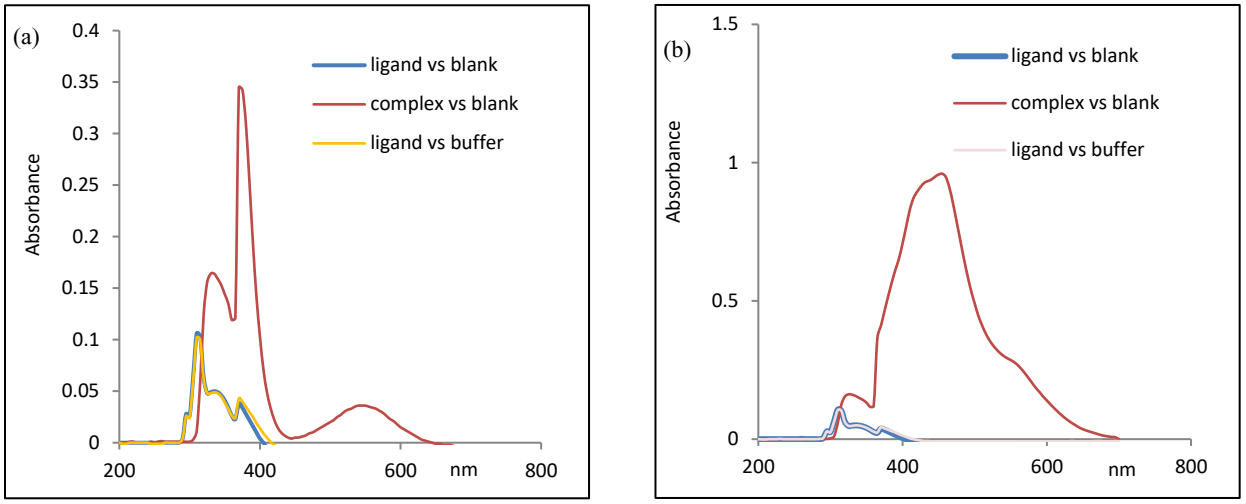

Figure 2. Absorption curves for the complexes of ninhydrin with (a) hydroxylamine and (b) hydrazine

Effect of pH and buffer solutions

The influence of pH on the formation of complexes between ninhydrin and hydroxylamine or hydrazine was studied in a pH range of 1.26–11 using 0.1 M NaOH and 0.1 M HCl solutions. The pH required for complete complex formation ranged between 9 and 11. To adjust the pH, the influence of different buffer solutions (universal, phosphate, and borate buffers) was studied. The maximum absorbance and color Intensity of the complex was attained using the phosphate buffer at pH 9.14 for hydroxylamine and at pH 9 for hydrazine, and 2.00 mL of phosphate buffer gave the maximum absorbance. Figure 3 illustrates the results.

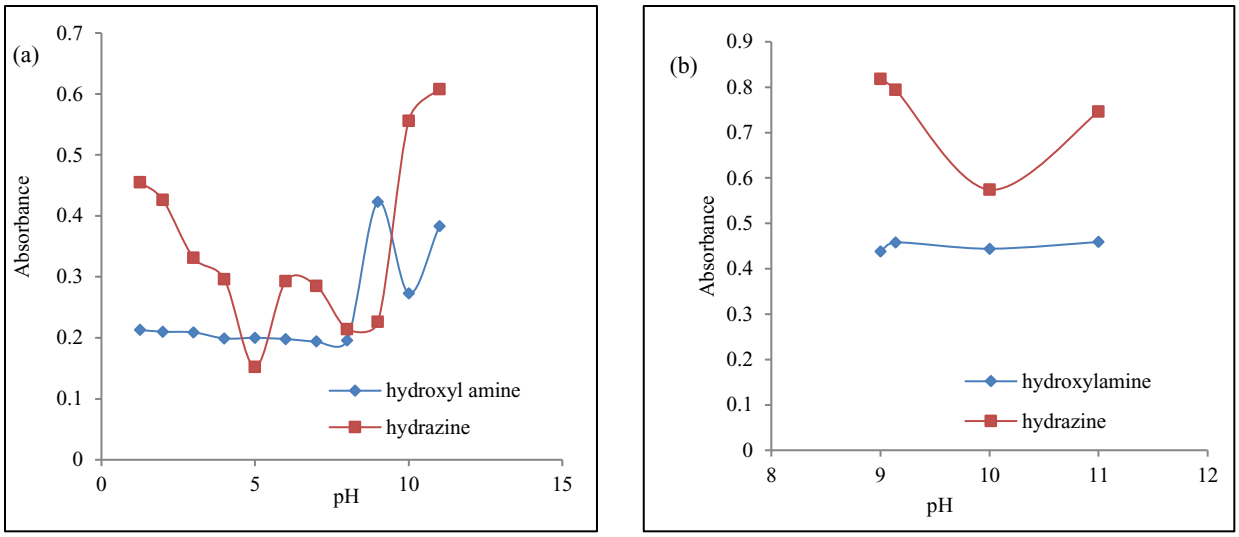

Figure 3. Effect of (a) pH and (b) phosphate buffer on the formation of hydroxylamine and hydrazine complexes with ninhydrin

Influence of the sequence of addition

To determine the optimum sequence of addition, the absorbance of different samples prepared by changing the order of addition of hydroxylamine or hydrazine, ninhydrin, and phosphate buffer was recorded. The total volume of the samples was 10 mL which comprised about 2.00 mL of hydroxylamine or hydrazine, 2.00 mL of ninhydrin, 2.00 mL of phosphate buffer, and 4.00 mL of distilled water. The results showed that the most suitable sequence of addition was hydroxylamine or hydrazine – buffer – ninhydrin, as shown in Table 1.

Table 1. Effect of the sequence of addition on hydroxylamine and hydrazine with ninhydrin

Sequence of addition	Absorbance of Hydroxylamine	Absorbance of Hydrazine
Hydrazine or hydroxylamine + ninhydrin + buffer	0.414	0.835
Hydrazine or hydroxylamine + buffer + ninhydrin	0.422	0.838
Buffer + ninhydrin + hydrazine or hydroxylamine	0.420	0.816
Ninhydrin + buffer + hydrazine or hydroxylamine	0.394	0.822

Effect of time

The effect of time on the color intensity of the ninhydrin complexes was studied by measuring the absorbance of the colored solution at different times (2 to 120 min). The results showed that the absorbance of both complexes reached its maximum at two min time and then decreased slightly with time, which indicates that time had no significant effect on the absorbance of the produced complexes, as shown in Figure 4.

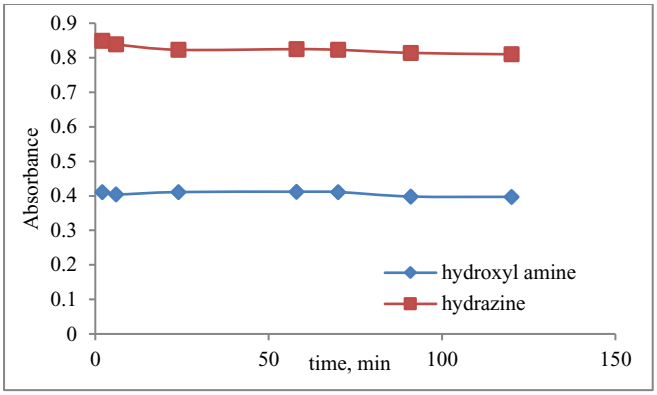

Figure 4. Effect of time on the hydroxylamine and hydrazine complexes with ninhydrin

Effect of temperature

Different samples were prepared by heating in a water bath at different temperatures to investigate the effect of temperature on the hydroxylamine and hydrazine complexes with ninhydrin, and the maximum absorbance was measured against the blank. The results showed that the hydroxylamine complex reached its maximum absorbance at 70 °C, whereas that of the hydrazine complex was observed at 85 °C (Figure 5).

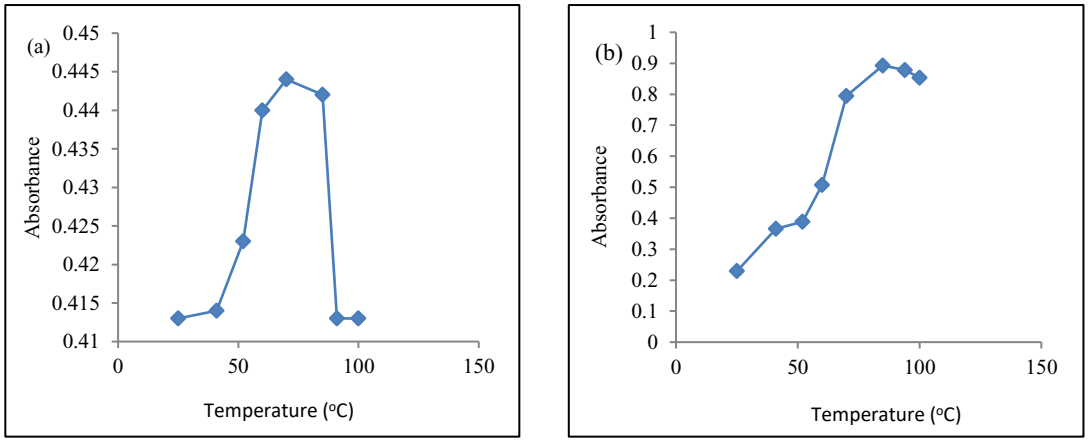

Figure 5. Effect of temperature on the ninhydrin complexes with (a) hydroxylamine and (b) hydrazine

Effect of the addition of an organic solvent

To evaluate the effect of the addition of an organic solvent, 2.00 mL of various organic solvents were added to the prepared samples and the absorbance was measured against the blank. The results depicted in Figure 6 shows that ethanol, ethylene glycol, and glycerin shifted the absorbance to higher values in the case of the complex with hydroxylamine, whereas the addition of the organic solvents decreased the absorbance of the hydrazine complex.

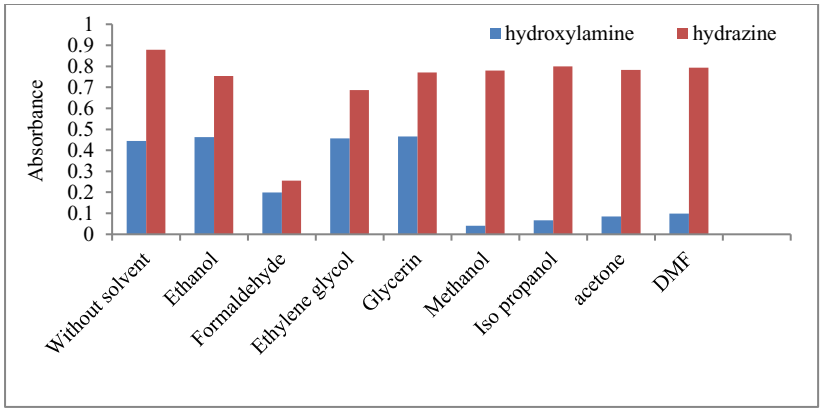

Figure 6. Effect of organic solvent on hydroxylamine and hydrazine complex with ninhydrin

Effect of surfactant

To study the effect of a surfactant on the formed complex, 1.00 mL of cationic surfactant (CTAB), nonionic surfactant (Triton X-100), and anionic surfactant (SLS) was added to a sample solution containing 1.00 mL of hydroxylamine or hydrazine (1×10^{-2} M), 2.00 mL of ninhydrin (1×10^{-2} M), and 2.00 mL of phosphate buffer at pH 9.14 or 9. Then, the absorbance was measured versus the blank. As shown in Table 2 and Figure 7, the presence of the three surfactants decreased the absorbance.

Table 2. Effect of surfactants on the hydroxylamine and hydrazine complexes with ninhydrin

Surfactant	**Absorbance of Hydroxylamine**	**Absorbance of Hydrazine**
Without surfactant	0.444	0.878
SLS	0.136	0.792
Triton X-100	0.040	0.765
CTAB	0.099	0.758

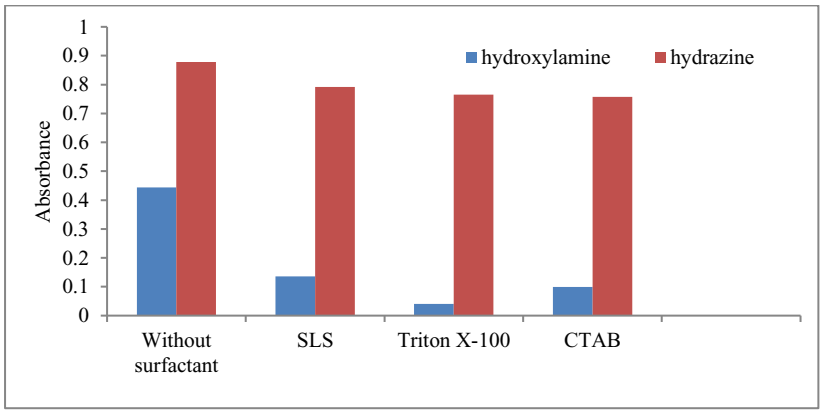

Figure 7. Effect of surfactants on the hydroxylamine and hydrazine complexes with ninhydrin

Determination of the stoichiometric ratio: The molar ratio method

To determine the precise stoichiometry of the complexes formed between hydroxylamine or hydrazine and ninhydrin, a series of solutions were prepared by varying the amount of 1×10^{-2} M solution of ninhydrin from 1.00 to 5.00 mL while keeping the amount of hydroxylamine or hydrazine sulfate constant (2.00 mL of 1×10^{-2} M solution). The absorbance of the samples was then measured and plotted against the molar ratio [ninhydrin] / [hydroxylamine or hydrazine sulfate] [29], as shown in Figure 8 revealing that the complexes were formed in a molar ratio of 1:2.

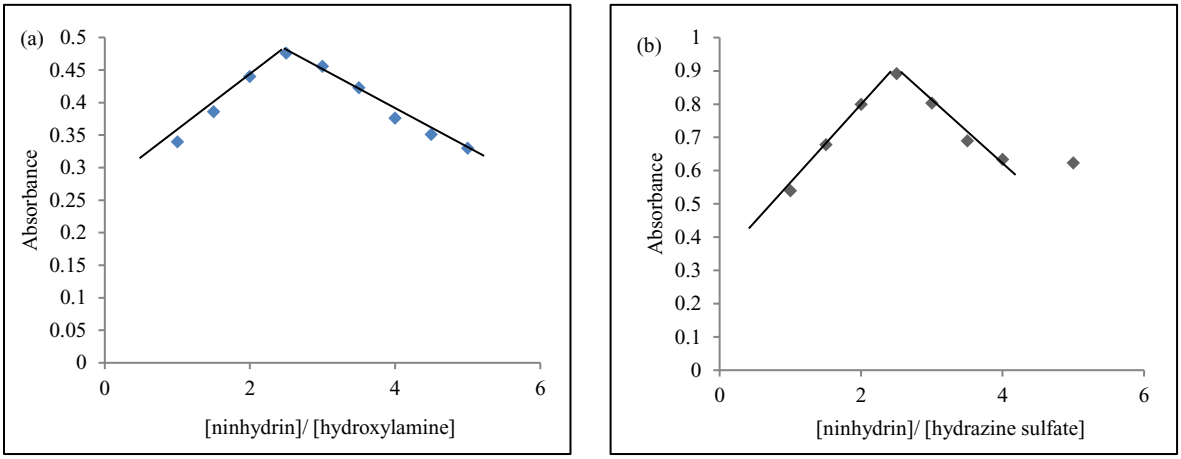

Figure 8. Effect of molar ratio of ninhydrin complexes with (a) hydroxylamine and (b) hydrazine

The continuous variation method

A series of solutions were prepared by combining an equimolar amount of hydroxylamine or hydrazine with 1×10^{-2} M ninhydrin in various proportions (0.10–0.90 mL) while keeping the total molar concentration constant, and the absorbance was measured and plotted against the mole fraction [30], as shown in Figure 9.

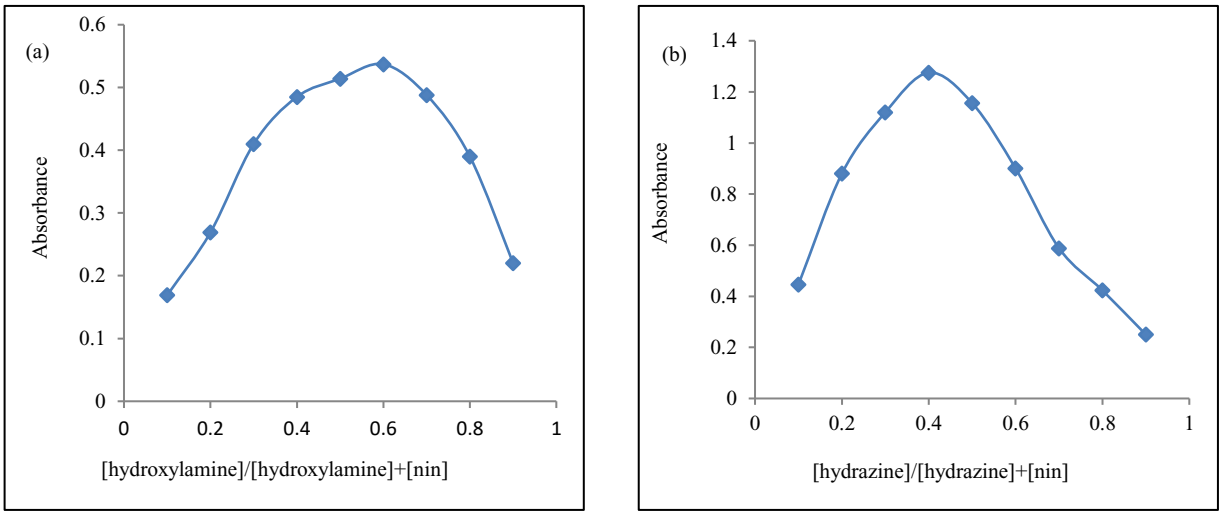

Figure 9. Continuous variation of the ninhydrin complexes with (a) hydroxylamine and (b) hydrazine

Calibration curve (Beer's law)

To determine whether Beer's law was obeyed in the present system, several solutions were prepared by varying the concentration of hydroxylamine and hydrazine while maintaining the concentration of ninhydrin constant at 1×10^{-2} M. The results depicted in Figure 10 show that Beer's law was obeyed in the concentration range 0.033-3.3µg mL^{-1} for hydroxylamine and 0.130-3.25 µg mL^{-1} for hydrazine.

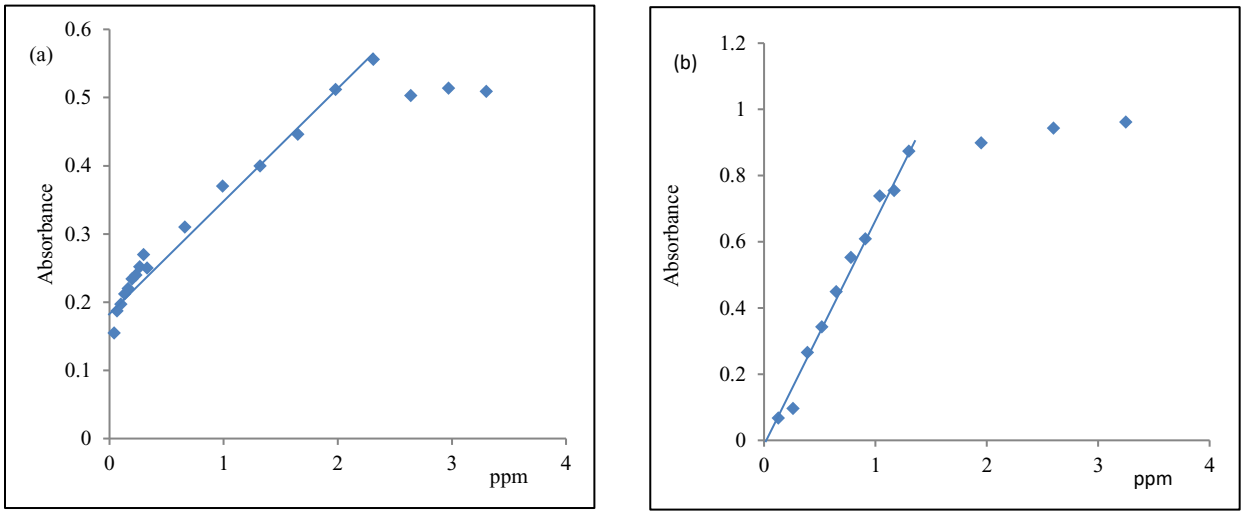

Figure 10. Calibration curves of the ninhydrin complexes with (a) hydroxylamine and (b) hydrazine

Effect of interferences

A variety of interfering materials such as thiourea, urea, ascorbic acid, sodium nitrate, ammonium sulfate, sodium nitrite, fructose, trisodium citrate, sodium benzoate, magnesium sulfate, and hydroxide ammonia at a concentration of 1×10^{-1} M were added to 1×10^{-2} M of hydroxylamine or hydrazine to study their interference effect. The results showed that sodium nitrite and hydroxide ammonia caused interference with hydroxylamine and magnesium sulfate caused interference with hydrazine.

Statistical treatment

Seven measurements were conducted for concentrations of 0.33 and 0.91 µg mL^{-1} of hydroxylamine and hydrazine sulfate, respectively, under the optimum conditions to evaluate the reproducibility of the method. Table 3 summarizes a series of statistical parameters, such as standard deviation, molar absorptivity, Sandell's sensitivity, Student's t-test, correlation coefficient, limit of detection, and limit of quantification. The results indicate that the proposed method exhibited excellent linearity, high sensitivity, and good accuracy and precision. Analytical properties such as pH and buffer, time, temperature, and Beer's law are also listed in Table 3.

Table 3. Statistical treatment and analytical properties for the determination of hydroxylamine and hydrazine using ninhydrin as a chromogenic reagent in the presence of phosphate buffer

Parameter	Hydroxylamine	Hydrazine
Molar absorptivity L mol^{-1} cm^{-1}	0.21508×10^2	0.8583×10^2
Standard deviation (SD)	0.003134	0.004887
(RSD %)	0.930246	0.53136
Standard error of the mean (SE)	0.0011845	0.001847

Time (min)	2	2
Temperature °C	70	85

Applications of hydroxylamine and hydrazine

The suggested method was used to determine hydroxylamine in urine, hydroxylamine and hydrazine in tap water. The results in a Table 4 were in good agreement with the recommended method, indicating that the proposed method could be used.

Table 4. Determination of hydroxylamine and hydrazine in urine and tap water

Sample	Taken (mg)	Found (mg)	Recommended Method	% Recovery	% RSD
Hydroxylamine in urine	2.1	2.202	2.04	99.998	0.0022
Hydroxylamine in tap water	0.32	0.31	0.317	99.9999	0.00007
Hydrazine sulfate in tap water	0.25	0.27	0.24	99.9997	0.0003

Recommended method according to Watt [31] and Frear [32]

Conclusion

A simple, accurate, cost-effective, and sensitive method for the determination of microamounts of hydroxylamine and hydrazine has been demonstrated. The method is based on the use of ninhydrin as a chromogenic reagent, which reacts with the amino group of the substrates. The color of the formed complex between ninhydrin and hydroxylamine or hydrazine remains stable for a long time. The use of organic solvents or high temperature is not required. However, some foreign substances interfere with hydroxylamine and hydrazine, leading to a decrease or increase in the absorbance. The feasibility of the method for determining hydroxylamine and hydrazine sulfate in real samples, i.e., tap water and urine, is demonstrated.

Abstract

Over the past decade, the corrosion inhibition of organic ligands has been extensively studied in numerous experiments in acid media. The number of published papers related to corrosion inhibition studies of organic ligands has been rising exponentially. The organic ligands have high inhibitive properties due to their capability to adsorb on the surface of metal by forming a protective layer. Having lone pair electrons (S, N, O) and multiple bonds (π bonds) allow them to adsorb on the surface of metals efficiently. However, there is very limited and less comprehensive information on the characterization of corrosion inhibition performance of organic ligands on the surface of metals. Therefore, this review paper provides a comprehensive review on the corrosion inhibition performance through various characterization methods, which are the electrochemical method [Electrochemical Impedance Spectroscopy (EIS), Polarization], Scanning Electron Microscope (SEM) with Energy Dispersive X-ray (EDX), and Langmuir Isotherm, which are thoroughly discussed herein.

Keywords: electrochemical impedance spectroscopy, polarization, scanning electron microscope with energy dispersive X-ray; Langmuir isotherm

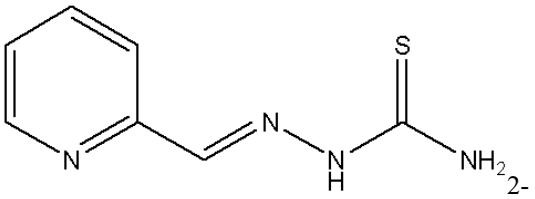
Abstrak

Sepanjang dekad yang lalu, perencatan kakisan ligan organik di dalam media berasid telah diuji di dalam eksperimen secara meluas dalam banyak eksperimen dalam media asid. Bilangan makalah yang diterbitkan berkaitan dengan kajian perencatan kakisan ligan organik telah meningkat secara eksponen. Ligan organik mempunyai sifat perencat yang tinggi kerana keupayaannya untuk menjerap pada permukaan logam dengan membentuk lapisan pelindung. Mempunyai pasangan elektron tunggal (S, N, O) dan ikatan berganda (ikatan π) membolehkan ligan organik menjerap pada permukaan logam dengan berkesan. Walau bagaimanapun, terdapat maklumat yang sangat terhad dan kurang komprehensif mengenai pencirian prestasi perencatan kakisan ligan organik

pada permukaan logam. Oleh itu, kertas kajian ini menyediakan ulasan kajian secara menyeluruh tentang pencirian prestasi perencatan kakisan melalui pelbagai kaedah pencirian seperti kaedah elektrokimia [Spectroskopi Impedan Elektrokimia (EIS), Polarisasi], Mikroskop Elektron Pengimbas (SEM) dengan Sinar-X Serakan Tenaga (EDX), dan Isoterma Langmuir dan telah dibincangkan dengan teliti di sini.

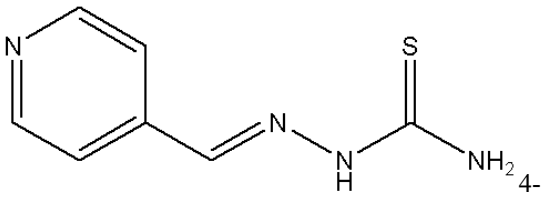
Kata kunci: spektroskopi impedan elektrokimia, polarisasi, mikroskop elektron pengimbas dengan sinar-X serakan tenaga, isoterma Langmuir

Introduction



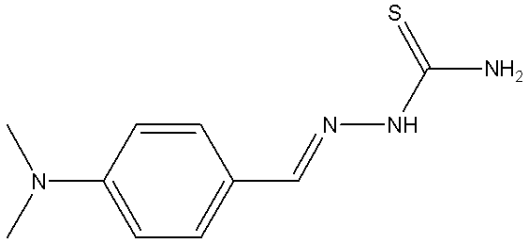
Corrosion is the term used for the natural oxidation of metal. Corrosion is also prescribed as the electrochemical corrosion or deterioration of metals and alloys in the presence of an environment [1-2]. When metals and alloys are unprotected in an acidic environment, they corrode rapidly. When metals come into contact with inorganic acids, pits and cracks formation on the surface causes machinery and equipment to fail [3-4]. Organic and inorganic compounds are the two major classes of corrosion inhibitors. Inorganic corrosion inhibitors are legislation restricted due to their potential for toxicity and pollution, while organic inhibitors are the most common means of preventing metal corrosion in harsh environments [5-6]. The organic inhibitor, when introduced in small amounts to the environment where a metal would corrode, results in lessened oxidization of the metal [7-9]. By adsorbing on the metal surface and generating an obstacle that inhibits the metal active sites, the organic inhibitor improves mild steel's resistance to corrosive media [10]. Organic ligands having π bonds, C=N, and lone electron pairs (S, O, N) would produce high inhibitive characteristics because they can enhance effective adsorption by covalent bonding with metal atoms' unoccupied *d*-orbitals [11-13]. Khaled et al. proclaimed that the S and N atoms have been shown to have the capability to form stable complexes that are closely arranged in the coordination sphere of metal ions [14]. Inhibitor molecules adsorb on metal surfaces, forming thin films that prevents corrosion by 'insulating' the metal from the corrosive electrolyte and altering the processes as well as the kinetics of corrosion reactions [15]. The organic corrosion inhibitor can be adsorbed on the metallic substrate through physical or chemical adsorption [16]. Multiple electrochemical and physical characterization techniques were used to deduce the nature of adsorption and evaluate the inhibitor's corrosion inhibition efficacy.

This review presents the electrochemical techniques, Electrochemical Impedance Spectroscopy (EIS) and Polarization, which have been used to evaluate the efficacy of organic compounds as corrosion inhibits on the surface of metal. Besides, the adsorption behavior of the inhibitors was also thoroughly reviewed through EDX and isotherm characterization.



Corrosion Inhibition Performance Studies

Electrochemical impedance spectroscopy



EIS is a common method for exploring organic-coated metals because it is a quick and easy approach to figure out the protective characteristics of organic inhibitors on metal surfaces [17]. Besides, Nikooa et al., proclaimed that EIS is a valuable tool for learning more about the corrosion inhibition characteristic of organic inhibitors and their mechanism of protection [18]. Corrosion inhibitors, 2-pyridinecarboxaldehyde thiosemicarbazone (2-PCT), 4-pyridinecarboxaldehyde thiosemicarbazone (4-PCT) [19], 4-(*N*,*N*-dimethylamino)benzaldehyde thiosemicarbazone (DMABT) [28] and {[(Benzylsulfanyl)carbonothioyl] amino} acetic acid (BDTC), {[(Propylsulfanyl) carbonothioyl] amino} acetic acid (PDTC) [18] structures, as shown in Figure 1, are examples that are used for the discussion.

Figure 1. Structures of 2-PCT, 4-PCT, DMBAT, BDTC, and PDTC

There was a single depressed semicircle as shown in Figure 2 in all of the impedance spectra acquired for DBMAT, which consisted of two loops, one capacitive loop at a higher frequency and an inductive loop at a lower frequency. It indicated that the electrochemical solid/liquid barrier has a non-ideal capacitive behavior [20-21]. The non-homogeneity or crack (roughness) of the metal surface results in a depressed semicircle, which is attributed to frequency dispersion [22-23]. In addition, the "dispersing effect" of the depressed semicircle is a phenomenon that is commonly linked to surface roughness, chemical inhomogeneity, inhibitor adsorption, and the degree of poly crystallinity [24-26]. The existence of roughness and non-homogeneity on the metal surface because of the formation of corrosive chemicals and metal oxides might alter the density of active sites on the surface. The semicircle-shaped Nyquist plots signify the development of a barrier on the surface and a charge transfer process that is principally responsible for metal corrosion [27]. Mourya et al. revealed that in an acid media, the DMABT [28] created a single semicircle with its center below the real axis (x-axis), indicating the existence of a single charge-transfer process during the metal dissolution [28-29]. Overall, the impedances spectra showed that the diameters of imperfect semicircles steadily increase as the inhibitor concentration rises, implying that the inhibitor molecules can prevent metal dissolution in acidic conditions and so improve corrosion resistance [18, 30]. Increased surface coverage of inhibitive molecules on the surface of metal can be linked to increased capacitive loop diameters [19, 31].

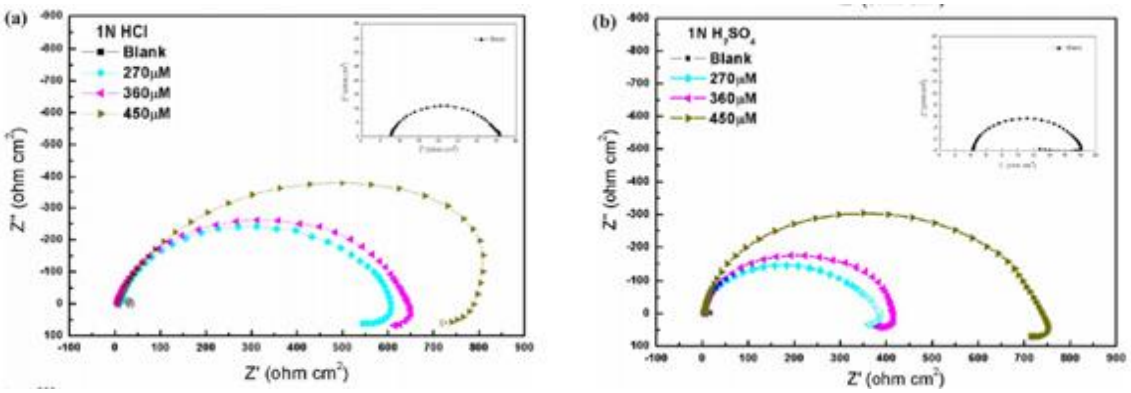

Figure 2. Nyquist plots of the corrosion of mild steel in acidic media absence and existence diverse concentrations of DMABT at 298 K: (a) 1N HCl; (b) 1N H_2SO_4 [28]

In general, the impedance curve contains three patterns, which are the high, medium, and low frequency capacitive loops. The impedance spectra possess a large capacitive loop at high frequencies, followed by a smaller inductive loop at low frequencies. The charge transfer of the corrosion process and double-layer behavior is frequently correlated with the high-frequency capacitive loop. The relaxation process of the adsorbed intermediates regulating the anodic process could be the reason for the low inductive loop induced by the adsorption of inhibitors or Cl^-_{ads} and H^+_{ads} from HCl on the electrode surface [28, 32-33]. Additionally, the layer stabilization consequences of the corrosion action on the electrode surface, involving inhibitor molecules and their reactive products, are most likely responsible for the inductive behavior at low frequencies [32]. It could also be the outcome of passivated surface re-dissolution. The medium capacitive loop is linked to the adsorption of corrosion inhibitors on the metal surface, which increases as the inhibitor 's concentration increases [32]. Mourya et al. reported that in the absence and existence of an inhibitor, the form of the curve in the two electrolytes remained unchanged [28]. This signifies that the addition of an inhibitor has no effect on the corrosion mechanism [34].

The intercept complements electrolyte resistance (R_s), solution resistance at the higher frequency end, and electrolyte resolution (R_s) + charge transfer resistance (R_{ct}) at the lower frequency end. The charge transfer resistance is R_{ct}, which is the contrast between these two quantities. R_{ct} is a measure of electron transfer over a surface that is inversely proportional to the corrosion rate [35]. Corrosion reactions that are strongly charged transfer-controlled and have impedance characteristics could be demonstrated using a simple and frequently used equivalent circuit consisting of a double layer capacitance, R_{ct}, and R_s. Instead of a pure double layer capacitance, a constant phase element, CPE, is used in the circuit compared to the capacitor, providing a more definite fit as shown in Figure 3 [36-37].

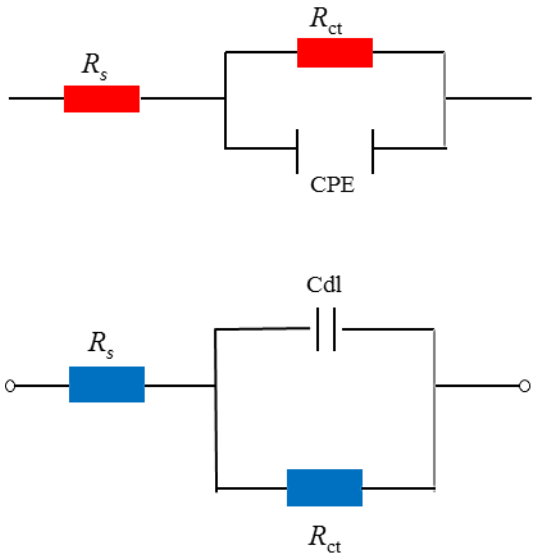

Figure 3. Equivalent circuit used to suit the EIS data of mild steel in 1N HCl consisting of diverse concentrations of inhibitors [36]

The CPE incorporates the component C_{dl} and the coefficient of exponential value of CPE α, which explains physical processes such as surface roughness, inhibitor adsorption, and the development of porous layers [38-39]. A few studies reported that the C_{dl} values dropped when the concentration of various inhibitors increased and deduced that inhibitor molecules were deposited on the steel surface [36, 40-41]. In addition, lower C_{dl} values possibly be induced by a decrease in local dielectric constant and an increment in electrical double layer thickness [42-44]. The Helmholtz model can be used to explain the decreasing C_{dl} values [45]:

$$C_{\mathrm{dl}} = \frac{\varepsilon\varepsilon_0}{\delta} S, \tag{1}$$

Where, ε = the dielectric constant of the medium, ε_0 = the vacuum permittivity, S = the electrode area, and δ = the thickness of the protective layer.

Most studies proclaimed that with the increase of inhibitor concentrations, the R_{ct} values increased. The increase in charge transfer resistance could be ascribed to the creation of a protective layer on the metal/solution interface [46-48]. The CPE's impedance function is denoted by the expression [19, 49]:

$$Z_{\mathrm{CPE}} = Y_0^{-1}(j\omega)^{-n} \tag{2}$$

where, Y_0 = a proportional factor, ω = the angular frequency, n = a deviation parameter ($-1 \leq n \leq +1$); n shows phase shift that is the degree of surface in-homogeneity, and n = 0, the CPE represents a pure resistor, f or n = 1 an inductor and for n = +1, a pure capacitor.

The values of the double layer capacitance (Q_{dl}), and inhibition effectiveness (η) are computed as follows:

$$Q_{\mathrm{dl}} = \mathrm{Y}_0(\omega_m^{''})^{n-1} \tag{3}$$

where, ω" = the angular frequency at the maximum value of the imaginary part of the impedance spectrum, and a constant phase angle element (CPE) Q_{dl} is used to define the C_{dl}.

According to the Helmholtz model [50], the Q_{dl} can be computed as follows:

$$Q_{\mathrm{dl}} = \frac{\varepsilon^0\varepsilon}{d}\mathrm{S} \tag{4}$$

where, d = the thickness of the protective layer, ε° is the permittivity of the air, and ε = the local dielectric constant, and S is the electrode surface area.

$$\eta = \frac{R_{ct} - R_{ct}^0}{R_{ct}} \times 100\% \tag{5}$$

R_{ct} = polarization resistance values observed in the presence of the inhibitor molecule, and R_{ct}° = polarization resistance values observed in the presence and absence of the inhibitor molecule [51].

Xu et al. reported that the values of R_{ct} rose dramatically and values of Q_{dl} decreased when the inhibitor concentration rose [19]. A reduction in Q_{dl} denotes a lowering in the local dielectric constant or a buildup in the electrical double layer thickness. As a result, the addition of 2-PCT and 4-PCT to the electrode surface may adsorb on the electrode surface by exchanging water molecules. The R_{ct} value in the blank solutions without the inhibitor is comparatively low due to the high conductivity of the HCl solution.

According to the phase angle graphs shown in Figure 1, more negative phase angle readings were observed when the concentration of corrosion inhibitors was increased in 1.0M HCl, and showed better inhibitive activity due to more inhibitor molecules adsorbed on the metal surface at higher concentrations. Adsorption of inhibitors results in increased surface smoothness [33]. Furthermore, the broadening of the curves is observed, confirming the buildup of the inhibitor molecule on the mild steel surface [52]. Nikooa et al. reported the uninhibited HCl solution exhibits a phase angle of -54.6° at 63 Hz, which increases to a maximum of -72.6 at 398 Hz for BDTC and -71.4 at 316 Hz for PDTC [18]. It can be supported by the presence of π electrons in the aromatic ring of BDTC. In comparison to the PDTC, the BDTC's more planar structure provides better interaction and coverage on the metal surface.

As a conclusion from the EIS study, corrosion inhibitors are effective on metal surfaces in an acid solution, as demonstrated by the results. The inclusion of electronegativity atoms such N and S, which are active centers of adsorption, could explain the greater inhibitory effectiveness. These groups increase electron density on the adsorption centers in inhibitor compounds, enabling smoother electron transfer between the functional group and the metal. The adsorption of inhibitors on the metal surface increases the R_{ct} because of the formation of a protective layer. Indirectly, Q_{dl} and local dielectric values decrease because of the increasing electrical double layer. An increment of surface coverage on the metal surface by corrosion inhibitors might be due to the lessening of water molecules and other ions. Besides, the impedance behavior of the metal surface was significantly altered when the inhibitor was added, and the diameter of the semicircle produced in the Nyquist plots was subsequently enlarged in the presence of inhibitors.

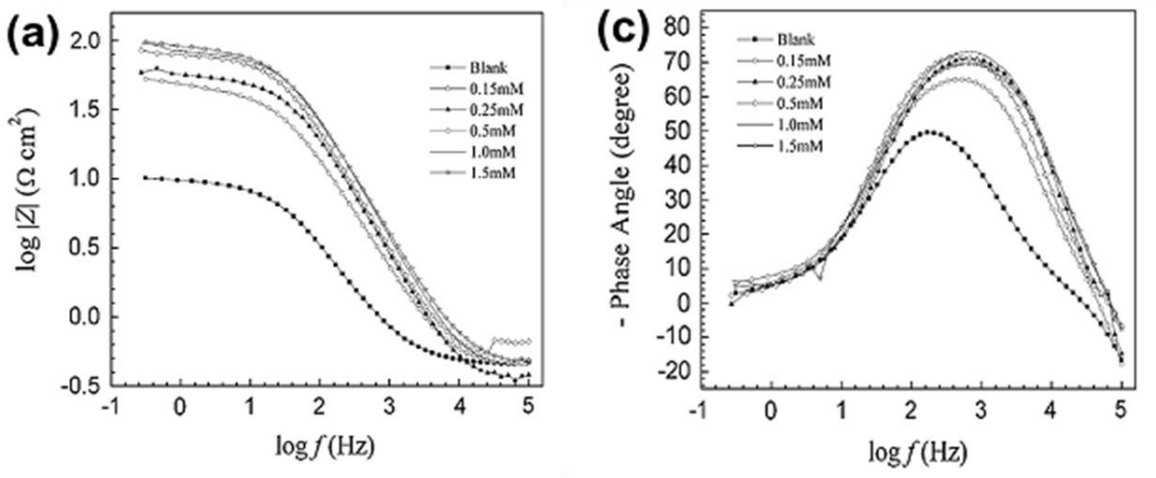

Figure 4. The Bode and Phase Angle plots for mild steel in 1.0M HCl solutions absence and existence diverse concentrations of inhibitors at 30ºC: (a and c) 2-PCT [19]

Polarization plot

The shift in potential induced by concentration changes the environment, surrounding the electrode surface is known as concentration polarization. The voltage difference between the anode and the cathode, as well as the resistance of the corrosion cell, affects the rate of corrosion (or current density). The current flow is present in all corrosive reactions, and it changes the potential of the metal surfaces involved. Tafel curves were used to compute corrosion potentials (E_{corr}) and corrosion current densities (I_{corr}) [53]. The anodic reaction of corrosion occurs when metal ions from the metal surface flow into the solution or electrolyte, and the cathodic reaction occurs when hydrogen ions are discharged to form hydrogen gas or a reduction of dissolved oxygen in acidic solutions [54]. Cao stated that if the E_{corr} of the inhibitor-containing solution is almost equivalent to the uninhibited solution, it can be deduced that the inhibition effect is mediated by adsorption inhibitive species obstructing the surface of the metal electrode geometrically [55].

The addition of the Thiophene derivative as a corrosion inhibitor reduces the corrosion rate dramatically, lowering current densities by modifying both the anodic and cathodic Tafel curves [56]. Both anodic and cathodic reactions are impeded by this pattern, with the suppression effect becoming stronger as the inhibitor concentration rises. It is plausible that this is due to the inhibitors' adsorption at the active sites on the surface.

The mechanisms of anodic reaction in acid are shown below:

The process of Fe dissolution pathways in HCl [57]:

$$\begin{aligned} &Fe + Cl^- \longrightarrow (FeCl^-)_{ads} \\ &(FeCl^-)_{ads} \longrightarrow (FeCl^-)_{ads} + e \\ &(FeCl)_{ads} \longrightarrow FeCl + e \\ &FeCl^+ + e \longrightarrow Fe^{2+} + Cl^- \end{aligned} \quad (6)$$

According to the mechanism depicted below, the iron electrodissolution in H_2SO_4 solvent is mostly dependent on the intermediate adsorption of $FeOH_{ads}$:

$$\begin{aligned} &Fe + H_2O \longrightarrow Fe.H_2O_{ads} \\ &FeH_2O_{ads} \longrightarrow FeOH_{ads} + H^+ + e \\ &FeOH_{ads} \longrightarrow FeOH^+ + e \\ &FeOH^+ + H^+ \longrightarrow Fe^{2+} + 2e \end{aligned} \quad (7)$$

As a conclusion, Okafor and Zheng described that the anodic dissolution of iron in an H_2SO_4 solution is mostly reliant on the adsorbed intermediate $(FeOH)_{ads}$, whereas in an HCl solution, Shukla and Quraishi stated that it is mostly reliant on $(FeCl)_{ads}$ [58-59]. The corrosion inhibitors mechanism in the acid solution can be described as:

Anodic oxidation in H_2SO_4 [60]:

$$\begin{aligned} &Fe.H_2O_{ads} + Inh \longrightarrow FeOH_{ads}^- + H^+ + Inh \\ &Fe.H_2O_{ads} + Inh \longrightarrow Fe.Inh_{ads} + H_2O \\ &FeOH_{ads}^- \longrightarrow FeOH_{ads} + e \text{ (rate-determining step)} \\ &Fe.Inh_{ads} \longrightarrow Fe.Inh_{ads}^+ + e \\ &FeOH_{ads} + Fe.Inh_{ads}^+ \longrightarrow FeOH^+ + Fe.Inh_{ads} \\ &FeOH^+ + H^+ \longrightarrow Fe^{2+} + H_2O \end{aligned} \quad (8)$$

Anodic oxidation in HCl [60]:

$$\begin{aligned} &(FeCl^-)_{ads} + InhH^+ \longrightarrow (FeCl^-InhH^+)_{ads} \\ &(FeCl^-)_{ads} + InhH^+ \longrightarrow (Fe.InhH^+)_{ads} + Cl^- \end{aligned} \quad (9)$$

The adsorption of H^+_{Inh} onto the adsorbed $FeCl^-$ present at the metal/electrolyte interface causes the I_{corr} values to drop at varied inhibitor concentrations. In the presence of corrosion inhibitor, the cathodic reaction process can be computed as follows:

$$\begin{aligned} &Fe + H^+ + e \longrightarrow (FeH)_{ads} \\ &Fe + (InhH^+) + e \longrightarrow (Fe.InhH)_{ads} \\ &(FeH)_{ads} + (FeH)_{ads} \longrightarrow Fe + H_2 \end{aligned} \quad (10)$$

The corrosion inhibitory effectiveness (Tafel) of compounds is computed using the following formula [61-62]:

$$\eta \text{Tafel } (\%) = \frac{I_{corr} - I_{corr(i)}}{I_{corr}} \times 100 \quad (11)$$

where, i_{corr} = corrosion current densities in the absence of inhibitors, and $i_{corr(inh)}$ = corrosion current densities in the absence and in the presence of inhibitors

$$\eta(\%) = \left(\frac{R_{ct} - R_{ct}^0}{R_{ct}}\right) \times 100 \quad (12)$$

where, R_{ct} = charge transfer resistance in the presence of the inhibitor, and R^0_{ct} = charge transfer resistance in the absence of the inhibitor [63].

Figure 5 shows that the E_{corr} of the corrosion inhibitors are shifted to a more negative side and the E_{corr} displacement is less than 85 mV. As a result of this finding, corrosion inhibitors were classified as mixed-type inhibitors, with cathodic polarization being the most prevalent. A reduction in the rate of anodic metal dissolution as well as a delay in the cathodic hydrogen evolution reaction reflect the inhibitors' mixed inhibitory nature [54, 68-69]. If the difference in corrosion between the inhibitor and the blank exceeded 85 mV, the inhibitor was categorized as cathodic or anodic [64-65]. As shown in Figure 6, when the inhibitors were added to the corrosive solutions, the E_{corr} values changed in a more positive manner than when they were absent. The inhibitors' corrosion potentials have shifted to the positive side and the E_{corr} displacement was less than 85 mV, indicating that they behave as mixed-type inhibitors with an anodic reaction-predominant effect. Besides, the corrosion inhibitor can be deduced by $ß_a$ and $ß_c$ values. Sahin et al. and Nazir et al. reported that $ß_c$ values are higher than $ß_a$ in different concentrations. It can be concluded that the inhibitor is predominantly cathodic in nature, as supported by the polarization curve and E_{corr} values [66-67]. The parallel cathodic current–potential curves as shown in Figure 5 implies that the addition of this inhibitor has no effect

on hydrogen evolution and that hydrogen evolution is controlled by activation. Fathabadi et al., deduced that the charge-transfer mechanism is primarily responsible for the reduction of H^+ ions on the metal surface [70]. The observation can be elucidated by the fact that the metal surface has been covered with adsorbed corrosion inhibitor molecules, which has suppressed the corrosion process. This indicates that the presence of the inhibitor has no effect on the reduction pathway, and so the hydrogen evolution is retarded by the inhibitor's surface blocking effect [71-72].

The shape of polarization curves with and without the corrosion inhibitor is identical for most corrosion inhibition performance studies in the acid media. The occurrence explained that the addition of corrosion inhibitors had no impact on the corrosion mechanism of metal dissolving in acid solution, and the inhibitory impact of these inhibitors was due to the covering of inhibitor molecules at the active sites to limit their exposure to the acidic environment [73].

The inhibitor molecule attaches to the mild steel surface and blocks the anodic reaction's available reaction sites [74-75]. With increasing inhibitor concentrations, the surface coverage increases. At varying inhibitor concentrations, the surface coverage, θ of the inhibitor was estimated using the equation:

$$\theta = \frac{i_{corr} - i_{corr(inh)}}{i_{corr}} \quad (13)$$

where; i_{corr} = corrosion current densities in the absence of inhibitors, and $i_{corr(inh)}$ = corrosion current densities in the presence of inhibitors.

Therefore, the inhibition effectiveness can be computed using:

$$\eta(\%) = \theta \times 100 \quad (14)$$

The rise in polarization resistance in the presence of the inhibitor supports the development of a non-conducting physical barrier of compound on the metal surface, leading to an increase in corrosion inhibiting effectiveness. Besides, the formation of a plateau at anodic polarization refers to a passivation process that arises after oxygen evolution [76]. Desorption potential is described as a sudden increase in current density with increasing potential, as evidenced by the flat region on the anodic curve. The simultaneous adsorption of inhibitor molecules on the metal surface and desorption of inhibitor molecules due to the metal's dissolution in corrosive media can explain these phenomena. The desorption rate of the inhibitor is greater than its adsorption rate in this circumstance, resulting in an increase in the corrosion current as the potential increment [77-78].

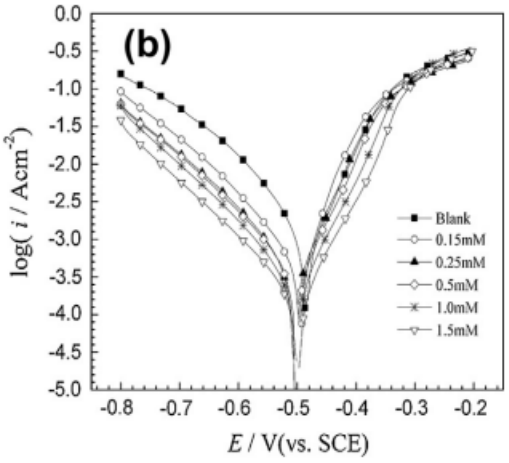

Figure 5. Potentiodynamic polarization curves for mild steel in the absence and presence of diverse concentrations of inhibitors in 1.0 M HCl: (a) 2-PCT, (b) 4-PCTat30ºC [19]

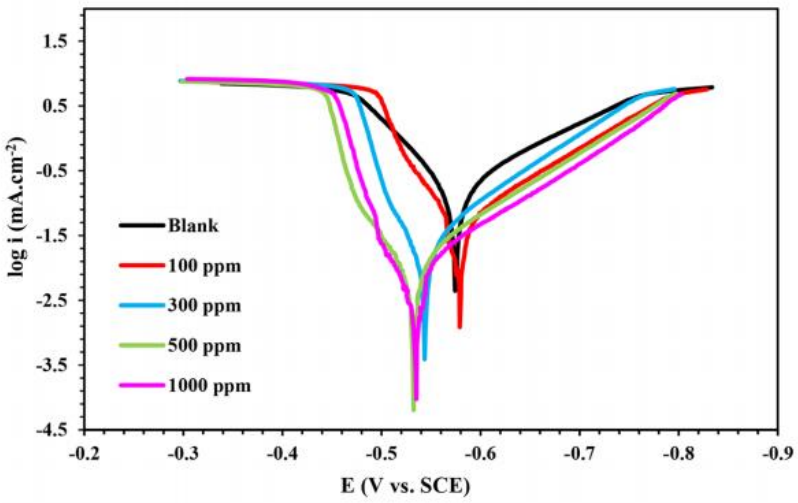

Figure 6. Potentiodynamic polarization curves for CRS in the presence and absence of diverse concentrations of the inhibitor at room temperature in 0.5 M HCl: (a) BDTC [18]

Scanning electron microscope-energy dispersive X-ray

SEM is used to scrutinize the morphology of mild steel surfaces before and after their immersion in acid solution. While EDX is used to confirm the creation of the protective coating owing to inhibitor adsorption on the surface of mild steel [79-80]. EDX spectra displayed the presence of N, S, P (corrosion inhibitors) and decreased composition of Fe on the metal surface as a proof of protective layer formation [81-82]. This increased inhibitory efficacy was presumably due to a strong interaction between the ($-NH_2$) and (=S) groups classified as electronegative atoms in the inhibitors' molecular structures and the metal surface, which blocks the active sites of adsorption. According to a few studies, the availability of free electron pairs, heteroatoms, and π orbitals permits the corrosion inhibitor to have a significant inhibitory performance, resulting in the blocking of active sites and, as a result, a reduction in corrosion rate [83]. Therefore, it improves the metal surface roughness (smoothness) and reduce the pits [84-85]. The development of iron oxide on the metal surface causes a peak of O to be extremely high in an uninhibited hydrochloride solution [86-87]. Whereas, due to the adsorption of the BDTC molecules, the oxidation of CRS on the surface is reduced, showing that there is less oxidation of CRS on the surface. The surface of uninhibited metal is severely eroded, and due to the Cl^--induced attack, a surface deep hole can be seen at greater resolutions [88] Besides, the corroded metal showed an uneven, pit-shaped pattern and the formation of crystal gain corrosion products [89]. Al-Amiery et al. deduced that because the surface was dried before SEM scanning, the cracks in the film are attributable to surface dehydration [90]. The electrochemical analysis correlates well with these findings.

Adsorption isotherm

Adsorption isotherms are commonly used to indicate the efficacy of organic adsorbent type inhibitors and are crucial in understanding how organic electrochemical reactions occur. The adsorption behavior of inhibitors can be depicted using two different types of interactions: physisorption and chemisorption. The adsorption of organic inhibitor molecules from an aqueous solution onto a metal surface has the following equilibrium equation:

$$Org_{(sol)} + xH_2O_{(ads)} \longrightarrow Org_{(ads)} + xH_2O_{(sol)} \quad (15)$$

From the equation, it can be deduced that the adsorption of corrosion inhibitors (organic compounds) was

complemented by the desorption of H_2O molecules from the metal surface [91-92]. Langmuir, Temkin, and Frumkin isotherms, which characterizes the relationship between surface coverage, θ and concentration of corrosion inhibitor, are the most utilized adsorption isotherms using weight loss data. Ozkir et al. surmised that an adsorption isotherm can reveal a lot about how corrosion inhibitors interact with the metal surface [93].

The following attempts were made to suit θ values to Langmuir, Frumkin, Freundlich, and Temkin isotherms [94-96]:

$$\text{Langmuir: } \frac{C}{\theta} = \frac{1}{K} + C \tag{16}$$

$$\text{Frumkin: } \frac{\theta}{1-\theta}\exp(-2f\theta) = KC \tag{17}$$

$$\text{Temkin: } \exp(f\theta) = KC \tag{18}$$

where; θ = surface coverage, K = the adsorption-desorption equilibrium constant or adsorptive equilibrium constant ($Lmol^{-1}$), C = inhibitor concentration ($molL^{-1}$), and f = factor of energetic inhomogeneity.

$$\theta = \frac{w_0 - w_i}{w_0} \tag{19}$$

$$\theta = \frac{i_{\mathbf{corr}} - i_{corr}^{inh}}{i_{\mathbf{corr}}} \tag{20}$$

$$\theta = \frac{R_{ct} - R_{ct}^0}{R_{ct}} \tag{21}$$

where, w_0= weight loss of metal in the blank, w_i = weight loss of metal in the inhibitor solution, i_{corr} = current density of metal in the blank, i^{inh}_{corr} = current density of metal in the inhibitor solution, R_{ct} = charge transfer resistance in the blank, and R_{ct}°= charge transfer resistance in the inhibitor solution [36, 97, 98].

The isotherm that significantly suited the experimental data was determined using the correlation coefficient (R^2). Mostly, the corrosion inhibition studies of organic compounds' weight losses values were fitted with Langmuir Isotherm. The Langmuir equation is based on the presumption that the adsorption is monolayer, that all active sites have a consistent distribution of energy levels, and that adsorbed molecules do not interact with each other [99-100] Its phenomenon is supported if the R^2 value is close to 1 or unity [101] The intercepts of the straight lines were used to compute the values of k_{ads} from the graphs of C/θ versus C or log(θ/1-θ) versus log C. The high K_{ads} value demonstrates the inhibitor's high adsorption capacity on metal surfaces. Additionally, increasing the temperature reduced the value of k_{ads}, indicating that increasing the solution temperature generates more agitation, and consequently, the desorption of some inhibitor molecules from the metal surface [102-103] The following equation can be applied to estimate the standard free energy of inhibitor adsorption using the value of k_{ads} [104]:

$$\Delta G_{ads}^0 = -\mathrm{RTln}55.5\mathrm{k}_{\mathbf{ads}} \tag{22}$$

where, 55.5 = molar concentration of water, R = universal gas constant (8.314 $JK^{-1}mol^{-1}$), T = temperature (K), and ΔG°_{ads} = Gibbs free energy of adsorption.

The negative value of G°_{ads} suggests that the process is spontaneous, implying that the inhibitor molecules are efficiently adsorbed on the mild steel surface [105]. Yurt et al. stated that the presence of electrostatic interactions between charged molecules and metal surface charges are indicated by the magnitude of ΔG°_{ads} smaller than 20 $kJmol^{-1}$ (physisorption) [106]. When ΔG°_{ads} is more than 40 $kJmol^{-1}$, it suggests that electrons from the inhibitor molecules are shared or transferred to the metal surface, forming a coordinate type of bond (chemisorption) [107-109]. The ΔG°_{ads} values are in the range of -20 to -40 $kJmol^{-1}$, showing that both chemisorption and physisorption are involved in the adsorption process [110-111]. Adsorption initiates electrostatic interactions between water molecules and metal surfaces, followed by chemical interactions between the metal surface and the adsorbate (inhibitor). Zhang et al. reported that if the value of ΔG°_{ads} is in between -20 to -40 $kJmol^{-1}$,but near to -40 $kJmol^{-1}$,then it can be concluded that the inhibitor is a combination of chemisorption and physisorption which is predominantly chemisorption [112]. Therefore, if the ΔG°_{ads} is near to -20 $kJmol^{-1}$, it is predominantly physisorption.

Conclusion

In this review paper, different techniques were discussed that will help researchers explain the phenomenon and mechanism that have occurred on the metal surface after the adsorption of the inhibitor. The type of adsorption of inhibitors on the metal surface can be deduced using electrochemical techniques (EIS and polarization), SEM-EDX, and Langmuir isotherm.

Abstract

The concept of feasibility in green synthesis of zinc oxide (ZnO) nanoparticles has been discussed in many studies. However, size control using volume of plant extracts undermines the process upscaling potential. This study is aimed at improving the repeatability and reproducibility of green synthesis of ZnO by controlling total phenolic content of plant extracts. Leaf extracts of *Camellia sinensis*, *Manilkara zapota* and *Elaeis guineensis* were incorporated at gallic acid equivalent of 100 mgg^{-1} to synthesize ZnO. The phytochemical profile of plant extracts and physical properties of ZnO were determined. In addition, antibacterial activity of ZnO against *Escherichia coli* and *Staphylococcus aureus* was examined. Consistency in particle sizes of ZnO has justified the feasibility of using total phenolic content for size control. Under neutral pH, role of phytochemicals as chelating agents predominated. Under basic condition, complex phytochemicals demonstrated structure-directing effect on ZnO microparticles. The antibacterial strength of ZnO has been reduced by 16 times with reduction in particle size. Meanwhile, the incorporation of phytochemicals enhanced antibacterial activity of ZnO by fourfold. This study proposed that particle size and morphology of ZnO could be controlled through manipulation of total phenolic content of plant extracts and the reaction pH of green synthesis.

Keywords: green synthesis, polyphenol, zinc oxide, size control

Abstrak

Konsep dalam kebolehlaksanaan proses sintesis hijau terhadap nanopartikel zink oksida (ZnO) telah diperjelaskan dalam pelbagai kajian. Namun begitu, kawalan saiz menggunakan isipadu ekstrak tumbuhan menjejaskan potensi dalam meningkatkan skala proses. Kajian ini bertujuan untuk meningkatkan kebolehulangan sintesis hijau ZnO dengan mengawal jumlah kandungan fenolik ekstrak tumbuhan yang digabungkan. Ekstrak daun *Camellia sinensis*, *Manilkara zapota* dan *Elaeis guineensis* telah dicampurkan pada persamaan asid gallik sebanyak 100 mgg^{-1} untuk menghasilkan ZnO. Profil fitokimia ekstrak tumbuhan dan sifat fizikal ZnO telah ditentukan. Di samping itu, aktiviti antibakteria ZnO terhadap *Escherichia coli* dan *Staphylococcus aureus* telah diperiksa. Ketekalan dalam saiz partikel ZnO menjustifikasikan kebolehlaksaan penggunaan jumlah kandungan fenolik untuk kawalan saiz

dalam sintesis hijau. Di bawah pH neutral, peranan fitokimia sebagai agen pengkelat berdominasi. Di bawah keadaan alkali, fitokimia kompleks menunjukkan kesan pengarahan struktur pada mikropartikel ZnO. Kekuatan antibakteria ZnO berkurangan sebanyak 16 kali ganda dengan pengurangan saiz partikel. Sementara itu, penggunaan fitokimia dalam proses sintesis telah meningkatkan aktiviti antibakteria ZnO sebanyak 4 kali ganda. Kajian ini mencadangkan bahawa saiz partikel dan morfologi ZnO boleh dikawal melalui manipulasi jumlah kandungan fenolik ekstrak tumbuhan dan pH tindak balas sintesis hijau.

Kata kunci: sintesis hijau, polifenol, zink oksida, kawalan saiz

Introduction

Nanotechnology is an extensively researched field with an anticipated global market share of approximately 55 million dollars by 2022 [1]. Nanomaterials are categorized depending on their compositions, which includes carbon, organic, inorganic, and composite compounds [2]. Metal oxide nanoparticles fall under composite-based nanomaterials. Metal oxide nanoparticles are synthesized in the laboratory via physical and chemical methods [3,4]. However, the upscaling of two methods suffers from the limitations due to the need for sophisticated technology, high-energy consumption, and the use of toxic chemicals [5]. Recent trends in nano synthesis reveal a growing interest in the utilization of biological materials to react with metal precursors under regulated conditions [6, 7]. The terms "green synthesis" and "biosynthesis" are used interchangeably to describe the synthesis of nanoparticles using biological components derived from bacteria, fungi, algae, and plants [4]. Green synthesis that utilizes plant extracts as the bioreductants is a sustainable route since phytochemicals can be extracted from any plant parts [8]. Due to the essential starting materials which are metal precursors, plant extracts, and water, green synthesis of metal oxide nanoparticles are both cost-effective and environmentally friendly [3, 4]. Apart from being reducing and chelating agents, phytochemicals can act as capping agents to regulate the morphology and particle size of nanoparticles [3, 4].

Zinc oxide (ZnO) nanoparticles have gained attention for a wide range of applications due to their distinctive physical and chemical properties. They have been described as a photocatalytic adsorbent for water treatment, gas sensors, solar cells, and an active component in cosmetics [9]. Meanwhile, the biocidal action of ZnO nanoparticles against harmful microbes has piqued the interest of researchers in commercializing them as preservatives and biocidal products [10, 11]. The versatility of ZnO nanoparticles has prompted the development of a green synthetic pathway that incorporates different plant extracts. However, the incorporation of plant extracts is expressed in weight, volume, or percentage, with no quantitative information on the phytochemicals present in the reaction. Xu et al. [12] emphasized that plant extract concentration is one of the major manipulating factors in the green synthesis of ZnO nanoparticles. Even though a trend was observed in which the size of nanoparticles decreased as the concentration of plant extract used increased, the method was not replicable because the unit employed to express the incorporation of plant extract was empirical. Lack of information in reaction mechanisms also limit the effort in advancing green synthesis. It is ideal for controlling the biologically active compounds present in the extracts. Polyphenols are the most prevalent phytochemicals in the plant kingdom [13]. They are regarded as a marker group for the quality evaluation of medicinal plants due to their significant roles in the biological activity of extracts [14]. In fact, a study has been carried out to determine the roles of isolated phenolic acids in the green synthesis of metal nanoparticles [15].

This work is fundamental research undertaken with the goal of improving the repeatability and reproducibility of green synthesis for ZnO size control. This study was also intended to elucidate the reaction mechanisms of the green synthesis of ZnO.

Materials and Methods

Materials

Commercial *Camellia sinensis* (black tea leaves) were purchased from local market while leaves of *Manilkara zapota* (sapodilla) and *Elaies guineensis* (oil palm) were obtained from local plantation. Folin-Ciocalteu (FC) reagent, sodium carbonate (Na_2CO_3), benzene, ammonia solution, methanol, aluminium chloride

($AlCl_3$), chloroform, sulphuric acid (H_2SO_4), and zinc oxide (ZnO) were bought from Merck (Darmstadt, Germany). Gallic acid, sodium hydroxide (NaOH), zinc nitrate hexahydrate [$Zn(NO_3)_2.6H_2O$], and resazurin sodium salt were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Wagner's solution was purchased from Avondale Laboratories (Banbury, England). Meanwhile, hydrochloric acid (HCl) and ferric chloride ($FeCl_3$) were obtained from QRëC (Selangor, Malaysia) and R&M Chemicals (Selangor, Malaysia) respectively.

Bacterial culture of *Escherichia coli* ATCC 8739 and *Staphylococcus aureus* ATCC 25923 were purchased from Remel Europe (Dartford, England). The McFarland Standard was supplied by ThermoFisher Scientific (Massachusetts, USA). Mueller Hinton Broth (MHB) and Mueller Hinton Agar (MHA) were from Condalab (Madrid, Spain). Meanwhile, oxacillin sodium salt monohydrate and ampicillin sodium salt were obtained from HiMedia Laboratories (Mumbai, India).

Aqueous extraction of phytochemicals

Commercial black tea leaves were used as-is. Fresh *chikoo* leaves and oil palm leaves were cleaned with tap water and dried overnight in convection oven at 65 ˚C (UFE500, Memmert GmbH + Co.KG, Germany). Dried plant leaves were ground using kitchen blender. Aqueous extraction method of Mercado-Mercado et al. [16] was employed with modification. Samples were decocted in deionized water through double boil method at 85 ˚C for 15 min. The decoction ratio was 1 part ground leaves to 10 parts deionized water. Decocted samples were filtered through muslin cloth. Then, the aqueous extracts were centrifuged at 1,500 rpm for 1 min at room temperature (Centrifuge 5804 R, Eppendorf, Germany). The aqueous extracts were filtered through Whatman No. 1 filter paper. Then, the crude plant extracts were dried in convection oven at 65 ˚C (UFE500). Dried crude plant extracts were ground into fine powder using pestle and mortar. Sample codes for the crude plant extracts were BTLE (black tea leaf extract), CLE (*chikoo* leaf extract) and OPLE (oil palm leaf extract).

Determination of total phenolic content

Folin-Ciocalteu assay was performed with reference to method of Dudonné et al. [17]. The reaction began by mixing 400 µL aqueous sample solution with 2.0 mL of FC reagent (diluted to 10-fold in deionized water). After 5 minutes, 1.6 mL of 7.5% Na_2CO_3 solution was added into the mixture and mixed thoroughly. The mixture was allowed to react for 1 h at room temperature. Absorbance value was measured at 765 nm using UV-Vis spectrophotometer (Spectrophotometer T60 U, PG Instruments Ltd., UK). All tests were performed at triplicates. The calibration curve was plotted using aqueous solution of gallic acid.

Identification of organic compounds

The organic compounds present in crude plant extracts were identified using Attenuated Total Reflection - Fourier transform infrared (ATR-FTIR) spectroscope (Spectrum Two, Perkin Elmer, USA). The FTIR spectra of the extracts were examined by placing powder of crude plant extract directly onto the crystal plate of ATR-FTIR spectroscope. The measurement was taken in the range of 4000-400 cm^{-1} with a resolution of 4 cm^{-1}.

Screening for phytochemicals

Aqueous solutions of BTLE, CLE and OPLE were prepared at concentration of 1 $mgmL^{-1}$ for the screening of phytochemicals. The aqueous plant extracts were screened for the presence of alkaloids, anthraquinones, flavonoids, saponins, steroids, tannins, and terpenoids.

Wagner's test was used to determine the presence of alkaloids. Few drops of Wagner's solution were added to the aqueous plant extracts. Formation of brown precipitate indicated the presence of alkaloid [18]. The presence of anthraquinones was tested by adding 10 mL benzene to 5 mL aqueous plant extracts. Then, 10 mL 10% ammonia solution was added to the mixture. The mixture was shaken vigorously. Presence of anthraquinones was indicated by pink, violet or red colour solution [19].

The presence of flavonoids was examined with Shinoda's test, aluminium chloride test and alkaline reagent test. In Shinoda's test, 4 mL aqueous plant

extract was mixed with 1.5 mL 50% methanol. Magnesium metal was added to the mixture followed by the addition of few drops of fuming HCl. Changes of colour of mixture to red indicated the presence of flavonoids [20]. In aluminium chloride test, 5 mL aqueous plant extract was added with 1 mL 1% $AlCl_3$ solution. The solution was shaken vigorously. Presence of yellow precipitates indicated presence of flavonoids [21]. Meanwhile, alkaline reagent test was performed by mixing 2 mL 2.0% NaOH solution with aqueous plant extract. In the presence of flavonoids, concentrated yellow solution would turn colourless with addition of 2 drops of 2 M HCl [19].

The presence of saponins in plant extracts was examined using method of El Aziz et al. [22] with modifications. Five millilitres (5 mL) aqueous plant extract was vortexed for 2 min. Presence of saponins was confirmed by persistent appearance of foam lasting for at least 15 min. Salkowski's test was performed to confirm the presence of steroids. Two millilitres (2 mL) chloroform and 2 mL concentrated H_2SO_4 were added to 5 mL aqueous plant extract. Red colouration in lower chloroform layer indicated presence of steroids [19]. Presence of tannins was indicated by greenish black colouration formed from reaction between 5 mL aqueous plant extract and 1 mL 5% $FeCl_3$ solution [23]. Screening for the presence of terpenoids commenced by mixing 2.5 mL aqueous plant extract with 2.5 mL chloroform. The mixture was evaporated to dryness. Then, 3 mL concentrated H_2SO_4 was added and boiled for 10 min. A grey solution would form in the presence of terpenoids [21].

Synthesis of ZnO

Synthesis method of Top et al. [24] was adapted with modification. The combinations of reaction mixture and sample codes are summarized in Table 1.

Table 1. Combinations of reaction mixture and sample codes of zinc oxide

Reaction Mixture	Molar Ratio of $Zn(NO_3)_2.6H_2O$ to NaOH	Sample Codes of ZnO with Reference to Incorporated Crude Plant Extract		
		BTLE	CLE	OPLE
B	1.0 : 2.0	$ZnO_{BTLE(B)}$	$ZnO_{CLE(B)}$	$ZnO_{OPLE(B)}$
C	1.0 : 1.8	$ZnO_{BTLE(C)}$	$ZnO_{CLE(C)}$	$ZnO_{OPLE(C)}$
D	1.0 : 1.6	$ZnO_{BTLE(D)}$	$ZnO_{CLE(D)}$	$ZnO_{OPLE(D)}$
E	1.0 : 1.4	$ZnO_{BTLE(E)}$	$ZnO_{CLE(E)}$	$ZnO_{OPLE(E)}$
F	1.0 : 1.2	$ZnO_{BTLE(F)}$	$ZnO_{CLE(F)}$	$ZnO_{OPLE(F)}$
G	1.0 : 1.0	$ZnO_{BTLE(G)}$	$ZnO_{CLE(G)}$	$ZnO_{OPLE(G)}$
Control sample				
A	1.0 : 2.0		$ZnO_{control(A)}$	
H	1.0 : 1.0		$ZnO_{control(H)}$	

The pH of reaction mixture was measured using pH meter (pH 700, Eutech Instrument, USA). The concentration of crude plant extracts employed for green synthesis was computed from volume of gallic acid equivalent (GAE) based on the results of total phenolic content (TPC) obtained prior to synthesis. All crude plant extracts were added at 100 mg GAE g^{-1}. The reaction mixtures were incubated in incubator shaker at 60 ˚C for 1 hour with constant agitation (KS 4000 i control, IKA, Germany). After 1 hour, the precipitates were collected through centrifugation followed by twice washing with deionized water (Centrifuge 5804 R). The collected precipitates were dried in convection oven at 60 ˚C for 24 hours (UFE500). Calcination was

conducted at 500 ˚C for 3 hours (ELF 11/14 Chamber Furnace, Carbolite Gero, UK). Each synthesis pathway was performed in triplicates. Representative samples were prepared for further analysis.

Determination of minimum inhibitory concentration and minimum bactericidal concentration

The viability of *E. coli* and *S. aureus* under exposure to different concentrations of ZnO was determined through Resazurin Cell Viability Test using method by He et al. [25] with modification. Bacterial culture was grown in MHB and incubated in incubator shaker at 37 ˚C for 24 hours with constant agitation (KS 4000 i control). The overnight bacterial cells were suspended in sterilized 0.9 % saline solution and adjusted to 2.0 McFarland Standard and 3.0 McFarland Standard for *S. aureus* and *E. coli* respectively.

Samples of ZnO were suspended in sterilized distilled water at concentration of 8 $mgmL^{-1}$. The suspension was mixed thoroughly with vortex mixer for 1 min (MX-S, Dragon Laboratory Instruments Ltd., China). The samples of ZnO were deployed with twofold dilution at starting concentration of 8 $mgmL^{-1}$ for *S. aureus* and 16 $mgmL^{-1}$ for *E. coli*. To each well containing 100 µL ZnO suspension, 100 µL bacterial suspension and 20 µL 0.02% resazurin solution were added. Positive control (without ZnO samples) and negative control (without bacterial suspension) were included in each plate. The 96 well microtiter plate was incubated at 37 ˚C for 24 hours (INB500, Memmert GmbH + Co.KG, Germany). To compare effectiveness of ZnO samples and commercial antibiotics against the tested strains of bacteria, Resazurin Cell Viability Test was performed by employing ampicillin and oxacillin at starting concentration of 8 $mgmL^{-1}$ under the same protocol.

Colour changes were observed and recorded after incubation period. The lowest concentration of ZnO samples that inhibited visible growth of microorganisms after overnight incubation was considered the minimum inhibitory concentration (MIC). A loopful of aliquot from the MIC well was transferred and streaked on MHA. The streak plates were incubated at 37 ˚C for 24 hours. Viability of bacterial cells was observed after 24 hours for the determination of bactericidal or bacteriostatic properties at MIC of ZnO samples. All tests were conducted at triplicates.

Statistical analysis

The results of replicated tests were expressed as mean value with standard deviations. Comparison between means of independent groups was analysed by one-way analysis of variance (ANOVA) followed by Tukey's honestly significant difference (HSD) post hoc test ($p<0.05$). Correlation analysis was performed using Pearson's correlation coefficient (R) in bivariate linear correlations ($p<0.01$). All statistical analysis was computed using IBM SPSS Statistics 22.0.

Results and Discussion

Morphology, particle size and elemental composition of ZnO

The designed pathways resulted in the synthesis of nano- and microsized zinc oxide (ZnO). In the current study, ZnO particles smaller than 100 nm were referred to as ZnO nanoparticles, while those larger than this size limit were defined as ZnO microparticles. Table 2 summarizes the particle sizes of ZnO obtained from the study. Morphologies of ZnO nanoparticles and ZnO with defined microstructures are shown in Figure 1. Elemental analysis validated the purity of all samples.

Reaction mixtures E, F, and G with the incorporation of CLE and OPLE and reaction mixture G with the incorporation of BTLE were capable of producing ZnO nanoparticles. The irregularly shaped nano- and micro-particles agglomerated into microstructures with no defined morphology as the molar ratio of $Zn(NO_3)_2$ to NaOH increased. Zinc oxide microparticles in the shape of microflower were obtained using the reaction mixtures control(A), BTLE(B), and CLE(B), while ZnO in the shape of spheroid microstructure was obtained from reaction mixture OPLE(B). It is important to highlight that the morphologies and size ranges of $ZnO_{control(A)}$ and $ZnO_{control(H)}$ are similar to those of their respective green synthesis counterparts.

The particle sizes of ZnO decreased within the crude plant extract group in response to a reduction in the molar ratio of $Zn(NO_3)_2$ to NaOH and a simultaneous increase in the ratio of plant extracts used at a

concentration of 100 mg GAE g^{-1}. Likewise, standard errors, which represent the range of particle size distribution, decreased along with the trend. However, the sample of $ZnO_{CLE(G)}$ contained a heterogeneous mixture of nanoparticles and microparticles. As the condition was an isolated case that was not observed in other samples produced under the same conditions ($ZnO_{BTLE(G)}$, $ZnO_{OPLE(G)}$, $ZnO_{control(H)}$), particle size measurements were only performed on nanoparticles that were not arranged into microstructures.

Table 2. Particle sizes and morphologies of zinc oxide

Reaction Mixture	**Shape and Morphology**	**Particle Size, nm**		
		ZnO_{BTLE}	**ZnO_{CLE}**	**ZnO_{OPLE}**
B	Microflower (ZnO_{BTLE} and ZnO_{CLE}); spheroid (ZnO_{OPLE})	Length: 838.97 ± 195.97[a]; width: 608.80 ± 112.67[a]	Length: 1736.63 ± 405.47[b]; width: 885.43 ± 196.06[b]	Length: 943.30 ± 118.61[a]; width: 719.53 ± 176.59[a]
C	Agglomerated microparticles	214.02 ± 39.69[a]	317.68 ± 48.30[b]	217.40 ± 42.99[a]
D	Agglomerated microparticles	159.30 ± 46.92[a]	239.72 ± 48.63[b]	154.92 ± 42.59[a]
E	Agglomerated microparticles	149.33 ± 32.00[a]	92.55 ± 23.89[b]	81.15 ± 26.17[b]
F	Agglomerated microparticles	121.80 ± 32.02[a]	71.22 ± 21.65[b]	80.62 ± 27.37[b]
G	Nanoparticles	70.77 ± 21.74[a]	41.87 ± 15.52[b]	63.80 ± 21.33[a]
A	Microflower	Length: 1193.30 ± 193.31; width: 700.47 ± 145.09		
H	Nanoparticles	81.17 ± 21.02		
Analytical grade ZnO	Nanorods	Length: 196.80 ± 79.93; width: 81.20 ± 29.65		

[a,b] denote significant difference for data within row ($p<0.05$)

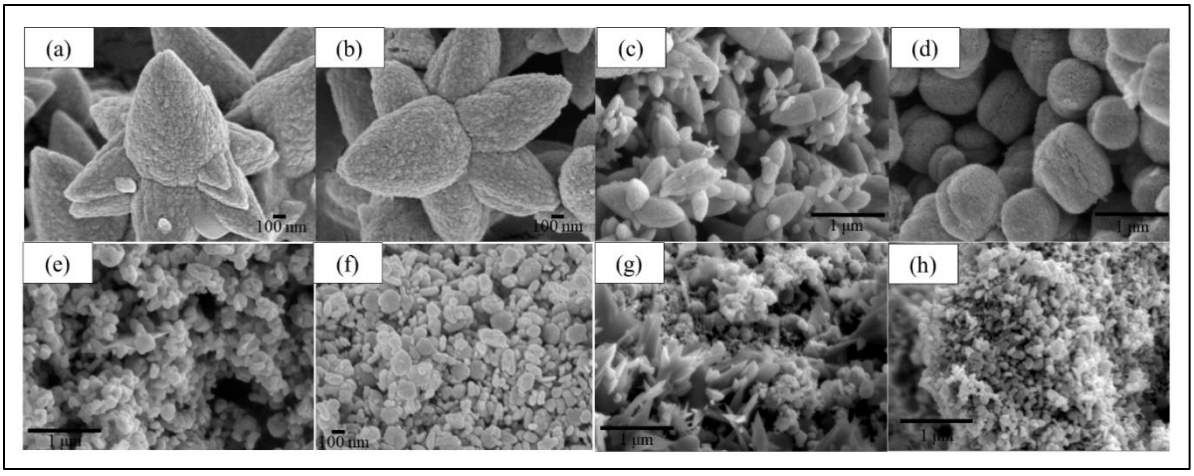

Figure 1. FESEM images of ZnO observed under magnification of 50,000x (a) $ZnO_{control(A)}$, (b) $ZnO_{BTLE(B)}$, (c) $ZnO_{CLE(B)}$, (d) $ZnO_{OPLE(B)}$, (e) $ZnO_{control(H)}$, (f) $ZnO_{BTLE(G)}$, (g) $ZnO_{CLE(G)}$, (h) $ZnO_{OPLE(G)}$

Meanwhile, particle sizes of ZnO were found to differ significantly (p <0.05) across the group of crude plant extracts. However, a statistically significant linear relationship with the trend in particle size reduction was observed for ZnO synthesized with the incorporation of crude extracts of black tea and oil palm leave (p <0.01). A positive linear relationship with a strong magnitude of association was observed (r=0.997). It is deduced that there is a potential in using the total phenolic content of plant extracts for size control of ZnO through the proposed pathway when different plant extracts are employed.

Moreover, the particle sizes of representative samples from the triplicate synthesis procedure showed no significant difference (p >0.05), implying that the synthesis pathway is repeatable. The designed protocol is feasible for size control in order to achieve consistency in the particle size of ZnO.

Phytochemical analysis of the crude plant extracts

The total phenolic content (TPC) of crude plant extracts differed significantly (p <0.05), with CLE containing the highest phenolic compounds (1.07 ± 0.13 mg GAE g^{-1}), followed by BTLE (0.87 ± 0.09 mg GAE g^{-1}) and OPLE (0.37 ± 0.10 mg GAE g^{-1}). During the green synthesis incorporation, significant differences in TPC of crude plant extracts had translated to significant weight differences. The OPLE was incorporated at the highest weight per volume.

A broad band recorded between 3650 and 3250 cm^{-1}, accompanied by the absorption bands between 1600 and 1300 cm^{-1} and 1200 and 1000 cm^{-1} indicated the presence of hydrogen bonds [26]. Grasel et al. [27] reported that bands in 3500 to 3100 cm^{-1} resulted from hydroxyl (–OH) group stretching, were common characteristics of polyphenolic compounds. The aromatic ring stretching group frequency was determined to be between 1615 and 1580 cm^{-1} [26, 28]. Absorption peaks around 2970-2950 cm^{-1} and 2880-2860 cm^{-1} were evidences of saturated aliphatic groups [28]. All tested plant extracts showed absorption peaks in the specified wavenumbers ranges except for alkanes (Figure 2). The spectra provided pieces of evidence for the presence of phenolic compounds with –OH and –COOH side chains in the samples.

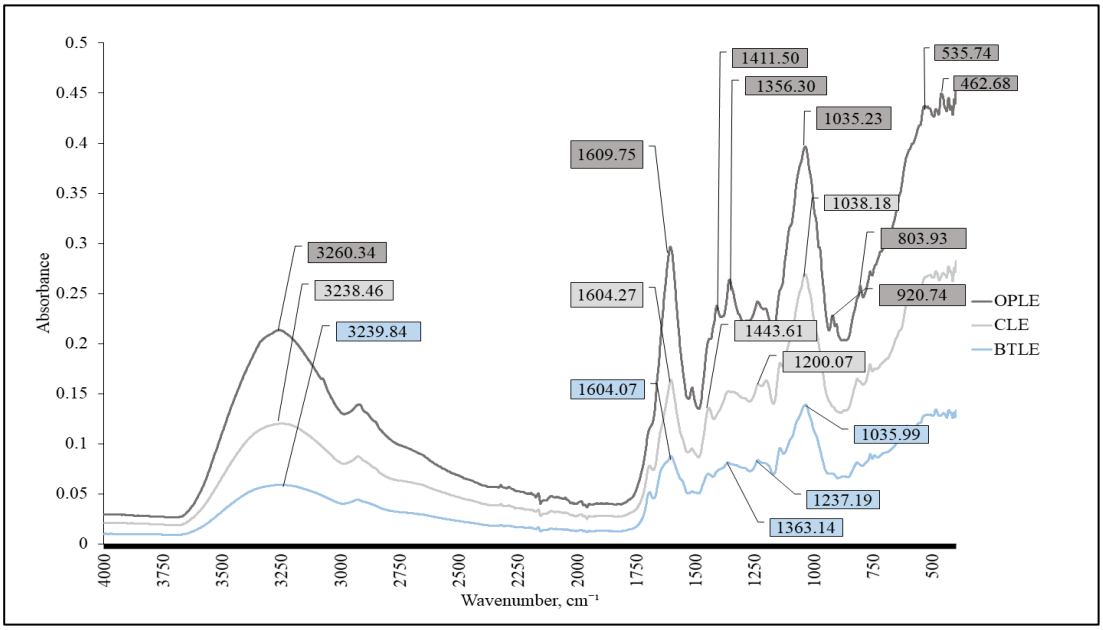

Figure 2. The crude plant extracts were composed primarily of phenolic compounds. OPLE registered the most number of peaks in the IR spectra. It is inferred to be composed of relatively more complex organic compounds compared to CLE and OPLE

Phytochemicals of OPLE were speculated to be larger organic molecules compared to those of BTLE and CLE. The presence of amine groups (C-N) were only observed in OPLE samples at 920.74 cm^{-1} and 535.74 cm^{-1}. Moreover, absorption bands less than 1000 cm^{-1} were only observed in OPLE. Bands at around 750-500 cm^{-1} were associated with alkenes =C-H bending [29]. The alkane C-C bending vibrations were manifested as absorption peak below 500 cm^{-1} [29]. In addition, the presence of absorption bands at wavenumbers less than 1000 cm^{-1} was claimed to be an indicator for the presence of isoprenoid [30,31]. The presence of isoprenoid in OPLE was speculated.

The phytochemical composition of plant extracts is summarized in Table 3. Oil palm leaf extract was the only crude plant extract that was screened positive for alkaloids. In addition, the absorption peaks at wavenumber 920.74 and 535.74 cm^{-1}, which were assigned to N-CH_3 symmetric stretching and C-N-CH_3 deformation of alkaloids [32], were observed in IR spectrum of OPLE. Although the IR fingerprint for isoprenoid was only observed in OPLE's IR spectrum, saponins, which is a form of polar isoprenoids, were found to be present in all crude extracts.

By combining the observations from the Folin-Ciocalteu assay and FTIR analyses, it was determined that all plant extracts were primarily composed of phenolic compounds. Overall, in comparison to both BTLE and CLE, OPLE contains relatively more complex phytochemicals, made up of phenolic compounds with hydroxyl, carboxyl, and amine groups. The complexity of phytochemicals in OPLE had contributed to the inconsistency in process output, in terms of morphologies of ZnO, across different crude plant extracts.

Table 3. Phytochemical compounds present in aqueous plant extracts

Phytochemical Compounds	**Type of Aqueous Plant Extract**

Effects of pH and concentration of plant extracts on the formation of ZnO

The pH of reaction mixtures did not differ significantly when the molar ratio of $Zn(NO_3)_2$ to NaOH was changed from 1.0:1.0 to 1.0:1.8 (p >0.05). The pH of the reaction mixtures was determined to be neutral (Table 4). However, significant difference was observed when the molar ratio of the reaction mixture was raised to 1.0:2.0 (p <0.05), where the pH increased to 11.44. It is worth noting that despite bearing no pH difference, a trend of particle size reduction was observed from reaction mixtures C to G. The trend was attributed to the additive effect of phytochemical capping properties, in addition to the size reduction effect of reaction pH

Table 4. The pH of reaction mixtures

Molar ratio of $Zn(NO_3)_2$ to NaOH	**pH**
1.0 : 2.0	11.44 ± 0.25^a
1.0 : 1.8	7.59 ± 0.24^b
1.0 : 1.6	7.46 ± 0.02^b
1.0 : 1.4	7.34 ± 0.03^b
1.0 : 1.2	7.23 ± 0.01^b
1.0 : 1.0	7.16 ± 0.03^b

[a,b] denote significant difference (p <0.05)

Studies showed that the degree of organization of ZnO nanoparticles increases with an increase in pH of reaction mixture [33, 34]. Meanwhile, studies in green synthesis of ZnO nanoparticles revealed that increasing the pH resulted in particle size increment despite the acclaimed function of plant extracts as capping agents [35-37].

The observations necessitate the answers to the following questions, 'Is the addition of base necessary in green synthesis?', 'Would the addition of base negate the effect or alter the role of plant extracts?' and 'What is the advantage of ZnO produced through green synthesis over the one produced through direct reaction between $Zn(NO_3)_2$ and NaOH when both exhibit the same morphology?'.

Proposed mechanisms for the green synthesis of ZnO nanoparticles

Plant extracts are widely accepted to act as reducing agents in green synthesis [38,39]. In the current work, no precipitation was observed when $Zn(NO_3)_2$ and plant extracts were used as the only process inputs. In fact, precipitation was observed upon mixing of NaOH and $Zn(NO_3)_2$ in the absence of phytochemicals. Additionally, it was observed that precipitates bearing the color of the incorporated plant extracts were produced following the addition of NaOH. Fine white ZnO powder was produced after calcination.

A review of recent studies reveals that all three pathways illustrated in Figure 3 are employed and classified as green synthesis. Pal et al. [7], Suresh et al. [38] and Sharmila et al. [40] implemented pathway B to produce ZnO nanoparticles, while Matinise et al. [41] adopted pathway C. Meanwhile, pathway A involves the addition of NaOH as an alkalizing agent or precipitating agent [42-44]. To elucidate the reaction mechanism, emphasis was made on the nature of divalent zinc (Zn^{2+}) ions and phytochemicals. Divalent zinc ion acts as an intermediate Lewis acid, which can interact with a wide range of ligand bases to form Zn complexes with up to six coordination numbers [45,46,47]. The nature of zinc relies on the redox potential and pH values, where it exists as hydrated zinc complexes in acidic conditions and as zinc hydroxo complexes in alkaline conditions [46].

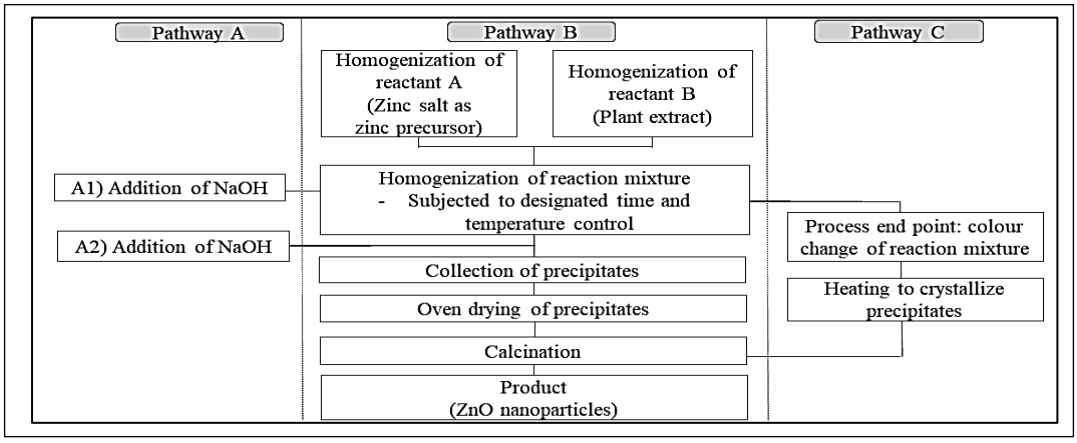

Figure 3. NaOH acts as alkalizing agent in pathway A1 and precipitating agent in pathway A2. Process endpoints of pathway A1, A2 and B are indicated by precipitation of zinc salts while that of pathway C is indicated by colour changes of reaction mixture.

Zinc oxide nanoparticles are formed in pathways B and C through the complexation of zinc with phytochemicals. The organic compounds are vaporized by calcining the zinc complexes. Based on the reaction mechanism, it is more precise to classify the phytochemicals as chelating agents rather than reducing agents. Since the mechanisms do not involve the nucleation and growth of ZnO particles, the nanoparticles produced should be smaller in size. However, the complexity of phytochemicals limits the repeatability of the pathway. Fluctuation in phytochemical quality would have a substantial impact on process yield and overall process duration.

Despite having a similar process flow with pathway B, pathway A2 requires the addition of NaOH at the end of synthesis. The acidity value (pKa) of the complex is determined by the acid-base properties of the ligand, where strong binding results in an increment of pKa [46]. A stable complex would precipitate at higher pH. The addition of NaOH is essential for the precipitation of Zn complexes after being subjected to a specific time and temperature control.

Present study employed pathway A1, which involved adding NaOH to the one-pot mixture of Zn precursor and plant extracts. The reducing properties of phytochemicals depend on their antioxidative activities. An antioxidant compound exhibits its properties via the hydrogen atom transfer (HAT) reaction and transfer reaction of a single electron (SET) [48]. Cited as reducing agents, the phytochemicals are favorable for their electron transfer tendency that would result in the formation of Lewis bases for Zn complexation. As per this study, deprotonated plant phenolic compounds were targeted as the main driving force in the formation of ZnO nanoparticles.

Depending on their pKa, phenolic compounds in liquid media exist as either weak acids or weak bases. Generally, the pKa of phenolic compounds lies between pH 8 and pH 10 [49]. When the pH of the surrounding falls below 8, the phenolic compounds exist as weak acids. Without the help of an alkalizing agent, a range of activation energies must be overcome for the –OH group of phenolic compounds to deprotonate. In present work, the addition of NaOH is crucial to accelerate the green synthesis of ZnO nanoparticles by aiding in phytochemical deprotonation.

In addition to assisting deprotonation of phytochemicals, an increase in reaction pH promotes the deprotonation of hydrated zinc complexes. This condition has a substantial effect on predominant species and the roles of phytochemicals. According to Krężel et al. [46], the deprotonation of hydrated zinc complexes begins at pH 7.8, and zinc hydroxo complexes predominate when the pH of the solution surpasses 8. The reaction ends at pH 11.8, with the final product being $[Zn(OH)_4]^{2-}$ complex [46]. Equations 1 – 4 represent the progression of hydrolysis and deprotonation.

$$[Zn(H_2O)_6]^{2+} + H_2O \rightleftharpoons [Zn(H_2O)_5(OH)]^{+} + H_3O^{+} \quad (1)$$

$$[Zn(H_2O)_5(OH)]^{+} + H_2O \rightleftharpoons [Zn(H_2O)_4(OH)_2] + H_3O^{+} \quad (2)$$

$$[Zn(H_2O)_4(OH)_2] + H_2O \rightleftharpoons [Zn(H_2O)_3(OH)_3]^{-} + H_3O^{+} \quad (3)$$

$$[Zn(H_2O)_3(OH)_3]^{-} + H_2O \rightleftharpoons [Zn(OH)_4]^{2-} + 2H_2O + H_3O^{+} \quad (4)$$

According to Krężel et al. [46], the precipitation of the uncharged $[Zn(H_2O)_4(OH)_2]$ results in the formation of an amorphous $Zn(OH)_2$ and five distinct types of $Zn(OH)_2$ crystals. The crystal forms of $Zn(OH)_2$ are unstable [46, 50], and their decomposition leads to the formation of ZnO nuclei. Meanwhile, $[Zn(OH)_4]^{2-}$ serves as growth template for the growth of ZnO nuclei in addition to decomposing into ZnO.

The pH profile of the reaction mixture reveals that the formation of ZnO nuclei occurs through the outlined mechanisms, with reaction mixtures A and B producing unstable $[Zn(OH)_4]^{2-}$ while reaction mixtures C, D, E, F, and G producing unstable $Zn(OH)_2$ crystals. According to LaMer's mechanism, this phase is critical for size control of ZnO nanoparticles since a high nucleation rate during a protracted reaction will result in the formation

of larger particles. This is evidenced by the fact that the particle sizes of ZnO generated from reaction mixtures A and B were larger than those of the other reaction mixtures. This reaction mechanism explained the effect of pH and NaOH concentration on the particle size of ZnO.

The roles of phytochemicals in green synthesis are inferred to be dependent on the reaction pH and the dominant species in the reaction mixture. In present study, the roles of phenolic compounds were defined with reference to particle sizes of green synthesized ZnO. When NaOH is added to the one-pot mixture, the role of phytochemicals as ligand bases for the formation of zinc complexes is expected to be diminished, while their role as capping agents, which stabilize the ZnO nuclei, becomes prominent under basic conditions. Nevertheless, increasing the pH of the solution would aid in the deprotonation of phenolic compounds [49]. Phenoxide ions could interact with the Zn hydroxo complexes to achieve ligand substitution. However, the role of phytochemicals as capping agents was more significant in this investigation, as demonstrated by the morphological differences between $ZnO_{control(A)}$ and $ZnO_{OPLE(B)}$. Meanwhile, when the concentration of NaOH used was relatively low, the involvement of phytochemicals as ligand bases for the formation of zinc complexes predominated in pathway A1. The condition was demonstrated by the decrement in particle sizes of ZnO as reaction pH was reduced. It is important to note that the addition of NaOH in pathway A1 does not negate the function of phytochemicals since deprotonation of phytochemicals is required for subsequent reactions.

In present study, phytochemicals and hydrated zinc complexes competed for NaOH to achieve deprotonation. Under basic conditions, the moiety rich in $[Zn(OH)_4]^{2-}$ complex ions will facilitate the growth of ZnO along the [0001] direction [50, 51]. In the meantime, the deprotonated phytochemicals with negative charges will be drawn to the Zn polar plane [0001], as well. A high concentration of $[Zn(OH)_4]^{2-}$ led to anisotropic growth and thus the formation of ZnO microflowers. As the concentration of $[Zn(OH)_4]^{2-}$ complex ions decreased, the adsorption of deprotonated phytochemicals on Zn polar plane became dominant.

The structure-directing effect of OPLE, as demonstrated by $ZnO_{OPLE(B)}$, could be attributed to its phytochemical complexity. It is speculated that the higher dosage of OPLE, which exhibited lower TPC, contributed to a higher content of amphiphilic phytochemicals in the aqueous plant extracts of green synthesis. This condition resulted in the isotropic growth of ZnO owing to the uniform adsorption by the phytochemicals.

Previously, the terms 'reducing agent', 'chelating agent', 'capping agent', and ‘structure-directing agent' were used interchangeably, and the definitions were ambiguous. Deprotonated phytochemical, which is a form of ligand base, is structurally a chelating agent when it interacts with either zinc hydroxo complexes or ZnO nuclei in the green synthesis. In the event that Zn complexes are formed, deprotonated phytochemicals shall be referred to as chelating agents; meanwhile, when deprotonated phytochemicals interact with ZnO nuclei to achieve electrostatic stabilization, they shall be defined as capping agents for precision. A structure-directing agent, on the other hand, possesses a structure-directing effect to control the growth of the nanoparticles [52]. It is illustrated in Figure 4 that nucleation and growth of ZnO nanoparticles occur via pathways A1 and A2, whereas the formation of Zn complexes occurs via pathways C and B.

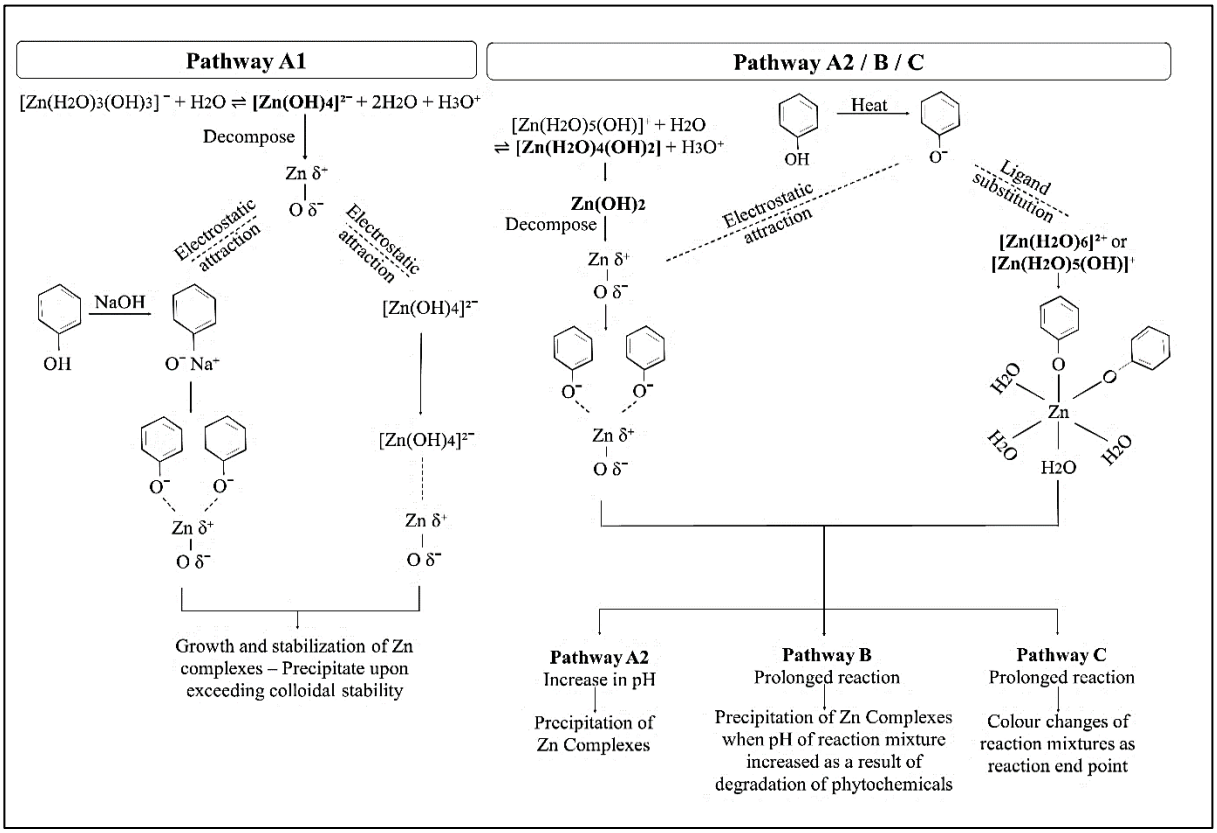

Figure 4. Deprotonated phytochemicals act primarily as capping agent when $[Zn(OH)_4]^{2-}$ is the predominant species while their roles as chelating agent are more prominent at neutral pH where Zn complexes are the predominant species.

Antibacterial strength of the green synthesized ZnO

Antibacterial activity of ZnO samples against *Staphylococcus aureus and Escherichia coli* was examined. There was a lack of antibacterial action against the latter. The minimum inhibitory concentration (MIC) of ZnO samples against *S. aureus* decreased with increasing ZnO particle size (Table 5). However, a slight dip was observed from $ZnO_{CLE(E)}$ to $ZnO_{CLE(F)}$. The condition was attributed to the colloidal stability of ZnO, which was dependent on the interplay of particle sizes and surface properties. It is worth noting that the antibacterial strength of ZnO synthesized through the incorporation of plant extracts ($ZnO_{BTLE(B)}$, $ZnO_{CLE(B)}$, and $ZnO_{OPLE(B)}$) were superior to that of $ZnO_{control(A)}$. In addition, the ZnO microstructures exhibited stronger antibacterial effects against *S. aureus* when compared to ampicillin and oxacillin. The two antibiotics showed no antibacterial activity when deployed at the same starting concentrations of 8 $mgmL^{-1}$ under the same experimental setup.

Table 5. Minimum inhibitory concentration of zinc oxide samples against *Staphylococcus aureus*

Reaction mixture	Minimum inhibitory concentration, mgmL^{-1}		
	ZnO_{BTLE}	**ZnO_{CLE}**	**ZnO_{OPLE}**
B	0.0313*	0.1250	0.1250*
C	0.2500*	0.2500	0.2500
D	1.0000	0.2500*	0.5000
E	1.0000	1.0000*	1.0000*
F	1.0000*	0.5000	2.0000*
G	2.0000	2.0000	2.0000*
A (control)		0.5000*	
Analytical grade ZnO		0.0625*	
Oxacillin		not effective	
Ampicillin		not effective	

*denotes minimum bactericidal concentration of ZnO samples

The antibacterial strength of ZnO microstructures had improved by at least fourfold when plant extracts were incorporated. Despite having similar morphologies, $ZnO_{BTLE(B)}$ and $ZnO_{CLE(B)}$ exhibited enhanced antibacterial effects against *S. aureus* than $ZnO_{control(A)}$. The capping of phytochemicals on the ZnO microstructures are speculated to have an additive effect on their antibacterial properties. However, no organic compounds were observed in the FTIR spectra of ZnO samples. This condition might be related to the method sensitivity, where particle size of samples negatively affected penetration depth of the IR light and intensity of bands the spectra [53].

Theoretically, the decrement in particle size would essentially enhance the antibacterial strength of nanoparticles since smaller particles have higher surface energy to aid in dissolution [54,55,56]. Raghupathi et al. [57] and Naqvi et al. [58] discovered the inversed relationship between particle size of ZnO and antibacterial activity against *S. aureus*. Contradictory to the theory, present studies found that the antibacterial strength against *S. aureus* reduced with a decrement in particle sizes, whereas ZnO with defined microstructures exhibited better antibacterial strength. It is speculated that the dissolution properties of nanoparticles might have contributed to the condition.

The dissolution of nanoparticles is affected by the chemistry of the administered condition, which includes ionic strength, pH, and temperature of the medium [59, 60]. The presence of dissolved organic matters would improve the colloidal stability of nanoparticles, which in turn reduces the rate of agglomeration [60, 61]. In the current investigation, however, ZnO samples and bacteria were suspended in sterile distilled water and 0.9 % saline. Peng et al. [60] reported that presence of inorganic ions would disrupt the electrostatic stability of nanoparticles. The presence of inorganic ions is speculated to be the factor contributing to the lack of ZnO nanoparticles' antibacterial action in present study.

The attack mechanisms of ZnO nanoparticles were theorized to be through the formation of ROS, cell internalization of abrasive ZnO, and the release of Zn^{2+} [9,62]. Despite being deployed at higher starting concentrations (16 mgmL^{-1}), ZnO samples and antibiotics had no antibacterial effect against *E. coli*. Meanwhile, Jin et al. [63] discovered that the UV irradiated spherical ZnO nanoparticles at 0.05 mgmL^{-1} had a remarkable activity against *E. coli*. The ZnO samples were used without any prior treatment in the present study. The absence of antibacterial activity against *E. coli* might be attributed to the incompatibility of attack mechanisms.

Based on these observations, it is postulated that the morphology of ZnO played a substantial role in its antibacterial properties against *S. aureus*. The abrasiveness and defined surface morphology of ZnO microstructures contribute to their improved antibacterial properties when compared to ZnO nanoparticles under the given experimental conditions. Meanwhile, the lack of antibacterial activity against *E. coli* might be due to the concentration-dependent effect of ZnO. Besides, the physical properties of ZnO microstructures and nanoparticles employed in this work are speculated to be incompatible with the target site of the tested strain of *E. coli*, making them incapable of exhibiting antibacterial activity.

Conclusion

The designed pathway is stable and repeatable for the green synthesis of ZnO nano- and micro- particles. Manipulation of total phenolic content is a feasible method to control concentration of incorporated plant extracts. The proposed synthesis pathway is feasible for size control of ZnO. Green synthesis is accelerated by the addition of NaOH where it assists deprotonation of phytochemicals to commence Zn chelation. Reaction pH influenced the roles of phytochemicals. The role of deprotonated phytochemicals as capping agent, which possesses structure-directing effect, is prominent under basic condition. Meanwhile, their role as chelating agent, which enhances particle size reduction, is prominent under neutral condition. In addition, it was deduced that the morphology of ZnO played a more substantial role in determining its antibacterial strength compared to particle size. In addition to quantitative phenolic profile, future studies are recommended to establish the interrelation between qualitative phytochemical profile of plant extracts and particle size of ZnO produced to improve universality of the green synthesis pathway.

Abstrak

Karbon aktif sekam padi (RHAC) dihasilkan dan digunakan untuk menghilangkan warna pewarna organik dan efluen kilang kelapa sawit (POME) melalui proses penjerapan. Sekam padi dikarbonisasi dan diaktifkan menggunakan kalium hidroksida (KOH) dan natrium hidroksida (NaOH) untuk menghasilkan karbon aktif. Sifat karbon aktif (AC) dikaji melalui analisis permukaan dan morfologi. Penjanaan semula bahan penjerap dengan proses penjerapan/penyaherapan menunjukkan bahawa AC dapat dijana semula hingga lima kitaran sementara masih memberikan maksimum 67.26% kapasiti penjerapan pada regenerasi pertama dan serendah 2.72% kapasiti penjerapan pada regenerasi kelima. RHAC juga digunakan untuk perawatan POME untuk penyahwarnaan dan pengurangan jumlah karbon organik (TOC) dan permintaan oksigen kimia (COD). Kajian ini menunjukkan bahawa RHAC berpotensi digunakan sebagai bahan penjerap untuk menghilangkan pelbagai jenis cas positif bahan terjerap dan POME dari larutan berair.

Kata kunci: karbon aktif, sekam padi, penjerapan, karbonisasi, efluen kilang kelapa sawit

Abstract

Rice husk activated carbon (RHAC) is produced and used to remove the color of organic dyes and palm oil mill effluents (POME) through an adsorption process. Rice husk is carbonized and activated using potassium hydroxide (KOH) and sodium hydroxide (NaOH) to produce activated carbon. The properties of activated carbon (AC) were studied through surface and morphological analysis. Adsorbent regeneration by adsorption/absorption process showed that AC could be regenerated for up to five cycles while still providing a maximum of 67.26% adsorption capacity on the first regeneration and as low as 2.72% adsorption capacity on the fifth regeneration. RHAC is also used for POME treatment for discoloration and reduction of total organic carbon (TOC) and chemical oxygen demand (COD). This study shows that RHAC has the potential to be used as an adsorbent to remove various types of positive charge adsorbate and POME from aqueous solutions.

Keywords: activated carbon, rice husk, adsorption, carbonization, palm oil mill effluents

Pendahuluan

Pemprosesan minyak sawit menghasilkan dua jenis produk sampingan, iaitu biojisim pepejal dan enapcemar cecair atau dipanggil POME. Setiap tan pemprosesan buah kelapa sawit, 5.5% biji minyak, 13.5% serat mesocap dan 23.4% tandan buah kelapa sawit dihasilkan sebagai sisa biojisim pepejal. Selain itu kira-kira 67% POME juga dihasilkan [1]. POME dihasilkan dari 3 aktiviti pembuatan iaitu pensterilan (0.2-0.25 tan per tan buah kelapa sawit), pencerahan (0.4-0.45 tan per tan buah kelapa sawit) dan hidroklon (0.03-0.05 tan per tan buah kelapa sawit) pada nisbah 6:15:1 [2].

Ciri-ciri POME bergantung pada kualiti buah kelapa sawit dan aktiviti pembuatan di kilang kelapa sawit. POME adalah cecair pekat, likat dan warna keperangan yang terdiri daripada 95-96% air, 0.6-0.7% minyak dan 4-5% pepejal. Ia juga mempunyai nilai BOD (> 18 000 mg/L) dan COD (> 45 000 mg/L), yang dikeringkan pada suhu 80-90 °C pada pH berasid. POME mengandungi nitrogen, organik, fosforus, dan sisa selulosa yang merupakan campuran karbohidrat dan minyak. Kandungan organik yang tinggi dalam POME disumbangkan oleh beberapa gula seperti xilosa, glukosa, galaktosa dan mannos [3]. POME juga terdiri daripada sejumlah nutrien seperti nitrogen, kalium, magnesium, kalsium, kromium, tembaga dan zat besi [4]. POME bukan bahan cemar yang berbahaya kerana tidak ada bahan kimia yang dimasukkan semasa pemprosesan buah kelapa sawit, ia mengandungi sumber nutrien yang baik, namun POME yang tidak dirawat mempengaruhi alam sekitar kerana kandungan organik dan nutriennya menyebabkan pengurangan kandungan oksigen dalam sistem akuatik [5]. Terdapat beberapa kaedah untuk merawat POME iaitu teknologi membran [6, 7], pembekuan/flokulasi [8, 9], proses pengoksidaan [10] serta penjerapan menggunakan arang teraktif (AC) [11, 12, 13].

Amalan biasa dalam rawatan POME adalah melalui sistem kolam, yang memerlukan kawasan tanah yang besar dan masa pendedahan yang lama [13]. Sebagai tambahan, POME yang dirawat masih mengandungi tahap pencemaran yang tinggi kerana keberkesanan kaedah rawatan sedemikian yang rendah. Oleh itu, penjerapan sering digunakan untuk merawat POME yang dirawat sebelum dialirkan ke sungai. Terdapat beberapa kajian mengenai penggunaan bahan penjerap AC dari biojisim dalam merawat POME seperti yang ditunjukkan dalam Jadual 1.

Jadual 1. Penjerapan POME menggunakan penjerap AC

Bahan	Kaedah Ujian	Efisensi (%)	Rujukan
AC tempurung kelapa	TSS, COD dan warna POME	TSS (39), COD (66), warna (61)	[13]
Gentian kelapa sawit	COD dan SS POME	SS (80), COD (70)	[14]
AC kulit pisang	TSS, BOD, warna	TSS (96), BOD (100), warna (95)	[15]
AC komersial	COD dan TSS	COD (73.08), TSS (98.33)	[16]
AC tempurung kelapa sawit	SS	71.26	[17]

AC cenderung untuk berinteraksi dengan zarah bukan polar pada bahan yang terjerap dalam larutan hidrofobik. Zarah hidrofobik mempunyai kecenderungan untuk berinteraksi dengan zarah yang serupa berbanding dengan titisan minyak. Proses ini mengakibatkan pemutusan ikatan hidrogen antara zarah air. Begitu juga, bahan penjerap hidrofilik boleh berkesan untuk pengurangan larutan polar dalam air sisa. Gabungan zarah hidrofilik mempunyai interaksi termodinamik yang lebih baik daripada interaksi dengan zat hidrofobik seperti minyak. Tahap zarah hidrofobik atau hidrofilik ditentukan oleh ketegangan permukaan bahan dalam fasa berair dan gabungan bahan penjerap sangat berkesan untuk pengurangan air buangan berkekuatan tinggi yang mengandungi larutan polar dan bukan polar [18]. POME juga dianalisis oleh jumlah

karbon organik (TOC) dan permintaan oksigen kimia (COD). TOC bertujuan untuk menentukan jumlah karbon yang terdapat dalam bahan organik. TOC adalah penentu kualiti air yang tidak spesifik. Manakala COD dapat menentukan jumlah oksigen yang dimakan oleh tindak balas dalam larutan yang dikaji.

Penjanaan semula bahan penjerap (AC) mampu mengurangkan kos penghasilan bahan penjerap setelah bahan terjerap dapat dikeluarkan. Walaupun begitu, potensi penjanaan semula bahan penjerap adalah salah satu sifat khas bahan penjerap. Keupayaan penjerapan dan kecekapan bahan yang dijerap adalah antara kelebihannya. Didapati bahawa dengan bertambahnya kitaran regenerasi maka kapasiti penjerapan penjerap akan menurun. Penjanaan semula AC memerlukan prosedur khusus untuk mengeluarkan molekul bahan yang terjerap dari permukaan AC. Terdapat tiga kaedah regenerasi utama untuk AC iaitu termal, kimia dan biologi [19-23]. Setiap kaedah mempunyai batasannya iaitu tenaga haba yang tinggi, kehilangan karbon, penggunaan bahan kimia mahal dan masa. Penjanaan semula bahan penjerap setelah tepu dilakukan dengan proses penjerapan. Kajian penjerapan diperlukan untuk pemulihan bahan yang dijerap dan untuk memahami mekanisme penjerapan. Proses penjerapan dilakukan dengan mencampurkan penjerap tepu dengan bahan nyahjerap (NaOH, HCl, CH_3COOH, C_3H_6O, C_2H_5OH) untuk penyingkiran bahan yang dijerap dan dipisahkan dengan penapisan [24-27]. Pewarna yang dijerap dapat dinyahjerap dengan menggunakan air neutral, pewarna dijerap dengan penjerap melalui ikatan yang lemah. Sekiranya pewarna dapat dijerap dengan asid sulfurik atau air alkali, penjerapan pewarna melalui pertukaran ion. Penggunaan pelarut organik seperti aseton atau asid asetik untuk menjerap, pewarna telah dijerap melalui penjerapan kimia. Manakala dengan asid mineral seperti HCl, pewarna telah dijerap melalui penjerapan fizikal [28].

Bahan dan Kaedah

Penyediaan sekam padi

Sekam padi diambil dari sawah di Sekinchan, Selangor, Malaysia. Ia dibersihkan dengan air untuk menghilangkan kotoran dan dikeringkan di dalam oven pada suhu 105 °C selama semalaman.

Penyediaan AC sekam padi

Sekam padi diprolisis pada suhu 400 °C selama 4 jam untuk menghasilkan arang sekam padi (RHC). Kemudian, RHC diayak untuk memperolehi saiz 60 mesh. RHC direndam dengan larutan KOH (13M) pada nisbah 1:4 (RHC: KOH) selama 24 jam. Ia ditapis dan dikeringkan dengan oven pada suhu 105 °C semalaman. Proses pengaktifan dilakukan di dalam relau tiub dengan aliran gas nitrogen (100 mL/min) selama 2 jam pada suhu 850 °C. Sampel disejukkan dan dicuci dengan larutan asid hidroklorik (HCl) (1 M) dan air deionisasi sehingga pH 6 hingga 7 diperoleh. Proses yang sama seperti dilakukan bagi NaOH. Sampel diberi label sebagai RHC (arang sekam padi), RHACK (rawatan dengan KOH) dan RHACNa (rawatan dengan NaOH).

Pencirian AC

Luas permukaan sampel RHC, RHACK, dan RHACNa dikaji dengan menggunakan analisis penjerapan-penyaherapan N2 (Micromeritics ASAP, 2010) kemudian diikuti oleh piawai penjerapan-penjerapan nitrogen pada 77 K. Sifat morfologi permukaan sampel diperolehi dengan menggunakan mikroskopi elektron imbasan (SEM) model FEI Quanta 400.

Kajian perubahan warna, COD dan TOC POME

Efluen industri kelapa sawit (POME) diperoleh dari kilang kelapa sawit KPSB di Gua Musang, Kelantan, Malaysia. Sifat POME yang asal adalah seperti di Jadual 2. POME pertama kali disaring kotoran dan enapan dan disimpan di dalam peti sejuk sebelum menjalani analisis perubahan warna dengan AC. POME (pH 8.5) dilakukan analisis penyahwarnaan (Persamaan 1) menggunakan kaedah Platinum-Cobalt (Pt-Co) yang dianalisis oleh Spectrophotometer (HACH DR 3900) pada panjang gelombang 450 nm. Analisis dilakukan dengan 100 mL POME diaduk dengan bahan penjerap AC pada 0.1 g, 0.4 g dan 0.6 g dan nilai Pt-Co POME diambil pada selang waktu yang ditetapkan sehingga titik keseimbangan penjerapan warna POME tercapai. Nilai perubahan dikira seperti Persamaan 1. Analisis permintaan oksigen kimia (COD) dan jumlah karbon organik (TOC) masing-masing mengikuti kaedah 5220D dan kaedah TNT yang dianalisis dengan instrumen HACH DRB 200.

$$\text{Perubahan warna (\%)} = \frac{C_0 - Ce}{(C_0)} \text{ x } 100 \quad (1)$$

di mana C_0 dan C_e masing-masing adalah nilai perubahan warna awal dan akhir POME.

Jadual 2. Sifat POME yang asal

Parameter	Nilai
pH	9.5
DO (mg/L)	7.32
BOD5 (mg/L)	11.5
COD (mg/L)	280
SS (mg/L)	17
Warna(Pt-Co)	888
NH_3-N (mg/L)	0.5
Minyak & Gris (mg/L)	5
TOC (mg/L)	96

Kajian penjerapan dan penjanaan semula AC

Larutan metilena biru (MB) dengan kepekatan 450 mg/L disediakan untuk proses kajian penjerapan dan penyaherapan MB dengan sampel RHACK dan RHACNa. Serbuk AC seberat 0.05 g diaduk bersama 50 mL larutan MB pada pengaduk magnet pada 300 rpm selama semalaman. Kepekatan larutan MB sebelum dan selepas proses penjerapan diperoleh menggunakan spektrofotometer UV. Serbuk AC yang telah melalui proses penjerapan disaring dari larutan MB dan dibilas dengan air suling untuk membersihkan sisa larutan MB di permukaan AC. Proses penyaherapan dengan kaedah kimia dilakukan dengan merendam AC dalam larutan agen penyaherapan (3 M) selama 3 jam. Tiga jenis agen penyaherapan adalah aseton (CH_3H_6O), asid asetik ($C_2H_4O_2$) (kedua-duanya adalah pelarut organik) dan asid sulfurik (H_2SO_4) (pelarut bukan organik). Nilai kepekatan larutan yang dijerap diambil dengan spektrofotometer UV. AC ditapis dan dibilas dengan air suling sebelum dikeringkan semalaman di dalam ketuhar pada suhu 60 °C. Proses di atas diulang untuk penjanaan semula seterusnya hingga lima kitaran. Nilai peratusan penjerapan bahan yang dijerap diperoleh berdasarkan Persamaan 2.

$$\text{Peratusan penjerapan bahan dijerap} = \frac{A}{B} \text{ x } 100\% \quad (2)$$

di mana A ialah kepekatan larutan penjerapan (mg/L), B adalah kepekatan larutan bahan dijerap (mg/L).

Keputusan dan Perbincangan

Analisis permukaan

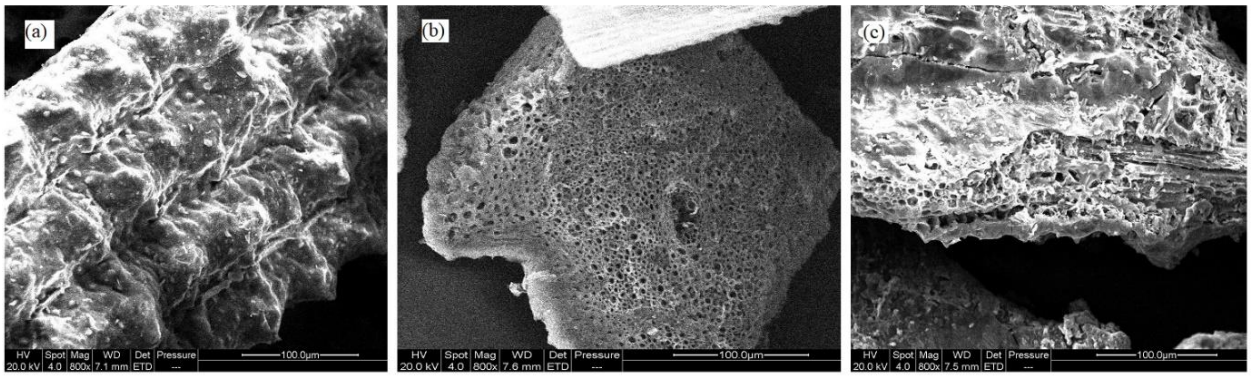
Jadual 3 menunjukkan sampel RHACK dan RHACNa mempunyai nilai luas permukaan yang tinggi masing-masing pada 1131.73 m^2/g dan 429.82 m^2/g dibandingkan dengan RHC pada 0.23 m^2/g. Peranan kenaikan suhu membantu meningkatkan pembentukan liang pada struktur karbon. Hasil ini mungkin didorong oleh kesan pemanasan dalaman dan pembukaan liang [29]. KOH sebagai agen pengaktif telah bertindak balas dengan pusat reaktif bahan karbon seperti karbon tidak berstruktur, karbon dengan heteroatom dan karbon di sisi grafin menghasilkan liang baru dan melebarkan yang sedia ada, ia meningkat dengan peningkatan kehadiran KOH [30]. Jumlah keseluruhan liang AC telah meningkat dengan peningkatan suhu pengaktifan. Sebagai contoh, isipadu liang RHC pada 0.0026 cm^3/g meningkat menjadi 0.76 cm^3/g untuk RHACK dan RHACNa pada 0.29 cm^3/g. Peningkatan luas permukaan menyumbang kepada peningkatan jumlah liang berukuran meso [31]. Saiz liang RHACK dan RHACNa masing-masing adalah 2.67 nm dan 2.69 nm. Fenomena ini menunjukkan bahawa liang-liang berukuran antara 2-50 nm, iaitu bersaiz meso. Menurut IUPAC 1972, ukuran liang boleh dikelaskan kepada tiga jenis iaitu liang mikro (di bawah 2 nm), liang meso (2-50 nm) dan liang makro (lebih dari 50 nm) [32].

Jadual 3. Keputusan analisa permukaan

Sampel	Luas Permukaan (m^2/g)	Isipadu Liang (cm^3/g)	Saiz Liang (nm)
RHC	0.23	0.0026	4.42
RHACK	1131.73	0.76	2.67
RHACNa	429.82	0.29	2.69

Nilai luas permukaan RHACK adalah 1131.73 m^2/g berbanding RHACNa 429.82 m^2/g. Didapati bahawa KOH bertindak sebagai agen pengaktifan yang lebih baik daripada NaOH. Ia menyebabkan pembentukan liang dan isipadu liang dan seterusnya menghasilkan karbon berliang dengan luas permukaan yang lebih tinggi [33]. Peningkatan keliangan didapati berkaitan dengan kation alkali agen pengaktif mengikut urutan: Li <Na <K <Rb <Cs, dalam hal ini KOH mempunyai lebih banyak kation alkali daripada NaOH, oleh itu KOH lebih banyak bertindak balas dengan karbon dan menghasilkan lebih liang [34]. Tindak balas kimia antara alkali hidroksida dan karbon berlaku semasa proses pengaktifan seperti dalam Persamaan 3, 4 dan 5 [35].

$$4KOH + C \rightarrow K_2CO_3 + K_2O + 2H_2 \quad (3)$$



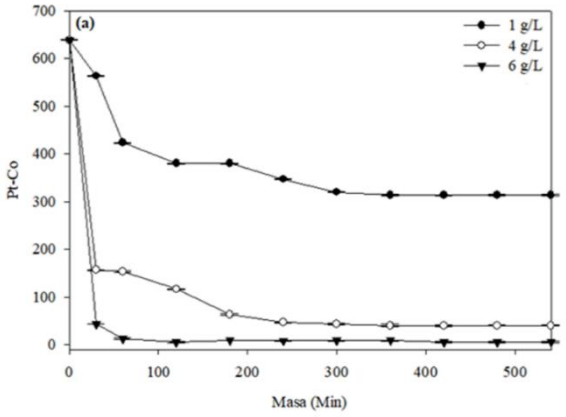
$$2K_2O + C \rightarrow 4K + CO_2 \quad (4)$$

$$K_2CO_3 + 2C \rightarrow 2K + 3CO \quad (5)$$

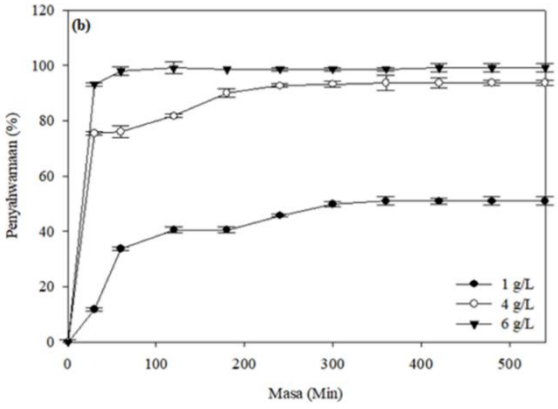
Proses pengaktifan menghasilkan gas hidrogen, karbonat dan kalium (K atau K_2O). Logam kalium dikeluarkan semasa proses pembasuhan dan K_2CO_3 terurai semasa proses pengaktifan dan gas CO_2 dihasilkan. Tindak balas antara agen pengaktif dan karbon menyebabkan penguraian organik meruap dan membentuk permukaan liang pada permukaan sampel AC. Proses gasifikasi semasa pengaktifan menggunakan agen pengaktifan yang sesuai sangat penting dalam proses pembentukan liang [36].

Mikroskopi elektron pengimbasan

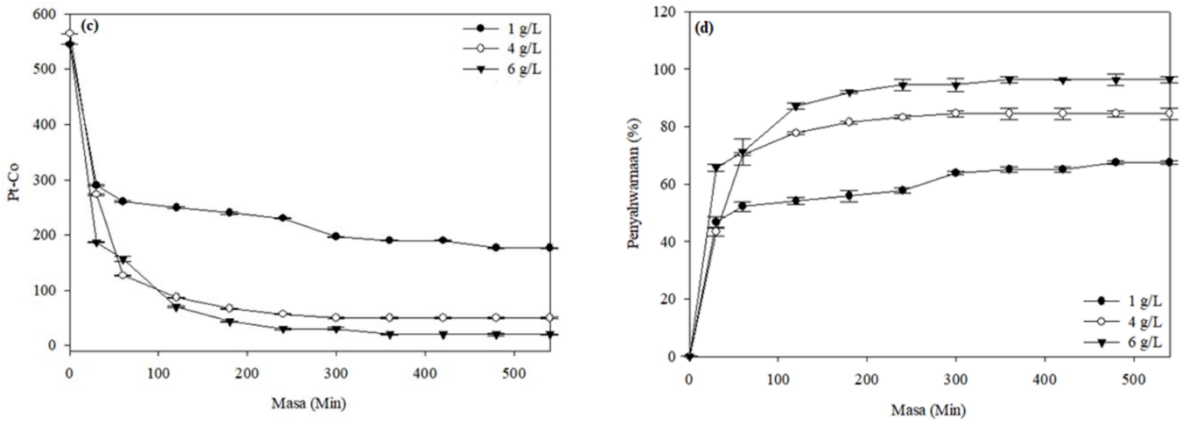
Rajah 1(a) menunjukkan mikrograf SEM RHC yang nampaknya hampir tidak mempunyai liang di permukaannya. Pembentukan struktur liang yang dihasilkan daripada pengaktifan KOH dan NaOH masing-masing ditunjukkan pada Rajah 1(b) dan 1(c). Pengaktifan kimia menghasilkan struktur karbon berliang di permukaan. Hasil yang serupa juga dilaporkan oleh para penyelidik yang lain di mana kesan pengaktifan telah menambah liang-laing pada permukaan AC [30, 37, 38].



Rajah 1. SEM (a) RHC, (b) RHACK dan (c) RHACN

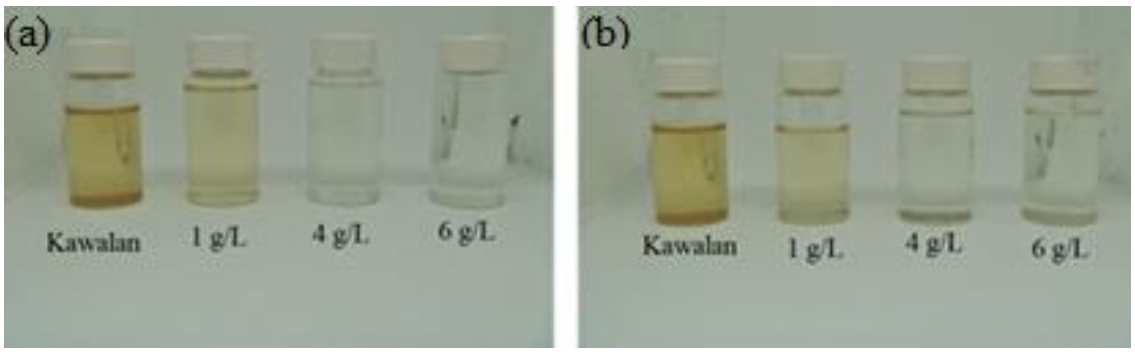


Analisis perubahan warna POME: Kesan bahan penjerap



Rajah 2 menunjukkan kesan RHACK dan RHACNa sebagai bahan penjerap terhadap peratusan penyahwarnaan POME. Peningkatan bahan penjerap telah mengurangkan peratusan warna POME. Sebanyak 50.94% (313 Pt-Co) warna POME dikurangkan dengan menggunakan bahan penjerap RHACK pada 1 g/L. Peratusan penyahwarnaan POME terus meningkat sebanyak 93.22% (43 Pt-Co) kepada 99.11% (13 Pt-Co) kerana bahan penjerap RHACK meningkat dari 4 g/L menjadi 6 g/L seperti yang ditunjukkan dalam Rajah 2(a) dan (b). Seterusnya, pola yang sama turut diperhatikan bagi sampel RHACNa yang menunjukkan peningkatan peratusan penyahwarnaan POME 67.56% (177 Pt-Co) pada 4 g/L, 84.49% (50 Pt-Co) pada 6 g/L dan 96.33% (20 Pt-Co) pada 10 g/L seperti dalam Rajah 2(c) dan (d). Pada peringkat pertama, penjerapan meningkat dengan cepat, menunjukkan bahawa terdapat luas permukaan aktif bahan penjerap AC. Hasil peningkatan bahan penjerap menyebabkan peningkatan peratusan penyahwarnaan POME di mana ia sejajar dengan laporan penyelidik sebelumnya [12, 39]. Keadaan ini akhirnya menunjukkan graf mendatar setelah mencapai keseimbangan, mungkin disebabkan oleh lapisan pencemar mono-organik yang menutupi permukaan bahan penjerap [40]. Secara amnya, bahan penjerap pada kadar 0.4 g dalam 100 mL POME mencukupi untuk menyahwarnakan POME.

Didapati bahawa kadar penyahwarnaan meningkat seiring dengan masa dan bahan penjerap [41], di mana daripada analisis didapati kadar penjerapan seimbang berlaku setelah 420 minit (1 g/L) untuk sampel RHACK. Keseimbangan meningkat dengan cepat untuk bahan penjerap 4 g/L pada 60 minit dan 30 minit untuk 6 g/L. RHACNa memberikan keseimbangan selepas 300 minit untuk bahan penjerap 4 g/L dan 6 g/L, sementara bahan penjerap 10 g/L berlaku selepas 60 minit. Para penyelidik sebelum ini telah melaporkan hasil yang serupa pada kadar penyahwarnaan dan kesan bahan penjerap AC dalam eksperimen penyahwarnaan POME menggunakan AC [11, 13, 42].



Secara umum, sampel AC-KOH menunjukkan peratusan penyahwarnaan yang lebih baik daripada AC-NaOH. Kemungkinan besar disebabkan oleh faktor luas permukaan yang lebih tinggi yang terbentuk di permukaan sampel yang membolehkan bahan organik tercemar mengisinya. Ini disokong oleh gambar-gambar pada Rajah 3(a) di mana kecerahan warna larutan sampel RHACK terbentuk lebih cepat yakni pada 4 g/L berbanding 6 g/L daripada sampel AC-NaOH pada Rajah 3(b).

Rajah 2. Graf warna (Pt-Co) dan peratus penyahwarnaan RHACK (a) dan (b) serta RHACNa (c) dan (d)

Rajah 3. POME selepas dinyahwarna oleh (a) RHACK, (b) RHACNa

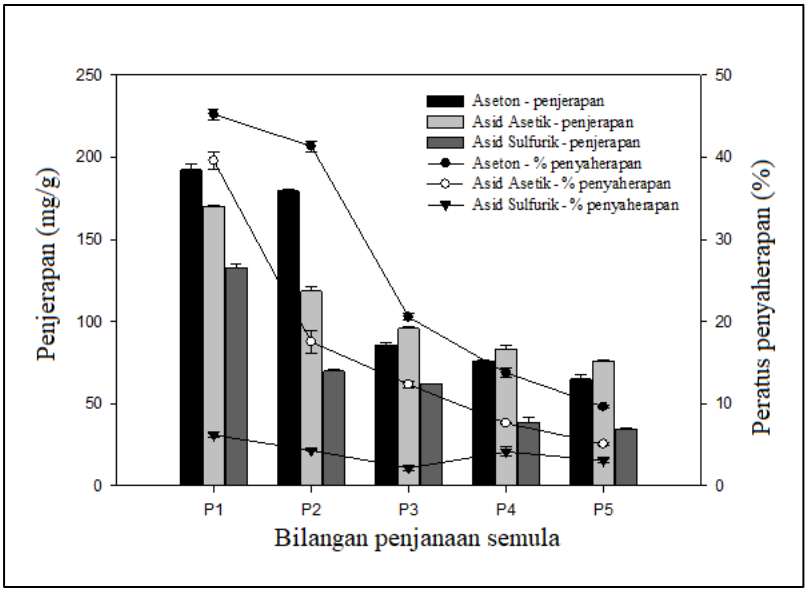
COD dan TOC

Jadual 4 adalah hasil analisis keperluan oksigen kimia (COD) dan jumlah karbon organik (TOC) terhadap POME sebelum dan selepas eksperimen penjerapan dengan 0.4 g sampel bahan penjerap sampel RHACK dan RHACNa. Keempat-empat sampel AC berjaya menurunkan peratusan COD dari serendah 69.57% hingga setinggi 72.82%. Ini mungkin kerana AC mampu menjerap bahan cemar organik pada permukaan aktif. Hasil ujian TOC juga menunjukkan penurunan nilai TOC setelah proses penjerapan POME dengan AC. Peratusan kehilangan nilai TOC antara 87.62% hingga 95.24%. AC mampu mengurangkan kandungan bahan organik yang tercemar dengan mengurangkan kandungan karbon dan oksigen POME. Terdapat penyelidik yang berjaya mengurangkan COD POME sebanyak 89.60% dan NH_3-N 75.61% dengan menggunakan AC sebagai bahan penjerap [18]. Pengurangan COD dan TOC berlaku semasa proses penjerapan di mana kawasan utama untuk penjerapan berlaku di permukaan luar AC. Sekiranya penjerapan berlaku di permukaan dalaman liang maka proses penjerapan memerlukan lebih lama [42].

Kajian sebelum ini mendapati bahawa AC pada 10 g/L telah menyebabkan penurunan COD dan SS secara drastik [43]. Penemuan ini selari dengan keputusan kajian sebelumnya di mana AC terbukti dapat mengurangkan karbon organik terlarut (DOC) [44]. AC mengurangkan bahan organik melalui ukuran liang yang sangat halus semasa proses penjerapan. Sebagai bahan penjerap, AC mempunyai luas permukaan berliang untuk memerangkap molekul organik yang menyumbang kepada penurunan kepekatan BOD dan

COD [45]. Oleh itu, AC boleh digunakan sebagai langkah rawatan awal yang membawa kepada pengurangan bahan penyumbatan/pembekuan dan penyingkiran organik yang lebih baik [44].

Jadual 4. Keputusan COD dan TOC



Sampel	COD (mg/L)	COD (%)	TOC (mg/L)	TOC (%)
POME (kawalan)	401	-	105	-
RHACK	122	69.57	5	95.24
RHACNa	109	72.82	13	87.62

Penjanaan semula dengan kaedah kimia terhadap AC-MB: Kesan agen penyaherapan

Hasil penjerapan dan peratusan penyaherapan untuk RHACK pada Rajah 4 mendapati bahawa peningkatan bilangan penjanaan semula telah mengurangkan kapasiti penjerapan dan peratusan penyaherapan sampel. Kecekapan penyaherapan AC oleh agen penyaherapan yang berbeza menghasilkan nilai yang berbeza. Peratusan penyaherapan MB pada RHACK (Rajah 4) dengan agen penyaherapan aseton tertinggi pada 45.22-9.63% dan penjerapan 192.30-65.14 mg/g untuk lima penjanaan semula, diikuti oleh asid asetik pada 39.58-5.10% dan penjerapan 170.28-76.14 mg/g, sementara asid sulfurik terendah adalah 6.18-2.18% dan penjerapan 132.86-34.56 mg/g. Hasil kajian menunjukkan bahawa agen penyaherapan pelarut organik, iaitu aseton dan asid asetik, lebih menyaherap daripada pelarut bukan organik asid sulfurik pada RHAC-MB. Pewarna yang terjerap dapat dinyaherap menggunakan air neutral, maka pewarna tersebut terjerap dengan bahan penjerap melalui ikatan lemah. Jika dapat dinyaherap pewarna dengan asid sulfurik atau air alkali, maka pewarna melakukan penjerapan melalui pertukaran ion. Penggunaan pelarut organik seperti aseton atau asid asetik untuk menyaherap pewarna telah terjerap melalui kimia jerapan. Manakala jika ternyaherap dengan asid mineral seperti HCl, maka pewarna telah dijerap melalui jerapan fizikal [28]. Ini menunjukkan jerapan kimia merupakan mekanisma penjerapan AC-MB.

Faktor berat molekul agen penyaherapan cenderung mempengaruhi hasilnya. Berat molekul agen penyaherapan lebih kecil daripada bahan yang dijerap (MB) akan memberikan pemindahan fizikal (pelarutan) molekul MB oleh molekul agen penyaherapan [46]. Aseton mempunyai berat molekul yang lebih kecil 58 g/mol diikuti oleh asid asetik (60 g/mol) dan asid sulfurik (98 g/mol) berbanding dengan MB 319.86 g/mol cenderung menghasilkan peratusan penyaherapan yang lebih baik oleh aseton daripada asid asetik dan asid sulfurik.

Sebilangan besar pelarut organik mempunyai kumpulan hidrofobik ((-CH_3, -CH_2CH_3) dan hidrofilik (-OH, -CN, = O). Pelarut organik mempunyai kumpulan hidrofobik seperti kumpulan metil ((-CH_3) yang akan dijerap pada kumpulan hidrofobik aromatik struktur karbon, sementara kumpulan hidrofilik berinteraksi dengan kumpulan fungsi bahan penjerap. Hal ini kerana kumpulan metil lebih berkait rapat dengan kumpulan hidrofobik karbon, ada kekuatan pendorong untuk molekul MB tidak aktif daripada AC-MB yang diisi [47]. Aseton mempunyai kumpulan metil yang lebih besar yang memudahkan proses penyaherapan. Kumpulan hidrofobik agen penyaherapan akan lebih terjerap daripada kumpulan hidrofilik dengan bahagian hidrofobik AC, yang seterusnya membentuk dorongan kepada proses penyaherapan molekul bahan yang dijerap [48].

Rajah 4. Keputusan penjerapan dan peratus penyaherapan RHACK pada analisa penjanaan semula

Kesimpulan

Peningkatan bahan penjerap AC mengakibatkan peningkatan peratusan perubahan warna POME. Secara amnya, bahan penjerap pada kadar 0.4 g dan masa 60 min mampu menyahwarnakan POME. RHACK menunjukkan peratusan penyahwarnaan yang lebih baik daripada RHACNa kerana faktor luas permukaan liang. Sampel AC dapat menurunkan COD 69.57-72.82% kerana kemampuan AC menyerap bahan cemar organik. Nilai TOC diturunkan kepada 87.62-95.24% kesan AC yang dapat mengurangkan kehadiran C dan O dalam kandungan bahan organik POME. Kajian lima pusingan penjanaan semula analisa penjerapan-penyaherapan MB-AC mendapati bahawa penyaherapan menggunakan aseton menghasilkan peratusan penjerapan dan penyaherapan terbaik untuk sampel RHACK berbanding dengan menggunakan asid asetik dan asid sulfurik. Pelarut organik lebih cekap dalam proses penyaherapan pewarna kationik pada RHACK daripada pelarut bukan organik. Pengaruh jenis pelarut/agen penyaherapan adalah faktor penyebab kepada kebolehnyaherapan AC-MB. Sebagai perbandingan untuk ketiga-tiga jenis agen penyaherapan, aseton menghasilkan peratusan penyaherapan MB yang lebih tinggi diikuti oleh asid asetik dan asid sulfurik. Faktor berat molekul dan kumpulan hidrofobik pada agen penyaherapan mungkin antara sebab aseton lebih baik.

Penghargaan

Penulis ingin mengucapkan penghargaan dan ucapan terima kasih kepada pihak MARDI dan UKM kerana masing-masing telah menyediakan bantuan kewangan dan peralatan makmal semasa kajian ini dilakukan.

Abstract

Antifouling biocide such as Irgarol 1051 has been widely used as a replacement of tributyl tin (TBT). In Malaysia, we reported the level of Irgarol in coastal water up to 2021ng/L. This raises concern because high dosage of chemical pollutant in the seawater can affect the marine organisms. This study therefore, examined the effect of Irgarol 1051 on fatty acids composition of reef building coral *Galaxea fascicularis*, collected in Pulau Bidong, Malaysia. The corals were exposed to different doses of Irgarol 1051 under short term exposure (96 hrs) and the fatty acid compositions of the coral tissues were determined using the gas chromatography technique. The findings revealed no clear different (p >0.05) among untreated samples (fresh and control) and both were dominated by polyunsaturated fatty acids (PUFA), followed by saturated fatty acids (SAFA) and monounsaturated fatty acids (MUFA). In contrast, the treated samples of *G. fascicularis* (20, 100 and 500 µg/L) were significant different (p <0.05) where both SAFA and PUFA were significantly lowered than untreated samples especially at the samples exposed to higher dose of Irgarol 1051 (100 and 500 µg/L). As the level of dose increased, SAFA such as 16:0 and unsaturated fatty acid from ω3 and ω6 series were largely affected by the toxicology effect of the Irgarol 1051. The results indicate that Irgarol 1051 significantly affecting the health of the corals even at the lowest dose of Irgarol 1051 applied in this study. It is suggested that the antifouling biocide may have implication on metabolisms of the corals.

Keywords: booster biocides, antifouling chemicals, fatty acids, hard coral, coral reefs

Abstrak

Biosid anti-kotoran seperti Irgarol 1051 telah digunakan secara meluas sebagai pengganti kepada tributil tin (TBT). Di Malaysia, kami telah melaporkan tahap Irgarol di perairan pantai mencapai setinggi 2021ng/L. Ini menimbulkan kebimbangan kerana dos bahan pencemar kimia yang tinggi dalam air laut boleh menjejaskan organisma marin. Oleh itu, kajian ini mengkaji kesan Irgarol

1051 pada komposisi asid lemak di dalam karang keras *Galaxea fascicularis*. Pendedahan jangka pendek (96 jam) telah dilakukan ke atas spesis karang ini dengan menggunakan kepekatan Irgarol yang berbeza dan komposisi asid lemak didalam tisu karang ditentukan dengan menggunakan teknik gas kromatografi. Hasil kajian mendapati tiada perubahan yang ketara pada karang yang tidak terdedah dengan Irgarol (sampel segar dan kawalan) dan kedua-duanya mempunyai kandungan asid lemak yang didominasi oleh asid lemak poli tidak tepu (PUFA), diikuti dengan asid lemak tepu (SAFA) serta asid lemak mono tidak tepu (MUFA). Sebaliknya, terdapat perbezaan yang ketara antara sampel karang yang tededah dengan kepekatan berbeza Irgarol (20, 100 and 500 µg/L) dimana komposisi SAFA dan PUFA lebih rendah berbanding sampel segar dan kawalan, terutamanya pada sampel yang terdedah pada kepekatan Irgarol 1051 yang tinggi. SAFA seperti 16:0 dan asid lemak tidak tepu dari kumpulan ω3 dan ω6 adalah antara asid lemak yang sangat terkesan terhadap pendedahan pada bahan kimia ini. Dapatan kajian juga menunjukkan, Irgarol 1051 sangat mempengaruhi kesihatan karang walaupun hanya terdedah pada dos yang rendah. Ini menunjukkan bahawa terdapat implikasi pada metabolisma karang apabila terdedah kepada bahan kimia ini.

Introduction

Booster biocide such as Irgarol 1051 is categorized as priority hazardous substance by the European commission [1] but is used in worldwide as a means to control the fouling on boats and ships. The research to date has tended to report a contamination by alternative biocides Irgarol 1051 in coastal water of Malaysian peninsular [2] as well as in sediments and mussels around Malaysian coast [3]. Despite their increased use worldwide, far too little attention has been paid to the fate, toxicity and persistence of this booster biocide Irgarol as well as their potential risks on marine ecosystems [4]. The toxicity of this booster biocide on marine organisms, especially those from tropical and subtropical regions are still largely unknown, as most available and relevant toxicity data were generated with temperate species [5]. As a consequence, coral reefs around the world are facing a number of threats of the toxic chemical's inputs from terrestrial such as domestic activities, agricultural, and industrial [6, 7]. For example, in Japan, it was reported that, development activities such as road building, farming, and modification of drainage systems have increased runoff of red soil in coral reefs which have negative impact to coral reef ecosystems [4, 8]. Toxic chemical substances are contributing to the destruction of coral reef ecosystems. Research by Knutson et al. [9] revealed a potential effect of Irgarol 1051 on coral larvae which significantly reduce the larvae settlement even at low dose of Irgarol 1051 (100ng/l). However, in Malaysia most of the pollutant's studies have been focused on heavy metals either in ports, marinas and islands; but attention has not been paid to the distribution and impacts of antifouling chemicals (*e.g.,* Irgarol) in this region. Recently, we reported the effects of Irgarol on fatty acid of Asian sea-bass, *Lates calcarifer* in Malaysia [10] but still there is a significant gap on research information regarding to the toxicity of new antifouling chemicals such as Irgarol in relation with the health of coral reef organisms worldwide.

Comparatively few studies have dealt with the effects of new antifouling Irgarol in particular on different coral reef organism in aquatic systems. Furthermore, the studies that have dealt with the effects of Irgarol on lake or river bacteria, have seldom examined these effects on the composition of these communities [11] or have analysed the whole microbial communities or the whole plankton [12] without testing the direct effects of these pollutants on marine organisms using fatty acid as an indicator. Hence, the direct effects of Irgarol and many other pesticides on natural aquatic organisms are poorly known. Understanding the effects of Irgarol and other pesticides on coral reef is of interest, given that the alteration of marine communities might affect their ecosystem function. Therefore, this study was carried out to determine the fatty acid profile of fresh sample (control) and compared with those short term exposed *Galaxea fascicularis* in different doses of Irgarol to realize environmental causing damages to these vital marine natural resources.

Materials and Methods

Experimental design

Fresh corals (*Galaxea fascicularis*) were taken from Pulau Bidong, Terengganu, Malaysia (5°37′N 103°4′E). The corals were acclimatized for 2 weeks in well aerated holding polyethylene tanks (500 L), containing natural seawater with a salinity of 30 ppt, under a natural

photoperiod 12 h:12 h (light: dark) cycle. The water in the tank was passed through a 1-mm filter, treated with UV-sterilized and refilled daily. For the purpose of the experiment, the coral was not fed at all.

A stock solution of 1000 mg/l Irgarol (Sigma-Aldrich) was prepared by using acetone and the working concentrations were made up by spiking the required concentrations to the sea water (volume= 3000 mL). *Galaxea fascicularis* were acclimatized for two weeks in the laboratory before the acute exposure tests to Irgarol for 96 hrs [13] as shown in Figure 1. Water quality characteristics were measured daily: dissolved oxygen (DO) 7.2±0.5 mg/L, and pH 7.69±0.2, but the temperature was automatically controlled to 27 ^{0}C using cooling chiller throughout the whole experiment duration. After the two weeks acclimatization period, corals were transferred into different experimental tanks containing three litres of water and exposed to test concentrations of 0 (T1), 20 µg/L (T2), 100 µg/L (T3), and 500 µg/L (T4) of Irgarol in three replicates for 96h. Samples in control the control tank was kept for the sake of comparison. After four days (96hrs), the tissue of the coral was removed by using water pick and taken to the laboratory for fatty acid analysis.

T1 to T3 are Irgarol test concentrations of 20 µg/L, 100 µg/L, and 500 µg/L, respectively while TC as control.

Sample preparation

Fatty acid methyl ester extraction

Tissues of *Galaxea fascicularis* were taken as samples for fatty acid composition analysis. The one step method [14] was used in this experiment to combine extraction and esterification processes in a single tube. Three replicates of each tissue samples (200-300 mg) were mixed with 4 mL of hexane and 1 mL (1 mg/mL) of internal standard (analytical standard of nonadecanoic acid, C19:0, Sigma-Aldrich) solution in a 50 mL centrifuge tube. After adding 2 mL of 14% BF_3 in methanol and a magnetic stirring bar, the head space of tube was flushed with nitrogen gas and then closed tightly with a Teflon-lined screw-cap. The capped tube was heated on a hot plate at 100 °C for 120 min under continuous stirring. After cooling to room temperature, 1 mL of hexane was added followed by 2 mL of distilled water. The tube was then shaken vigorously for 1 min

and centrifuged for 3 min at 2500 rpm. Of the two phases which formed, the upper phase was hexane layer containing the FAMEs. Finally, ~1–2 ml of the hexane layer was transferred using a Pasteur pipette into a clean sample vial prior to for injection for the GC-FID FAME analysis. Fatty acid concentrations (CFA, mg/g of dry sample) were calculated by comparing the peak area of fatty acid in the sample with the peak area of internal standard as follows:

$$C_{FA} = {}^{A_S}/_{A_{IS}} \times {}^{C_{IS}}/_{W_S} \quad (1)$$

where; A_S = peak area of fatty acid in the sample in chromatogram, A_{IS}= peak area of internal standard in chromatogram, C_{IS} = concentration of internal standard (mg), and W_S = weight of sample (g).

Qualitatively (as a percentage), composition of individual fatty acids was calculated by comparing the peak area of each fatty acid with the total peak area of all fatty acids in the sample.

Gas chromatography conditions

The FAMEs were separated and quantified using a gas chromatography equipped with flame ionization detector, GC-FID (GC = Agilent Technologies 6890N, FID = Agilent 5973 MSD). Separation was performed with an FFAP-polar capillary column (30 m×0.32 mm internal diameter, 0.25 μm film thickness) in split-less mode. Hydrogen was used as a carrier gas. The inlet temperature is 250 °C. After injection at 60 °C, the oven temperature was raised to 150 °C at a rate 40 °C min^{-1}, then to 230 °C at 3 °C min^{-1}, and finally held constant for 30 min. The flame ionization was held at 240 °C. FAME peaks were identified by comparing their retention times with those of authentic standards (Supelco Inc.). Fatty acids were designated as an n:pωx, where n is the number of carbon atoms in the aliphatic chain, p is the number of double bonds and x is the position of the first double bond from the terminal methyl group. The analytical precision for samples was generally <5% for total amounts and major components of FAMEs.

Statistical analysis

Differences among the mean value of fatty acid compositions (ΣSAFA, ΣMUFA, ΣPUFA and fatty acid components) were examined by Generalize Linear Model (GLM) which involves the Multivariate Analysis of Variance (MANOVA). The null hypotheses of 'no difference between treatments' were tested and significant levels less than 0.05 (p <0.05) indicated significant differences for the test treatment. Any significance differences between the treatment samples were further tested via multiple comparison using Bonferroni post-hoc test. Prior to the analysis, data were tested for homogeneity of variances (Leven's test) and the normality of the data (Shapiro–Wilk's test). Statistical analysis was performed using IBM SPSS statistic software.

Results and Discussion

Major fatty acid composition

There was a significant different on the composition of ΣSAFA [$F_{(4,10)} = 39.965$, $p < 0.001$], ΣMUFA [$F_{(4,10)} = 81.811$, $p < 0.001$] and ΣPUFA [$F_{(4,10)} = 30.449$, $p < 0.001$] among the treatment samples. As shown in Figure 2, lower composition of ΣSAFA, ΣMUFA and ΣPUFA were found in the samples exposed with Irgarol 1051. Pairwise test revealed no clear different ($p > 0.05$) between fresh, control and T1 in ΣSAFA composition but significantly different (p <0.05) with the samples exposed to 100 μg/L (T2) and 500 μg/L (T3) Irgarol 1051. Both ΣMUFA and ΣPUFA were not significantly differ ($p > 0.05$) between fresh and control but the composition in the samples exposed to Irgarol 1051 do not follow the trend. Higher composition of ΣMUFA was found in T1 and T2 with palmitoleic acid (16:1) highly contribute to the MUFA composition while ΣPUFA significantly lowered as compared to fresh and control samples.

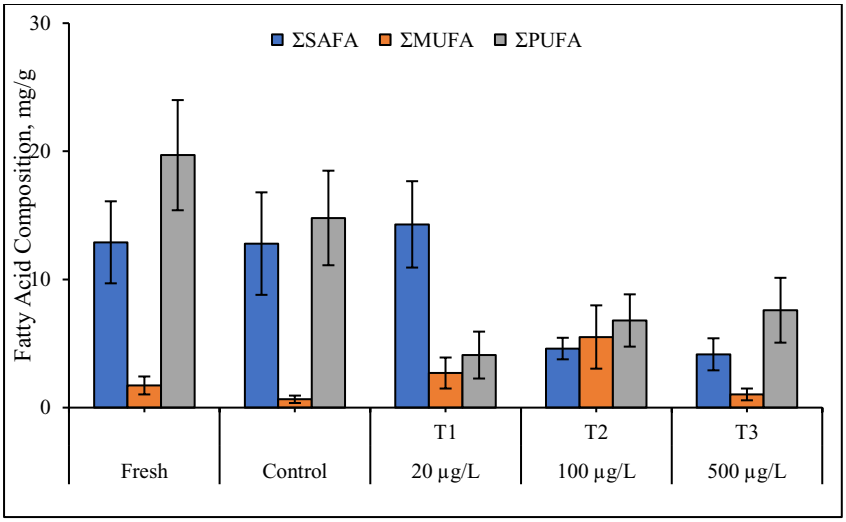

Figure 2. Composition (mg/g) dry weight of SAFA, MUFA, PUFA and total fatty acid in tissue samples of *Galaxea fascicularis* after 96hrs acute exposure test of Irgarol 1051. Values are means with standard deviation (n=3)

Fatty acid components

There was a statistically significant difference in the composition of C14:0 [F (4,10) = 6.101, p = 0.009], C16:0 [F (4,10) = 34.282, p <0.001] and other SAFA [F (4,10) = 46.661, p <0.001] among the treatment samples. Based on post-hoc test, the composition of C16:0 was found significantly lower (p <0.05) in the samples expose to 20 µg/L,100 µg/L and 500 µg/L Irgarol as compared to fresh and control sample, whereby no clear differences (p > 0.05) were found between fresh and control. As shown in Figure 3, the fatty acid compositions of 16:0 was largely affected when the samples were exposed to100 µ/g and 500 µ/g Irgarol. No clear trend was found in the composition of 14:0 and In this study, four PUFA components comprised of omega-6 and omega-3 fatty acids namely γ-Linolenic acid (18:3ω6), α-linolenic acid (18:3ω3 or ALA), eicosatrienoic acid (20:3n3) and eicosapentaenoic acid (20:5ω3 or EPA) were examined. The composition of 18:3ω6 [F (4,10) = 89.997, p < 0.001], 18:3ω3 [F (4,10) = 19.808, p <0.001], 20:3n3 [F (4,10) = 17.364, p <0.001] and 20:5ω3 [F (4,10) = 56.966, p <0.001] were significantly different among the treatment samples. No clear differences (p > 0.05) were found between fresh, and control as indicated by pairwise test but significantly lowered in the samples exposed to 20 µg/L/g ,100 µg/L and 500 µg/L Irgarol (Figure 4).

This study revealed the effect of different concentrations of Irgarol on fatty acid composition in the tissue of *G. fascicularis*. The present findings demonstrate that Irgarol 1051 affecting the health of corals due to changes of fatty acids composition of *G. fascicularis* and may have implications on metabolisms of the corals. Lower fatty acid composition of ΣSAFA and ΣPUFA was observed in the tissue of *G. fascicularis* especially when exposed to high concentration (100 µg/L and 500 µg/L) of Irgarol. Previously, similar trend was also found in a study using Asian sea-bass *Lates calcarifer* where lower ΣSAFA and ΣPUFA was found in the samples exposed to 10%, 30% and 50% of the 96 hrs LC50 = 0.535 mg/ml of triazine herbicides Irgarol 1051 as compared to fresh and control [10]. In contrast, toxicity test of Irgarol 1051 to hard coral *Fungia fungites* revealed that ΣSAFA, ΣPUFA and ΣMUFA were reduced in a as the dose of Irgarol 1051 increased [15]. The inconsistency of fatty acid composition between different species of hard corals can be related to their species-specific and dietary of the species [16, 17].

Lower ΣSAFA is largely associated with the lower composition of palmitic acid (16:0) when the samples exposed to Irgarol 1051 especially at higher doses (100 µ/g and 500 µ/g). Generally, the high content of palmitic acid is commonly found in healthy corals and can reach 50% of the total FA composition [15-17]. Toxicity test

of metal cadmium to marine macroalgae, *Ulva lactuca* revealed that reduction in palmitic acid can be due to an active desaturation process of fatty acid for the production of unsaturated fatty acid such as linoleic (18:2ω6) and linolenic acid (18:3ω6) [18]. However, in the present study, there was no evidence to support the biosynthesis process because some of the PUFAs such as linolenic acid was below the detectable limit.

Among the unsaturated fatty acid, ΣPUFA are largely affected by Irgarol 1051 as compared to ΣMUFA which significantly higher in control and fresh samples. ΣMUFA shows inconsistent trend as compared to fresh and control samples. Perhaps, the MUFA is the intermediate fatty acid in biosynthesis of fatty acid pathway for the conversion from SAFA to PUFA following the contemporary concept [16]. Hence, extensive change in both SAFA and PUFA possibly affecting the inconsistent of ΣMUFA composition. The ΣMUFA having the least composition in fresh and control samples, which is commonly observed in a healthy coral and could remain the low in the samples under stress condition by Irgarol 1051 [10, 15]. In contrast, high composition of ΣMUFA was found in the samples exposed to 100 µ/g of Irgarol 1051 where only palmitoleic acid (16:1) was detected in the GC-FID where the rest of MUFA components were below the detectable limit. High level of ΣMUFA than ΣSAFA possibly due to the active conversion of SAFA to unsaturated fatty acid which leading to high content of ΣMUFA and ΣPUFA in T2 samples [17].

Presently, ΣPUFA was largely affected and significantly lower in all tested samples as compared to fresh and control samples even at lower dosage of Irgarol 1051. It is known that unsaturated fatty acid such as PUFA is highly susceptible to oxidative stress [20]. There is an increasing interest in oxidative stress in the context of chemical stress in marine organisms [21-23]. In corals, cellular mechanism underlying the bleaching is tightly coupled with the accumulation of toxic reactive oxygen species (ROS) which is naturally counterbalance with other SAFA as indicated by the post-hoc test (Figure 3). antioxidant enzymes [24]. A study on acute exposure of Irgarol 1051 on branching coral *Madracis mirabilis* proven that the chemical toxicity greatly enhances the intracellular formation of toxic ROS which compromise by oxidative defence capacity [23]. However, under certain condition, coral will utilize their energy reserve as a barrier or as a repair system against the oxidative stress when the antioxidant enzymes cannot cope with excessive production of ROS [20]. It is well proven that the depletion of PUFA composition after the loss of symbiont can be associated with oxidative stress [20, 25, 26]. Additionally, all PUFA components from the n-3 (18:3ω3, 20:3ω3 and 20:5n3) and n-6 (18:3ω6) were significantly affected by Irgarol 1051. According to Okuyama et al. [27], the long-chain n-3 series such as the EPA (20:5ω3) which has an antioxidative effect are likely to function as a primary protective barrier against the oxidative stress caused by the accumulation of ROS. Among the PUFAs, the 18:3ω6 and 20:5ω3 are known as a fatty acid biomarker for the symbiotic algae [10, 16, 28]. Irgarol is highly toxic and powerful inhibitor to the symbiotic algae in coral because this antifouling chemical is used to prevent the growth of algae [30]. Symbiotic algae provide up to 90% of photosynthetically fixed carbon to corals including fatty acids which is an important nutrient for daily energy requirement of their host [28, 30]. Study on *Seriatopora histrix* [29] and *Acropora tenuis* [31] exposed to Irgarol 1051 revealed that the Irgarol 1051 able to inhibit the PSII that involve with the photosynthesis process in the symbiotic algae. Moreover, it is known that some of the fatty acids especially PUFA were translocated from symbiotic algae to coral [20, 26, 17], hence, lower composition of PUFA in the present samples exposed by Irgarol 1051 is partly associated with the disruption of the photosynthetically fixed carbon production by the symbiotic algae.

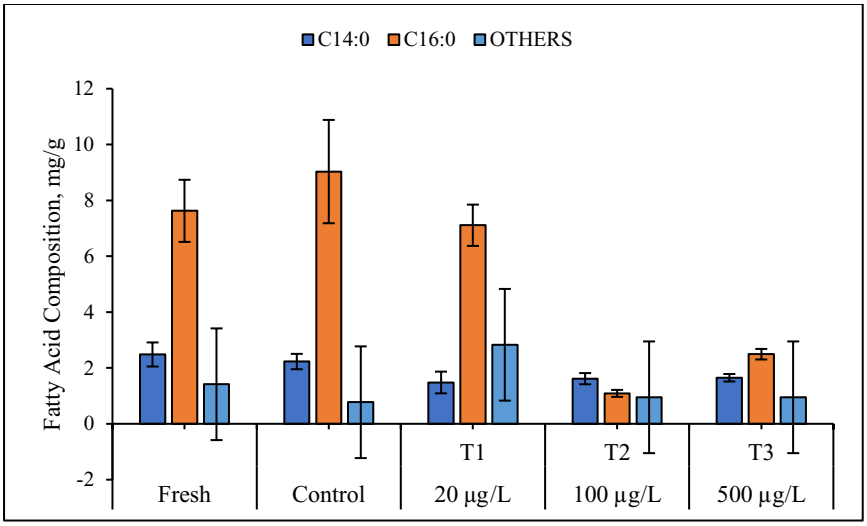

Figure 3. Composition (mg/g) dry weight of SAFA components namely myristic acid (14:0), palmitic acid (16:0) and other components of SAFA (total) in tissue samples of *Galaxea fascicularis* after 96hrs acute exposure test of Irgarol. Values are means with standard deviation (n=3)

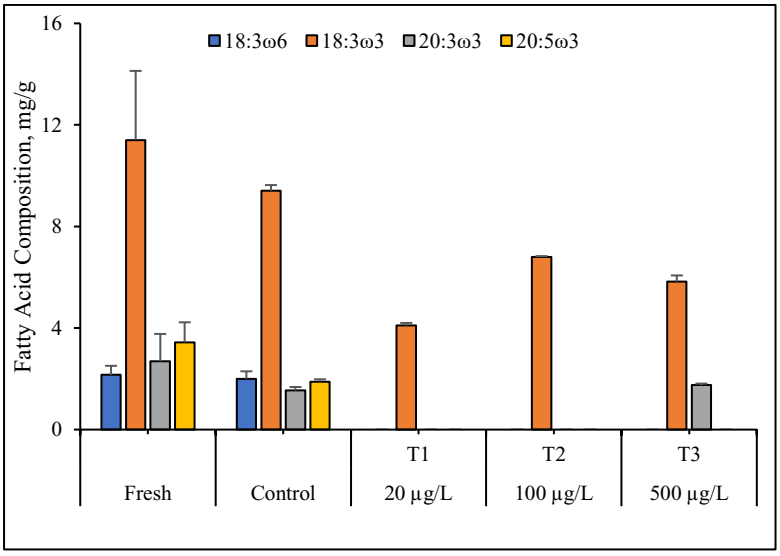

Figure 4. Composition (mg/g) dry weight of PUFA components namely γ-linolenic acid (18:3ω6), α-linolenic acid (18:3ω3), eicosatrienoic acid (20:3n3) and eicosapentaenoic acid (20:5ω3) in tissue samples of *Galaxea fascicularis* after 96hrs acute exposure test of Irgarol. Values are means with standard deviation (n=3)

Conclusion

This paper explains the toxicological responses of *Galaxea fascicularis* upon acute exposure to different concentrations of Irgarol in laboratory experiments. It can be concluded that; acute exposure to *Galaxea fascicularis* (96 hours) to different concentrations of Irgarol 1051 had shown significant impact to the fatty acid compositions of this organism. Moreover, fresh and control samples of *Galaxea fascicularis* were dominated by PUFA followed by SAFA and then MUFA which significantly different trend with the treated samples. It is proven that the Irgarol have affecting the fatty acids composition of the reef-building coral even exposed at the low levels of this biocide. As hard corals are the main reef-builder, further research is required to understand the ecotoxicological effect of Irgarol to their metabolism to comprehend the consequences of this antifouling chemicals to the health of coral reefs ecosystem.

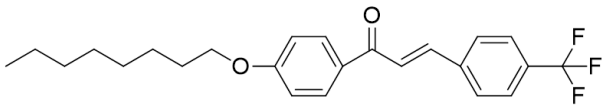
Abstract

A new alkoxylated-chalcone derivative displaying donor(D)-π-acceptor(A) system was successfully synthesized via Claisen-Schmidt condensation to be integrated as organic semiconductor material. The correlation between electronic, optical properties, electrochemical and DFT calculation of the designated system were assessed in thorough. This alkoxylated-chalcone (**OCT-CHAL**) reveals an absorption band at λ_{max} 312 nm with molar coefficient of *ca.* 10^5 L mol^{-1} cm^{-1} which corresponding to π-π* transition. The optical band gap gives the value of 3.40 eV which shows good agreement with the value of energy level between HOMO and LUMO for theoretical calculation. Meanwhile, this derivative also reveals good thermal stability up to 200 ℃ with total mass loss at 97 %. In turn, the electrochemical behaviour of **OCT-CHAL** was investigated and exhibited redox potential with the values of 2.40 V for oxidation potential while the reduction potential exhibited at value of -1.72 V as quasi-reversible reduction. From the outcome, the existence of conjugation effect on chalcone moiety with ideal relation between the experimental and theoretical approach provides good support of being a potential candidate in organic semiconductor material for advance material application.

Keywords: alkoxy, chalcone, bandgap, DFT, electrochemistry

Abstrak

Terbitan alkoksi-kalkon baharu yang memaparkan sistem penderma(D)-π-penerima(D) telah berjaya disintesis melalui kaedah kondensasi Claisen-Schmidt untuk diintegrasikan sebagai bahan organik semikonduktor. Perkaitan antara elektronik, sifat optik, elektrokimia dan pengiraan DFT bagi sistem yang direkabentuk telah dinilai secara menyeluruh. Alkoksi-kalkon (**OCT-CHAL**) ini menunjukkan jalur serapan pada λ_{mak} 312 nm dengan pekali molar 10^5 L mol^{-1} cm^{-1} yang selari dengan peralihan π-π*. Nilai jurang jalur optik memberikan nilai 3.40 eV yang mana keputusannya menunjukkan nilai yang selari dengan nilai aras tenaga antara HOMO dan LUMO bagi pengiraan teori. Sementara itu, terbitan ini juga menunjukkan kestabilan terma yang baik sehingga 200 ˚C dengan jumlah jisim yang hilang sebanyak 97 %. Selanjutnya sifat elektrokimia bagi **OCT-CHAL** telah dikaji dan



menunjukkan keupayaan redoks dengan nilai 2.40 V untuk potensi pengoksidaan manakala potensi penurunan adalah pada nilai -1.72 V sebagai penurunan kuasi-terbalik. Daripada keputusan yang diperolehi, kehadiran kesan konjugasi pada moiti kalkon dengan hubungan yang baik antara kaedah eksperimen dan teori memberikan sokongan yang baik untuk menjadi calon berpotensi dalam bahan organik semikonduktor bagi aplikasi bahan termaju.

Kata kunci: alkoksi, kalkon, jurang jalur, DFT, Elektrokimia

Introduction

In recent years, the development of organic semiconductor has been extensively explored due to its electronic delocalization in π-orbital system in optimizing the efficiencies of various application in electrical and optoelectronic application [1]. The materials have been extensively studied as a small molecule and polymer and mostly comprised of carbon and hydrogen atom in their molecular structure where the mobility of electron transfer is occurred within the molecule. Considering to the ability in transferring electron, chalcone backbone has been introduced as an organic material which fulfilled this criterion [2,3]. Chalcone, known as 1,3-diphenyl-2-propen-1-one is a molecule that consists of two phenyl rings with α, β-unsaturated ketone (C=C-C=O) moiety in their molecular build-up has attracted considerable attention among researchers due to its electronic properties according to the presence of π-conjugated system in their molecular backbone [4]. Generally, a conjugated system would generate a cloud of delocalized electron merging by π-electron system which enables the flowing of electron along the molecular framework thus activates its potential as charge carrier mobility [5]. Meanwhile, chalcone is considered as a molecule with high charge transfer mobility as it exhibits intramolecular charge transfer (ICT) properties and is known as considerably highly emissive molecule as reported previously [6]. However, the elections of substituents towards the terminals of the phenyl rings would determine their contribution as good charge transfer ability [7], and appropriate selection of these substituents lead to the development of application such as in optoelectronics particularly in potential non-linear optical interests [8].

In this context, the chalcone based compound is introduced with the attachment of ideal substituents to develop a molecule with donor-π-acceptor (D-π-A) system in enhancing the ICT properties of the molecule [9]. The introduction of alkoxy chain towards chalcone based molecule was believed in lowering the energy band gap due to the steric bulkiness of the compound [10], thus enables it to lie in typical band gap range of semiconducting materials. Various physicochemical evaluations were accomplished via cyclic voltammetry (CV) technique in order to study their electrochemical properties and behaviour to establish their potentiality as semiconducting materials. As part of our studies in this area, a model molecule of new alkoxylated-based chalcone derivative namely, 1-(4-octoxyphenyl)-3-[4-(trifluoromethyl)phenyl]prop-2-en-1-one **(OCT-CHAL)** featuring D-π-A system presented in Figure 1 was successfully designed, synthesized and demonstrated as a semiconducting material as reported herein.

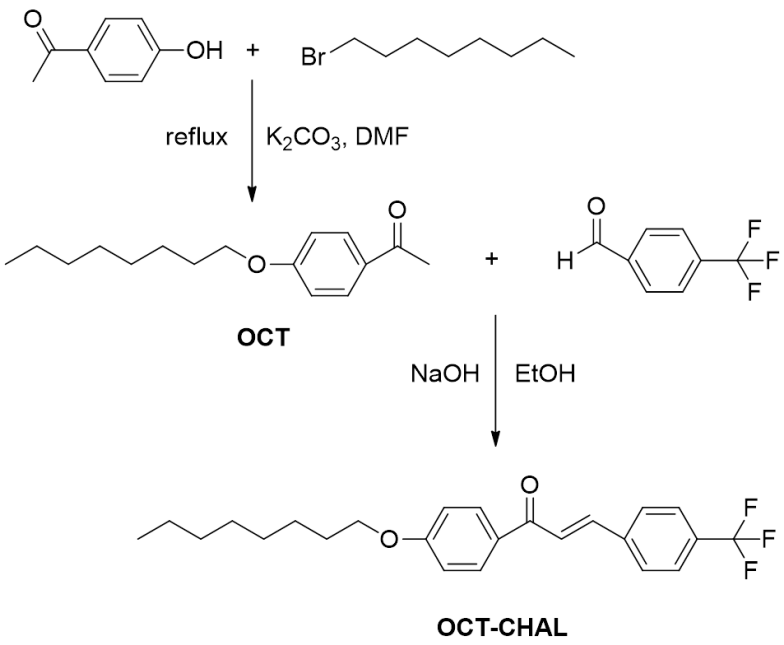
Figure 1. Molecular structure of **OCT-CHAL** derivative

Materials and Methods

4-hydroxyacetophenone, 1-bromooctane, potassium carbonate, 4-trifluoromethylbenzaldehyde, hexane, dimethylformamide (DMF), hexane, ethyl-acetate,



sodium hydroxide (NaOH), anhydrous hydrochloric acid (HCl), sodium sulphate and silica gel blue were commercially purchased form standard commercial suppliers namely Sigma Aldrich, Merck, Fisher Scientific and R&M Chemical without any further purification procedures were performed. The reaction was carried out under ambient atmosphere with no special condition including air or mixture exclusion.

Instrumentations

The infrared (IR) spectra were recorded by using Perkin Elmer Spectrum 100 Fourier Transform Infrared Spectrophotometer via Attenuated Total Reflection (ATR) in the spectral range of 4000 cm^{-1}-400 cm^{-1}. Whilst, ^{1}H and ^{13}C nuclear magnetic resonance (NMR) were determined by Bruker Avance III 400 spectrometer ^{1}H (400MHz) and ^{13}C (100.61MHz) by using deuterated chloroform ($CDCl_3$) acting as a solvent and tetramethylsilane (TMS) as an internal standard of δ_H (0-15 ppm) and δ_C (0-200 ppm) respectively. CH elemental analysis was carried out via Vario EL Cube Elemental Analyzer to determine the percentage weight of the elements of carbon and hydrogen presence in the synthesized compound. The UV-Vis spectroscopy spectrum was observed by using Spectrophotometer Shimadzu UV-1800 PC in 1 cm^3 quartz cuvette in dichloromethane solution with concentration of 1×10^{-5} M in the spectra range of 200–500 nm for absorbance analysis. The optimized molecular structure was obtained via density functional theory (DFT) calculation using ab initio quantum mechanical software of Gaussian 09 with correlation functional of B3LYP with basis set of 6-31G (d, p). Then, the excitation energies and correlation absorption wavelength were calculated through TD-DFT quantum mechanical calculation to obtain the energy level of HOMO-LUMO energy transition. The thermal stability was recorded via Perkin Elmer TGA Analyzer from 30 ℃ to 900 ℃ with heating rate of 10 ℃/min in the of presence nitrogen gas with flow rate of 10 mL/min. The electrochemistry was performed via AUTOLAB PGSTAT101 model potentiostat driven by NOVA 2.1 software which comprises three-electrode cell system which are working electrode (glassy carbon electrode), counter electrode (platinum wire) and reference electrode (Ag/AgCl). This experimental work-up were carried out in dichloromethane solution containing 0.1 M of tetrabutylammonium hexafluorophosphate $[NBu_4]PF_6$ as a supporting electrolyte with sample concentration of 1×10^{-3} M.

Synthetic approach

The synthesis work consists of two major parts which was the formation of 4-octyloxyacetophenone **(OCT)** as a precursor and the formation of 1-(4-octoxyphenyl)-3-[4-(trifluoromethyl)phenyl]prop-2-en-1-one **(OCT-CHAL)** as a targeted compound which were synthesized via Williamson ether synthesis and Claisen-Schmidt condensation respectively as shown in Scheme 1.

Scheme 1. Synthetic pathway for preparation of **OCT-CHAL** derivative

Synthesis of precursor: 4-octyloxyacetophenone (OCT)

Precursor of **OCT** was reported by previous literature [11], however some modifications in the experimental set-up were carried out in this study. The preparation of **OCT** was prepared by the mixture of 4-hydroxyacetophenone (1.0 g, 7.3 mmol), 1-bromooctane (1.41 g, 7.3 mmol) and potassium carbonate (3.02 g, 21.9 mmol) that were charged in 250 ml of two-necked round bottom flask. The mixture was treated with 40 ml of dimethylformamide (DMF) and was put at reflux with constant stirring for approximately 24 hours. After adjudged completion by thin layer chromatography, (TLC) (hexane: ethyl acetate; 4:1), the mixture was cooled down to room temperature and then was filtered and extracted with hexane and distilled water. The organic layer fraction obtained then was separated and washed with 1 M of aqueous NaOH (25 ml) and then with 1 M of aqueous HCl (25 ml). The organic layer obtained was dried over sodium sulphate, Na_2SO_4 and was dried *in vacuo*. (yellow viscous liquid; yield: 1.25 g, 69 %). IR (cm^{-1}): 2926.01 (*ν*C-H alkanes), 2856.58 (*ν*C-H alkane CH_2), 1676.14 (*ν*C=O), 1598.99 (*ν*C=C), 1465.90 (*ν*CH_2 bend), 1357.89 (*ν*CH_3 bend), 1251.80 (*ν*C-O carbonyl group), 1170.79 (*ν*C-O ether), 835.18 (*ν*C-H aromatic OOP). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.85 (pseudo-d, 2H, J = 8.8 Hz, Ar-H), 6.85 (pseudo-d, 2H, J = 9.2 Hz, Ar-H), 3.98 (t, 3H, J = 13.2 Hz, O-CH_2), 2.50 (s, 2H, H_3C-C=O), 1.75 (m, 2H, -CH_2), 1.45 (m, 2H, -CH_2), 1.25 (m, 9H, -CH_2), 0.85 (t, 3H, J = 14 Hz, -CH_3). ^{13}C NMR (100.61 MHz, $CDCl_3$) δ: 195.83, 162.11, 129.56, 129.05, 113.10, 67.24, 30.77, 28.29, 28.19, 28.07, 25.31, 24.95, 21.63, 13.08.

Synthesis of 1-(4-octoxyphenyl)-3-[4-(trifluoromethyl)phenyl]prop-2-en-1-one (OCT-CHAL)

The preparation of **OCT-CHAL** derived from the reaction of **OCT** (0.14 g, 0.8 mmol) and 4-trifluoromethylbenzaldehyde (0.2 g, 0.8 mmol) that both were charged in 250 ml of two-necked round bottom flask. The mixture was treated with 30 ml of ethanolic solution and then 20 % of NaOH was added dropwise to the mixture until the precipitate was formed under constant stirring for approximately 24 hours. When adjudged completion by thin layer chromatography, (TLC) (hexane: dichloromethane; 3:2), the mixture was

poured into icy water and the cooled mixture was filtered and washed with distilled water. The precipitate collected was dried over silica gel blue before recrystallized from methanol, CH_3OH (off-white crystalline solid, 0.2 g, 55 %). IR (cm^{-1}): 2921.24 (*ν*C-H alkanes), 2855.66 (*ν*C-H alkane CH_2), 1664.60 (*ν*C=O ketone), 1601.91 (*ν*C=C alkene), 1573.94 (*ν*C=C aromatic), 1470.75 (*ν*CH_2 bend), 1391.65 (*ν*CH_3 bend), 1328.01 (*ν*C-X fluoride), 1169.85 (*ν*C-O ether), 830.19 (*ν*C-H aromatic OOP). ^{1}H NMR (400.11 MHz, $CDCl_3$) δ: 7.95 (pseudo-d, 2H, J = 8.8 Hz, Ar-H), 7.72 (d, 1H, 16 Hz, HC=CH), 7.65 (pseudo-d, 2H, 8.4 Hz, Ar-H), 7.60 (pseudo-d, 2H, 8.4 Hz, Ar-H), 7.55 (d, 1H, 16 Hz, HC=CH), 6.90 (pseudo-d, 2H, J = 9.2 Hz, Ar-H), 3.95 (t, 2H, J = 13.2 Hz, -OCH_3), 1.75 (m, 2H, -CH_2), 1.35 (m, 2H, -CH_2), 1.20 (m, 9H, -CH_2), 0.85 (t, 3H, J = 10 Hz, -CH_3). ^{13}C NMR (100.61 MHz, $CDCl_3$) δ: 187.14, 162.36, 140.76 130.17, 129.44, 127.38, 124.86, 124.82, 123.16, 113.41, 67.35, 30.78, 28.30, 28.19, 28.08, 24.97, 21.63, 13.07.

Results and Discussion

Infrared spectroscopy analysis

The spectral data of **OCT-CHAL** were recorded and analysed spectroscopically. In IR spectrum of chalcone derivative as depicted in Figure 2, it revealed all the expected bands of interest *ν*(C-H alkanes), *ν*(C-H alkanes, -CH_2), *ν*(C=O), *ν*(C=C aromatic) and *ν*(C=C alkenes). The medium intensity at 2921.24 cm^{-1} and 2855.66 cm^{-1} were corresponded to vibrational of *ν*(C-H alkanes). The sharp peak of IR band was observed at 1664.60 cm^{-1} and 1601.91 cm^{-1} which assigned to *ν*(C=O) and *ν*(C=C) with good agreement to previous researchers [12]. The medium intensity at 1573.94 cm^{-1} shows the vibrations of *ν*(C=C aromatic) while strong band at 1328.01 cm^{-1} corresponded to *ν*(C-X fluoride), in which the absorption of its wavenumber increase with increment of force constant from C-F bonds due to the inductive effect between C-F bond and fluorine that are attracted by fluorine electrons [13], and the vibrational of *ν*(C-O) ether revealed at 1169.85 cm^{-1}.

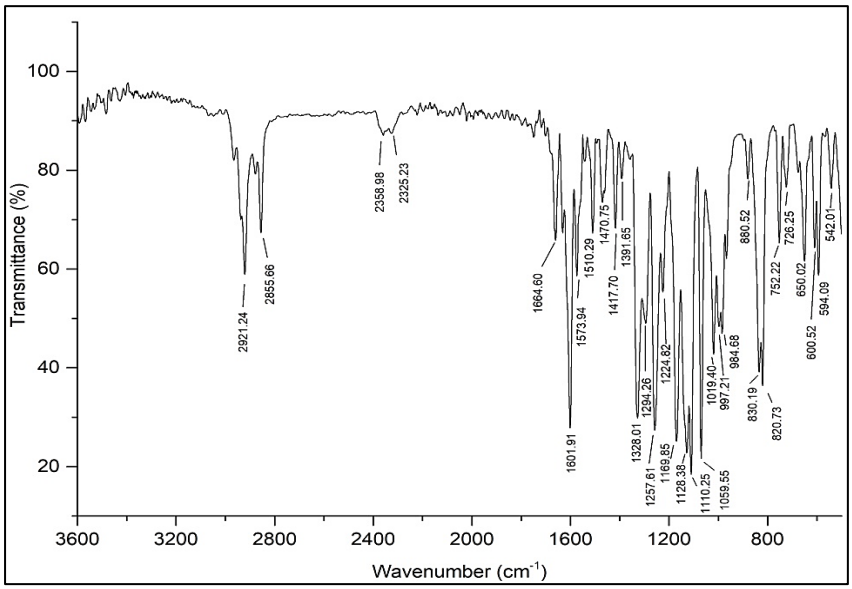


Figure 2. IR spectrum of **OCT-CHAL**

^{1}H and ^{13}C nuclear magnetic resonance analysis

In ^{1}H NMR, it revealed a pseudo-doublet resonance in the range of δ_H 7.95-6.90 ppm due to aromatic protons of para-substitution at the aromatic rings. A doublet resonance can be found at δ_H 7.72 ppm and δ_H 7.55 ppm while triplet resonance at δ_H 3.95 ppm was observed as OCH_2 due to the deshielding effect of the nearby oxygen atom which is more electronegative. Multiplet overlapping resonances lies on δ_H 1.75- 1.20 ppm while triplet resonance was recorded at shielded position δ_H

0.85 ppm. Figure 3 shows the spectrum of ^{1}H NMR for **OCT-CHAL**.

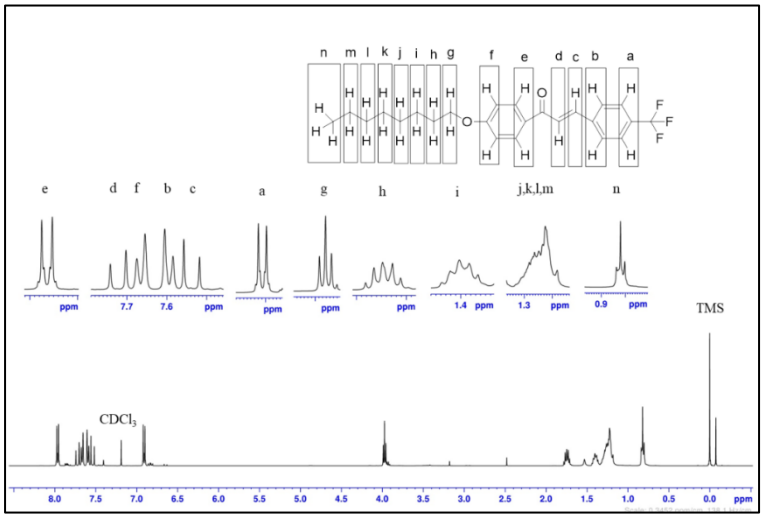

Figure 3. ^{1}H NMR spectrum of **OCT-CHAL**

The ^{13}C NMR spectrum of **OCT-CHAL** is represented in Figure 4. The C=O was identified as singlet resonance at δ_C 187.14 ppm according to deshielding effect due to the presence of nearby oxygen atom in which this trend of chemical shift position was also observed in prior reported literature [14]. Meanwhile, the aromatic carbons were recorded in the range of δ_C 162.36- 113.41 ppm. Two vinylic resonances were observed at δ_C 140.76 ppm and δ_C 123.16 ppm referring to the carbon splitting of α and β unsaturated carbons respectively due to their unsymmetrical nature within the molecular structure.

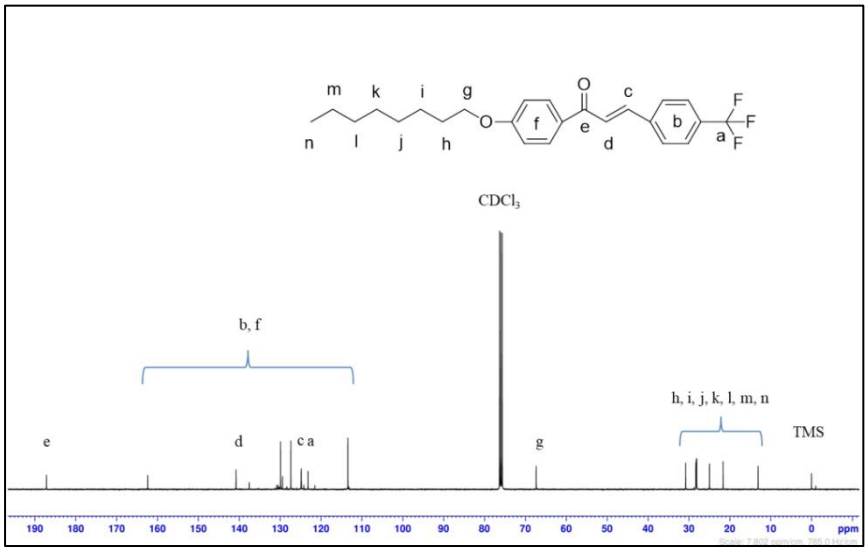

Figure 4. ^{13}C NMR spectrum of **OCT-CHAL**

Optical properties

In electronic transition of **OCT-CHAL**, it revealed π→π* transition attributed by C=O chromophore which lies in the range of 240 nm to 245 nm where the transition is shifted to longer wavelength due to the interaction of π-conjugation of carbonyl and phenyl rings. The strong absorption band between 280 nm to 330 nm can be contributed by π→π* and n→π* transitions that may correspond to C=C and C-O chromophores [8, 15]. The experimental spectrum of **OCT-CHAL** as depicted in Figure 5 (a) enables the calculation of optical band gap of this compound by referring to the formula of [E_g^{opt}= hc/ λ_{offset} (365 nm) eV]. The calculated optical band gap for **OCT-CHAL** is 3.40 eV. Comparatively, this finding has a good agreement with the values of theoretical energy band gap. The theoretical and optical band gap values are slightly different as the optical band gap are influenced by the type of solute-solvent interaction, where the solvent polarity would determine the level of ground state and excited state energy which then lead to bathochromic shift of optical spectrum. Whilst, the estimation of theoretical energy band gap was used has lowered solvatochromism in their calculation [16]. Moreover, the differences of theoretical and optical energy band gap values are also occurred due to the exciton energy binding [9], which stated that the different amount of energy band gap in the range from 0.45 eV to 1.0 eV.

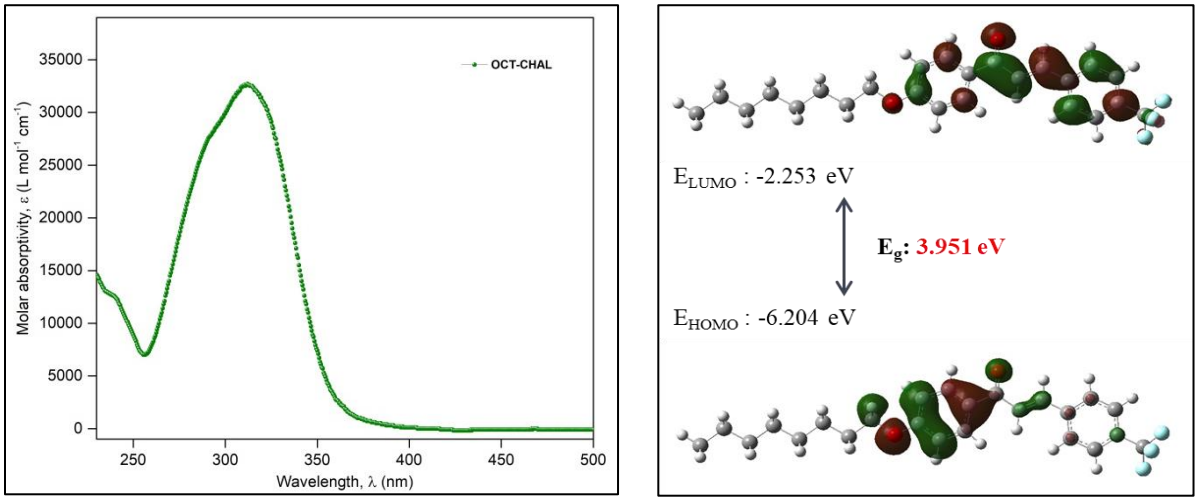

Figure 5. (a) UV-Vis spectrum of **OCT-CHAL** recorded in dichloromethane solution and (b) energy separation between HOMO-LUMO of **OCT-CHAL**

Computational calculations using time dependent density functional theory (TD-DFT) method with basis set of B3LYP-631G (d, p) was optimized from molecular structure of **OCT-CHAL** for further investigation of energy separation between the highest occupied molecular orbitals (HOMO) and lowest unoccupied molecular orbitals (LUMO). The energy separation between HOMO-LUMO energy level as depicted in Figure 5 (b). In **OCT-CHAL**, HOMO orbital density was located on electron donating alkoxy substituents while its LUMO coefficient was concentrated over enone and vinyl-substituted aryl group [17].

Molecular electrostatic potential

The molecular electrostatic potential (MEP) was performed to evaluate the molecular interaction of **OCT-CHAL**. MEP shows three-dimensional charge distributions of the molecules in which provide some information regarding to electron acceptor as well as electron donator which is displayed by colour as depicted in Figure 6. On MEP mapped surface, red area represents nucleophilic region which is rich of electron while blue area represents electrophilic region that poor

of electron and green area is zero potential as it is the halfway interaction of red and blue region. The evaluation of this potential region is necessary in estimate the intermolecular and intramolecular hydrogen bonds of the molecules [17].

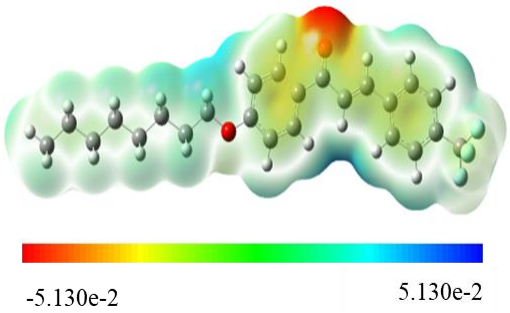

Figure 6. MEP mapped surface of **OCT-CHAL**

Global chemical reactivity descriptors

The differential global chemical reactivity descriptors (GCRD) were calculated by the evaluation of HOMO and LUMO energy level which reveal their ability as electron donor and acceptor in the compound. HOMO indicates to ionization energy (IP) while LUMO indicates to electron affinity (EA) where these findings determine the chemical properties of the molecule in term of chemical hardness (η), chemical softness (S), electronegativity (χ), chemical potential (μ) and electrophilic index (ω) as tabulated in Table 1. In addition, the calculation of HOMO-LUMO energy band gap determine the reactivity and stability of the molecule where the large optical energy band gap corresponding to less reactive and more stable and vice versa [15]. The stated parameters were used in measure the stabilities energy and reactivity of a molecule and the calculation of their quantum mechanical stabilities were calculated by equation as reported by previous literature [18, 19].

The calculation of Chemical hardness, [$\eta = (IP\text{-}EA) / 2$];
The Chemical Softness of the molecules evaluated as, [$S = 1 / 2\eta$];
The electronegativity of the molecule estimated as, [$\chi = (IP+EA) / 2$];
The chemical potential of the molecules calculated as, [$\mu = -\chi$];
The value of electrophilic index, [$\omega = \mu^2 / 2\eta$]

Table 1. Chemical properties of **OCT-CHAL** via GCRD calculation

Parameter	[DFT-B3LYP/6–31G (d, p)]
E_{HOMO} (eV)	-6.204
E_{LUMO} (eV)	-2.253
ΔE (eV)	3.951
Ionization potential I (eV)	6.204
Electron affinity EA (eV)	2.253
Chemical hardness η (eV)	1.976
Chemical Softness S (eV^{-1})	0.253
Electronegativity χ (eV)	4.229
Chemical potential μ (eV)	-4.229
Electrophilic index ω (eV)	4.525

Thermal studies

Thermal stability of **OCT-CHAL** was determined by thermogravimetric analyzer (TGA) where the molecule is stable up to 200 ℃ with two stages of major mass loss in the degradation process as shown in Figure 7. By observing the thermogram, the first degradation was occurred at around 201.47 ℃ (T_{onset}) and ended at 420.38 ℃ whilst second degradation was taken place at around 499.46 ℃ and ended at 570.16 ℃ with total mass loss of 97 %. Hence, the targeted alkoxylated-chalcone system of **OCT-CHAL** exhibits thermal stability at satisfactory temperature and gives good indication for the fabrication of thin film to be applied in any potential advanced materials application.

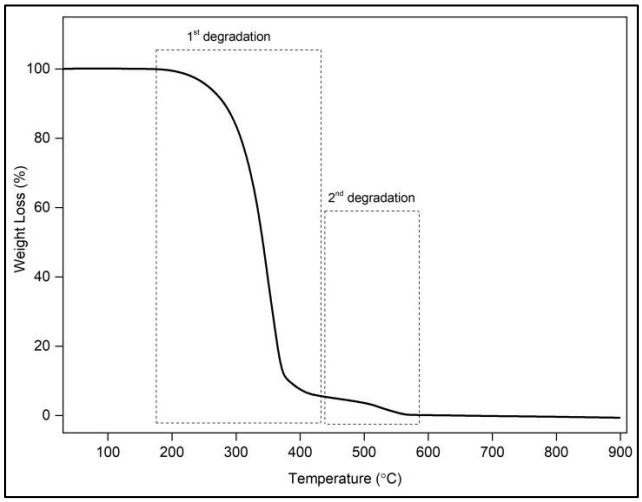

Figure 7. TGA of **OCT-CHAL**

Electrochemical properties

Cyclic Voltammetry (CV) analyzer was used in the evaluation of redox potential (oxidation and reduction) of **OCT-CHAL**. The measurement was carried out in dichloromethane solution with the presence of 0.1 M of tetrabutylammonium hexafluorophosphate, $[NBu_4]$ PF_6 acting as supporting electrolyte in the potential range of -3.0 V to 3.0 V as shown in Figure 8. From the cyclic voltammogram, the oxidation potential took place around 2.40 V at anodic peak which corresponding to oxidation of chalcone derivative due to the absorption of chalcone and/or oxidation of product occurred on the electrode surface [20]. The reduction of C=O may be corresponding to the peak revealed in the range of -1.30 V to -2.0 V with quasi-reversible reduction [21] and the process of quasi-reversibility reduction was determined by the calculation of energy separation between cathodic peak potential (E_{pa}= -1.55 V) with anodic peak potential which are (E_{pc}= -1.72 V). In addition, Ilhan and his team have confirmed this classification by evaluating the ratio of anodic peak current-to-cathodic peak current that are almost unity [22], with the values of (ΔE_p= 0.17 V).

Conclusion

A new alkoxylated-chalcone derivative featuring donor (D)-π-Acceptor (A) system has been successfully designed and synthesized via Claisen-Schmidt condensation. The semiconductor property of **OCT-CHAL** was investigated via optoelectronic using UV-Vis spectroscopy and DFT calculation. The preliminary result reveals that this derivative exhibited an optical band gap of 3.40 eV which showed good relationship between the experimental and theoretical data. The simulated data from frontier molecular orbitals (FMO) analysis, chemical reactivity and molecular electrostatic potential (MEP) also demonstrated that this chalcone based with alkoxy substituent significantly gives good HOMO-LUMO gap which lies in the range of organic semiconducting material. Hence, from this finding, **OCT-CHAL** has proven to exhibit favourable properties for advanced material applications in the near future.

Abstract

Utilizing volatile and flammable electrolytes in lithium-ion batteries has become a primary concern worldwide. Consequently, a safer high-performance electrolytes approach is required to solve the issue. In this circumstance, deep eutectic solvent (DES) might be the best option to substitute the harmful conventional liquid electrolytes. The present study explores the potential of ternary DES, which comprises choline chloride (ChCl), 1,4-butanediol (1,4-BD), and lithium triflate (LiTf), as an electrolyte in lithium-ion batteries. The structural and conductivity of ChCl/1,4-BD at 1:1, 1:2; and 1:3 mole ratios and ChCl/1,4-BD/LiTf at 2.5, 5, and 10 wt.% LiTf systems were investigated. The ChCl/1,4-BD at 1:1 ratio (DES1:1) recorded the highest ionic conductivity of 2.41 mS cm^{-1}, which resulted from the least amount of hydrogen bonds between ChCl and 1,4-BD. Subsequently, the DES1:1 was doped with different percentages of LiTf. The highest ionic conductivity, 2.56 mS cm^{-1}, was obtained from the ChCl/1,4-BD/2.5 wt.% LiTf system. The elevated ionic conductivity was attributable to the high amount of mobile lithium ions available due to fewer hydrogen bonds formed between the ChCl/1,4-BD and LiTf. Conclusively, the highly conducting ChCl/1,4-BD/2.5 wt.% LiTf demonstrated the best potential for application in lithium-ion batteries.

Keywords: deep eutectic solvents, liquid electrolytes, lithium salts, ionic conductivity

Abstrak

Penggunaan elektrolit yang mudah meruap dan terbakar dalam bateri ion litium merupakan isu utama di seluruh dunia. Oleh itu, elektrolit yang berprestasi tinggi dengan pendekatan yang lebih selamat diperlukan bagi menyelesaikan isu ini. Dalam keadaan ini, pelarut eutektik dalam (DES) dilihat sebagai alternatif terbaik untuk menggantikan cecair elektrolit konvensional yang berbahaya. Kajian ini meneroka potensi DES ternari yang terdiri daripada kolina klorida (ChCl), 1,4-butanadiol (1,4-BD) dan litium triflat (LiTf) sebagai elektrolit hijau dalam bateri ion litium. Struktur dan kekonduksian bagi sistem dengan 1:1, 1:2; dan 1:3 nisbah mol ChCl/1,4-BD dan ChCl/1,4-BD/LiTf dengan 2.5, 5, 10 wt.% LiTf telah dikaji. Sistem ChCl/1,4-BD dengan 1:1 nisbah mol (DES1:1) telah menunjukkan kekonduksian ionik paling tinggi, iaitu 2.41 mS cm^{-1}, yang terhasil daripada interaksi ikatan hidrogen yang rendah antara ChCl dengan 1,4-BD. Seterusnya, DES1:1 telah ditambah dengan LiTf pada peratusan yang berbeza.

Kekonduksian ionik yang tertinggi, iaitu 2.56 mS cm^{-1}, telah diperoleh sistem ChCl/1,4-BD/2.5 wt.% LiTf. Kekonduksian yang tinggi ini disumbangkan oleh kehadiran ion litium bebas yang tinggi hasil daripada kurang interaksi ikatan hidrogen antara ChCl/1,4-BD dengan LiTf. Kesimpulannya, ChCl/1,4-BD/2.5 wt.% LiTf dengan kekonduksian yang tinggi menunjukkan potensi terbaik untuk digunakan dalam bateri ion litium.

Introduction

The rapid increase in the world population and economic power has escalated energy demand. Accordingly, exceptionally efficient, stable, and ecologically benign energy storage systems are highly desired. Lithium-ion batteries are one of the most widely studied devices for energy storage as they possess great energy density and thermal stability and are less expensive than other types of batteries [1, 2]. Moreover, the application of lithium-ion batteries is not limited to mobile phones, they are also employed in medical and aerospace instruments [3]. Nevertheless, the conventional liquid electrolytes of lithium-ion batteries comprise flammable and volatile organic solvents [4] that result in issues such as leakages, corrosion, and even explosions.

The utilization of ionic liquids (IL)-based liquid electrolytes has been extensively investigated [4, 5]. The IL provides superior safety attributes to liquid electrolytes as it possesses distinctive physical properties, such as non-flammable, low melting point and volatility, and high thermal stability [6]. Nonetheless, deep eutectic solvents (DES) have been reported to exhibit more desirable properties, including cost-effectiveness, high biodegradability, and very low toxicity, despite sharing similar physicochemical properties with IL (non-flammable, low volatility, high thermal stability) [4, 7].

The DES is obtainable from the self-association of hydrogen bond acceptor (HBA) and hydrogen bond donor (HBD) via a simple heating technique [8]. Consequently, its biodegradability is contributed by their natural HBA (choline chloride (ChCl), phosphonium salts) and HBD (carboxylic acid, urea, renewable polyols, amines, amides, carbohydrates) contents. The DES consisted of N-methylacetamide (MAc) and different lithium salts (lithium bis[(trifluoromethyl)sulfonyl]) imide (LiTFSI) and lithium hexafluorophosphate ($LiPF_6$) has been reported as potential electrolytes for lithium-ion batteries. Nevertheless, liquid-state-electrolytes were not obtainable when the Li molar fraction was over 0.35, hence limiting the ionic conductivity to only 1 mS cm^{-1} [9]. The finding led to the development of ternary DES, such as ChCl/ethylene glycol/$LiPF_6$, that remains in a liquid state even at a 0.5 Li molar fraction, hence bearing higher ionic conductivity of 7.95 mS cm^{-1}. Nonetheless, the $LiPF_6$ exhibited low thermal decomposition temperature [10,11], thus deteriorating when subjected to high temperatures.

The lithium triflate (LiTf) has been demonstrated to possess higher thermal stability than $LiPF_6$ [11]. Consequently, the current study investigated a DES ternary system comprising a choline chloride (ChCl), 1,4-butanediol (1,4-BD), and LiTf mixture. The most optimum ChCl to1,4-BD mole ratio (1:1, 1:2; or 1:3) as the solvent for LiTf was first investigated. The study then doped the ChCl/1,4-BD with different weight percentages of LiTf (2.5, 5, and 10 wt.%). The structural and conductivity assessments of the systems were conducted with Fourier Transform Infrared Spectroscopy (FTIR) and conductivity meter, respectively.

Materials and Methods

Preparation of DES

The chemical components DES, 99% ChCl (Acros Organic), > 99% 1,4-butanediol (Sigma), and 99% LiTf (Sigma) were employed in the present study without further purification. Three ChCl/1,4-BD mixtures at 1:1, 1:2, and 1:3 mole ratios, labelled as DES1:1, DES1:2, and DES1:3, respectively, were mixed and heated at 80℃ while stirring until dissolution. Subsequently, LiTf with different weight percentages, 2.5, 5, and 10 wt.%, were dissolved in the highest conducting ChCl/1,4-BD while stirring and were designated as LE2.5, LE5, and

LE10, respectively. All the samples were kept in a desiccator before being characterized.

Fourier Transform Infrared Spectroscopy

The FTIR spectra of the samples evaluated in this study were recorded with a Perkin Elmer spectroscope at room temperature. First, the samples were dropped directly onto the crystal before measurements were obtained under the transmittance mode over the 4000-600 cm^{-1} frequency range with 4 cm^{-1} resolutions and 16 scans. Peak deconvolution was carried out with the Origin 8.1 software, in which the Gaussian function was employed to resolve overlapping bands. Prior to the deconvolution process, baseline corrections were conducted.

Conductivity meter

A conductivity meter (HANNA Instruments) was utilized to measure the ionic conductivities of the samples in the current study. The samples were placed in 50 ml beakers and the conductivity meter was dipped into each solution. The assessment was performed at room temperature and the ionic conductivities were recorded three times for each sample.

Result and Discussion

Preparation of the ChCl/1,4-BD mixture

The present study successfully obtained the homogenous liquid mixtures of ChCl/1,4-BD at varying mole ratios. Furthermore, the mixtures remained in their liquid conditions even at room temperature.

Structural analyses of the ChCl/1,4-BD

Figure 1 displays the FTIR spectra for the ChCl, 1,4-BD and the ChCl/1,4-BD mixtures at different mole ratios. The FTIR peaks representing ChCl were observed at 3222, 1480, and 1349 cm^{-1} due to OH stretching and CH_2 and CH_3 bending, respectively [12]. The FTIR spectra of the 1,4-BD appeared at 3292, 1169, and 1428 cm^{-1}, which denoted the O-H and C-O stretching and CH_2 bending, respectively [13]. The O-H stretching peak of the 1,4-BD also shifted to a higher wavenumber, from 3292 to 3297, 3298, and 3293 cm^{-1}, in the DES1:1, DES1:2 and DES1:3 samples, respectively. The observations confirmed the hydrogen bonding interactions between ChCl and 1,4-BD in the binary DES obtained. The peak intensities of the solutions were also reduced.

The decrease in the peak intensity of O-H stretching with the increasing amount of 1,4-BD indicated the diminished free O-H stretching in the system. The phenomenon might be due to the formation of hydrogen bonding interactions between the O-H···O-H and O-H···Cl in the ChCl/1,4-BD mixtures, as illustrated in Figure 2. The interaction between ChCl and 1,4-BD could also be further confirmed by the upshift in the CH_2 bending of 1,4-BD from 1428 to 1441, 1442, and 1448 cm^{-1} in the DES1:1, DES1:2, and DES1:3, respectively. The trends observed in this study agreed with a previous investigation on the formation of citric acid monohydrate-ChCl based DES [12].

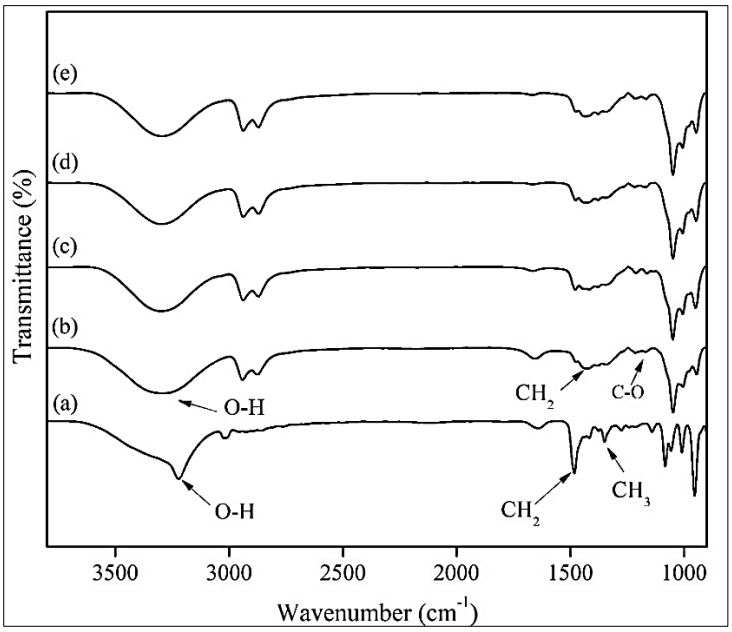

Figure 1. The FTIR spectra of (a) ChCl, (b) 1,4-BD, (c) DES1:1, (d) DES1:2, and (e) DES1:3

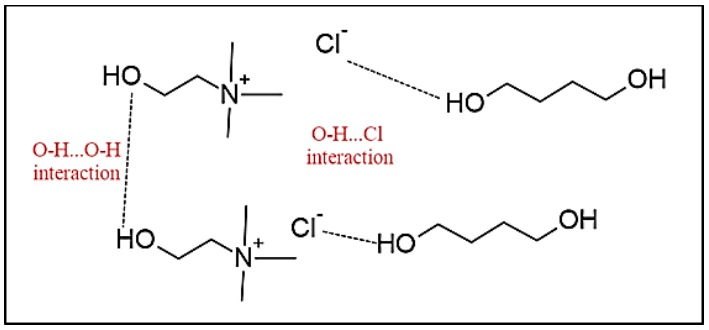

Figure 2. The possible hydrogen bonding interactions in ChCl/1,4-BD

Wang and co-workers [14] reported that the amount of hydrogen bonding interactions in ChCl-polyol DES could be further confirmed by the deconvolution and band-fitting of the broad O-H stretching peak between the 3700–3100 cm^{-1} region. Accordingly, the deconvolution and band fitting of DES1:1, DES1:2, and DES1:3 samples were conducted and is illustrated in Figure 3. Three types of O-H peaks were present at ~3400, ~3300, and ~3200 cm^{-1}, which corresponded to the free O-H stretching and inter- and intramolecular O-H⋯O-H and O-H⋯Cl stretching, respectively. As the amount of 1,4-BD increased, the amount of free O-H stretching decreased. The observations were due to the elevated inter- and intramolecular O-H⋯O-H and O-H⋯Cl interactions in the ChCl/1,4-BD mixtures.

Conductivity assessments of the ChCl/1,4-BD

Table 1 lists the ionic conductivity values of the varying mole ratios of ChCl/1,4BD produced in the current study. The highest ionic conductivity, 2.41 mS cm^{-1}, was recorded by the DES1:1, however, the value decreased with higher 1,4-BD in the DES1:2 and DES1:3 systems. The observations resulted from elevated hydrogen bonds confirmed in the FTIR analysis. Furthermore, the presence of an excessive amount of 1,4-BD alkyl chain in the ChCl/1,4-BD mixture might also contribute to the diminished ionic conductivity of the samples.

The HBD alkyl chain structure has been reported to affect the ionic conductivity of DES [6]. As the amount of 1,4-BD was increased, an excessive amount of alkyl chain was produced in the ChCl/1,4-BD system, resulting in higher van der Waals interactions within the ChCl/1,4-BD. Consequently, the mobility of the ions was lowered, hence decreasing the ionic conductivity of the system. Similar observations were reported by Zhang and co-workers [5].

The ionic conductivity values of the DES1:1 was slightly higher if compared to other DES systems such as ChCl/EG (1.79 mS cm^{-1}) [15] and TBABr/EG (0.53 mS cm^{-1}) [6]. The findings were attributable to the non-excessive hydrogen bonds formed between HBA and HBD, which would ease the movement of lithium ions. Hence, the ChCl/1,4-BD at a 1:1 mole ratio was the optimal solvent selection for dissolving LiTf in the present study.

Table 1. The ionic conductivities of the ChCl/1,4BD systems

System	Ionic conductivity (Mean ± SD, mS cm^{-1})
DES1:1	2.41 ± 0.27
DES1:2	1.34 ± 0.44
DES1:3	0.92 ± 0.12

Preparation of the ChCl/1,4-BD/LiTf

In the current study, homogenous liquid mixtures of ChCl/1,4-BD/LiTf with different LiTf weight percentages were successfully obtained. Furthermore, the mixtures remained as liquids even at room temperature.

Structural evaluations of the ChCl/1,4-BD/LiTf

Figure 4 demonstrates the FTIR spectra for the DES1:1 with LiTf LE2.5, LE5, and LE10. The SO_3 and CF_3 stretching peaks were recorded at 1265 and 1182 cm^{-1}, respectively, for pure LiTf. Upon incorporation of LiTf into the ChCl/1,4-BD system, the SO_3 and CF_3 stretching peaks of LiTf were observed, hence confirming the miscibility of LiTf in ChCl/1,4-BD [16]. The O-H stretching peaks of the DES1:1 shifted to higher wavenumbers, from 3297 to 3303, 3301, and 3335 cm^{-1}, respectively, in the LE2.5, LE5, and LE10 systems. Moreover, the peak intensities were diminished.

Meanwhile, the peak intensities of the SO_3 and CF_3 stretching of LiTf were recorded to increase with higher amounts of LiTf. The findings indicated that interactions between the LiTf anions and the hydrogen from the DES hydroxyl groups occurred, as demonstrated in Figure 5. Furthermore, the decreased peak intensity of the OH stretching in the samples indicated that more hydrogen bonding between the LiTf and ChCl/I,4-BD transpired as the percentage of the LiTf added was increased. Dhingra and co-workers also reported similar results in the study of ChCl/urea/lithium chloride DES [4].

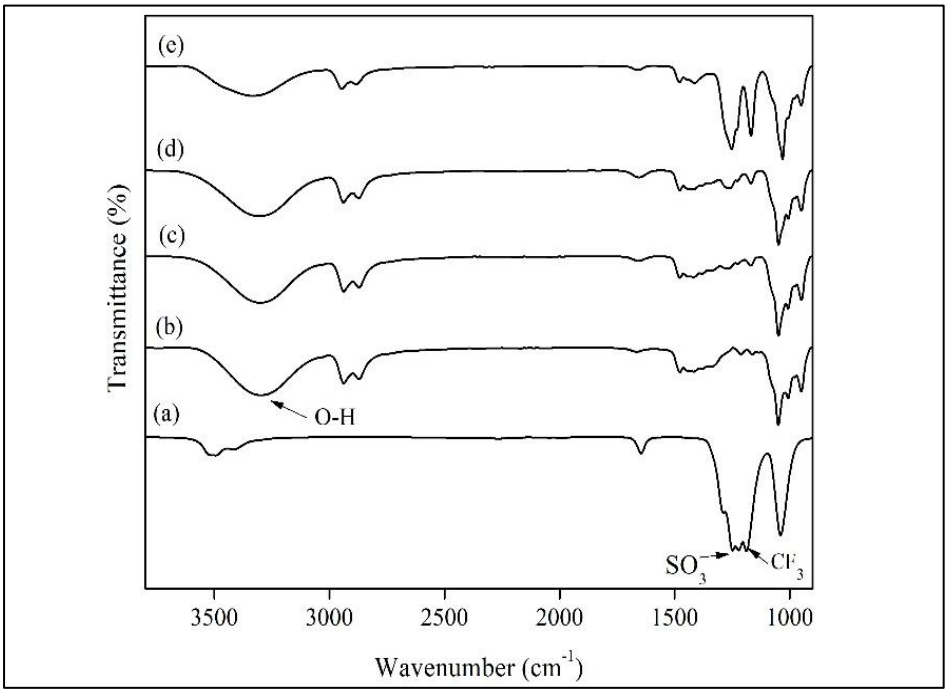

Figure 4. The FTIR spectra of the (a) LiTf, (b) DES1:1, (c) LE2.5, (d) LE5, and (e) LE10

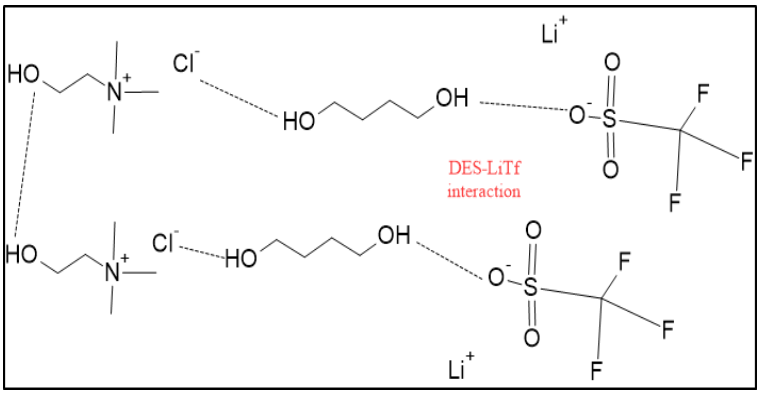

Figure 5. Possible hydrogen bonding interactions in the ChCl/1,4-BD/LiTf samples

Conductivity studies of the ChCl/1,4-BD/LiTf

Table 2 lists the ionic conductivity of the ChCl/1,4-BD/LiTf systems manufactured in the present study. The conductivity of the system increased from 2.41 to 2.56 mS cm^{-1} as 2.5 wt.% of LiTf was added into the ChCl/1,4-BD. The ionic conductivity increment was attributable to the free mobility of the lithium ions in the DES mixtures, which resulted from the formation of hydrogen bonds between the anions in the salt and DES that was confirmed with FTIR.

The amount of mobile lithium ions has been demonstrated to affect the ionic conductivity of DES systems [16]. Nevertheless, as the addition of LiTf in the current study was increased to 5 and 10 wt.%, the conductivity reduced to 1.84 mS cm^{-1} and 0.65 mS cm^{-1}, respectively. The observations might be due to the formation of more hydrogen bonds that eventually prevented lithium ions from moving freely. Nonetheless, the highest conductivity value obtained in the present study was comparable to other ternary DES systems comprising EG/ChCl/ $LiPF_6$ (7.95 mS cm^{-1}) [7].

Table 2. Ionic Conductivity for ChCl/1,4-BD/LiTf System

System	Ionic conductivity (Mean ± SD, mS cm^{-1})
LE2.5	2.56 ± 0.12
LE5	1.84 ± 0.26
LE10	0.65 ± 0.17

Conclusion

An increased 1,4-BD amount would lead to more hydrogen bonding formation, hence reducing the free mobility of ions and conductivity of ChCl/1,4BD systems. In the present study, the optimal ChCl/1,4-BD to dissolve LiTf was recorded at a 1:1 mole ratio as the solution contained non-excessive hydrogen bonds, thus easing lithium-ion movements. Moreover, adding 2.5 wt.% of LiTf to the ChCl/1,4-BD mixture resulted in the highest number of mobile ions, contributing to its conductivity, 2.56 mS cm^{-1}, which was the highest. Conclusively, ternary DES consisting of a 1:1 mole ratio of ChCl/1,4-BD and 2.5% LiTf exhibited the optimal potential of being applied in lithium-ion batteries.

Abstract

Durian (*Durio zibethinus*) is one of the most notorious fruits in the world, especially in Southeast Asian countries. It is well-known as the "King of Fruits" due to its rich flavour and large size. The unique taste of durian has created its own global demand, which continues to increase despite its unpleasant odour. However, only one-third of the entire durian is consumable, while the seeds and husks are ordinarily disposed of as waste. The seed waste can be potentially converted into value-added products such as seed gum. The high content of carbohydrates and starch in the seeds makes them suitable for use as biopolymers. A natural hydrocolloid can be obtained from durian seeds through a chemical extraction process. This review provides an overview of the effects of different extraction parameters on the physicochemical and functional properties of durian seed gum and discusses the potential application of durian seeds as a food gum. The physical and chemical properties of durian seed gum highly depend on the further extraction parameters and processing of the gum. The findings showed that the soaking process has a greater impact on the quality of the gum produced compared to the concentration of acid used in terms of solubility and water-holding capacity. The physicochemical properties of durian seed gum are comparable to those of commercial food gum, but its anti-nutrient content and sensory evaluation in food products must be further investigated to ensure its safety before consumption.

Keywords: seed waste, chemical extraction, durian seed gum, physicochemical properties

Abstrak

Durian (*Durio zibethinus*) adalah salah satu buah-buahan yang terkenal di negara-negara Asia Tenggara. Durian dikenali sebagai "Raja Buah" kerana ciri-cirinya yang kaya dengan rasa dan mempunyai saiz yang besar. Keenakan dan rasanya yang unik menyebabkan durian telah meraih permintaan yang tinggi di peringkat global walaupun mempunyai bau yang kurang menyenangkan. Walau bagaimanapun, hanya satu pertiga daripada keseluruhan buah durian yang dapat dimakan, iaitu bahagian isinya, manakala biji dan kulitnya biasanya dibuang sebagai sisa kerana dipercayai tiada nilai komersial. Biji durian berpotensi tinggi untuk diolah menjadi produk nilai tambah seperti gam makanan kerana mengandungi karbohidrat dan kanji yang tinggi. Objektif kajian ini adalah untuk menilai pengaruh perbezaan parameter pengekstrakan terhadap sifat fiziko-kimia serta fungsi gam biji durian dan menilai potensi penggunaan biji durian sebagai penstabil makanan. Ciri-ciri fizikal dan kimia gam biji durian bergantung pada parameter pengekstrakan dan pemprosesan yang lebih lanjut. Hasil kajian menunjukkan bahawa proses rendaman mempunyai kesan yang lebih besar terhadap kualiti gam yang dihasilkan dibandingkan dengan kepekatan asid yang digunakan dari segi kelarutan dan kapasiti pengekalan air. Ciri-ciri fiziko-kimia gam biji durian adalah setanding dengan gam makanan yang terdapat di pasaran, tetapi kandungan anti-nutrien dan penilaian berderia dalam produk makanan perlu dikaji dengan lebih mendalam untuk memastikan keselamatannya sebelum digunakan dalam pemakanan.

Kata kunci: sisa biji benih, pengekstrakan kimia, gam biji durian, sifat fizikokimia

Introduction

Durian (*Durio zibethinus*) belongs to the Bombacaceae family and is the most popular seasonal fruit in Southeast Asia, especially Thailand, Malaysia, the Philippines, and Indonesia. In 2019, the national production of durian increased tremendously due to its great demand on the global stage, such as China, Vietnam, Singapore, and the United States [1]. During the breakdown of the COVID-19 pandemic, between March and May 2020, the reported sales of durian in Malaysia had reached one tonne per day [2]. However, only one-third of the entire durian is consumable, while the seeds (20–25%) and the husk are ordinarily disposed of. For example, the Philippines, a country in Southeast Asia, faces a problem with the large amount of durian waste produced every year. According to Ana et al., about 40% of durian husks, including 25% of durian seeds (21,880), are considered waste in the Philippines annually [3]. Furthermore, in the first half of 2018, around 4000 tonnes of durian seeds were discarded in Singapore [4]. Subsequently, extensive research has been conducted on the growth of value-added products to reduce the wastage from the inconsumable part of durian. Mirhosseini and Amid stated that the unused durian seeds have great potential to be produced as value-added goods, such as flour and stabilisers, as they contain a high amount of carbohydrates, fibre, and vitamins [5].

Generally, durian seed gum can be obtained through a chemical extraction process as it produces a higher quality of gum compared to the aqueous extraction process. This is because the aqueous extraction process produces gum with a higher moisture content, which indirectly affects the shelf life of the gum produced. The difference in extraction parameters, such as soaking time, soaking temperature, and decolourisation time, was reported to have affected the physicochemical properties of the gum produced. Meanwhile, purification methods also affect the functional characteristics of durian seed gum [6]. Although there has been plenty of research conducted globally on the production and application of durian seed gum, much improvement is still required for a larger yield and better properties of the gum.

Based on current knowledge, the effects of acetic acid concentration and soaking time on the physicochemical properties of durian seed gum have not been fully investigated. Therefore, the present study aims to review the effects of acetic acid concentration and soaking time, especially on the physicochemical and functional properties of durian seed gum, and to explore the potential application of durian seeds as food gum. This study also intends to provide an overview and future perspective on the use of durian seeds in resolving the global food waste issue faced by Asian countries over the years. Converting food waste into useful products not only helps to reduce agricultural waste, but also helps to minimise environmental pollution [7].

Overview of food gum

Food gum, also referred to as natural hydrocolloid, is commonly used in food manufacturing as thickeners, gelling agents, stabilisers, coating agents, and packaging film. Gum is a complex polysaccharide that can be obtained from various sources, such as seaweed extract (e.g., agar), the endosperm of plant seeds (e.g., guar gum), and bacteria (e.g., xanthan gum). According to Clemens and Pressman, food gum consists of carbohydrates with a large number of hydroxyl groups, resulting in hydrophilic characteristics [8]. Therefore, food gums are highly water-soluble due to their polymers that form a cross-linked network by trapping and immobilising water in a viscoelastic, flow-resistant structure. One of the common functional properties of hydrocolloid is their thickening properties, which determine the viscosity of the gum produced. According to Phillips and Williams, the viscosity of the gum is significantly influenced by the molecular mass of the polymer [9]. The higher the molecular mass, the more viscous the gum produced. The next functional properties of food gum are emulsification properties. Golkar et al. reported that the emulsification properties of food gum are affected by its interfacial activity, which stabilises and forms oil droplets in emulsions [10].

Other functional properties of food gum are hydration and solubilisation. All polysaccharides have sections in their solid state where the chain segments or molecules are disordered and unorganised. As a result, these amorphous regions have a large number of unfulfilled hydrogen bonding spots that can easily hydrate [9]. Polysaccharides that are entirely dry have a slow but extremely significant affinity for water. When a soluble polysaccharide is immersed in water, the numerous water molecules directly enter amorphous regions and attach to accessible polymer sites. Subsequently, the number of other inter-polysaccharide linkages can be minimised. The inter-polysaccharide bonds are broken down by kinetic action and result in the full solubility of the polysaccharide chain.

Generally, polysaccharides can be found in four common structures: linear, single-branch, substituted linear, and branch-on-branch [1]. Figure 1 shows the different types of polysaccharide polymer structures. Glicksman stated that the solution of branched polysaccharides is more stable than the solution of a linear molecule [1]. The solution with branched molecules remains homogenous for a long period of time due to its high affinity for water and good adhesive properties. Durian seed gum exemplifies good adhesive properties as it is composed of branched molecules [5].

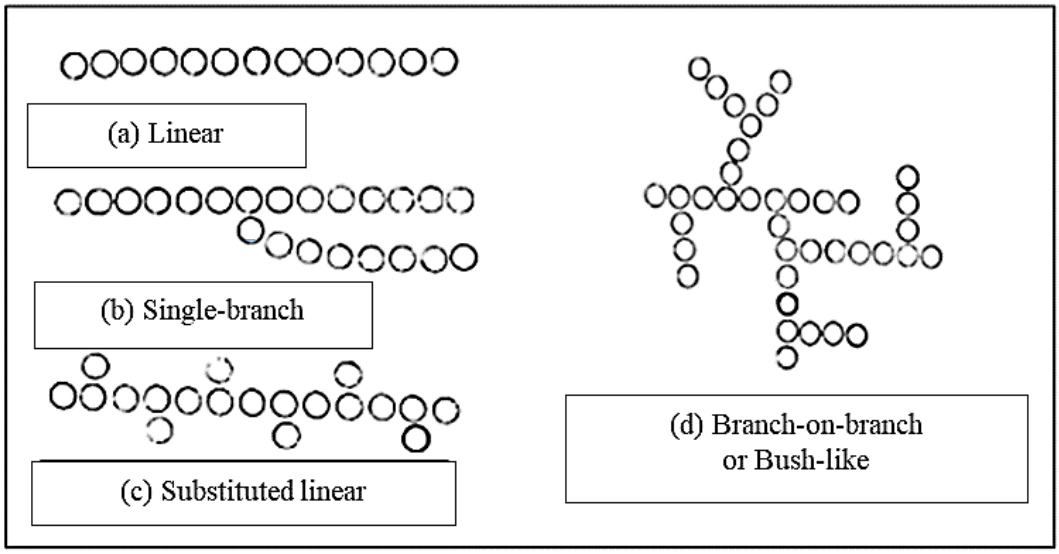

Figure 1. The types of polysaccharide polymer structures [1]

Potential application of durian seeds as food gum

The durian seed contains a high level of polysaccharides suitable for being used as gum for thickening and gelling properties [11]. The protein content of durian seeds is estimated to be 3.40%, the moisture content to be 54.90%, the starch content to be 18.92%, and the fat content to be 1.32% [12]. Amin et al. studied the composition of durian seed gum for the dehulled and whole durian seed flour. The study found that the entire durian seed flour contains 6.0% protein, 0.4% fat, 3.1% ash, 10.1% crude fibre, 73.9% carbohydrates, and 6.0% water [13]. Meanwhile, dehulled durian seed flour contains 0.4% fat, 3.8% ash, 7.6% protein, 4.8% crude fibre, 76.8% carbohydrates, and 6.6% water. The high carbohydrate content in both types of durian seed flour makes them suitable to undergo further processing due to their excellent thickening properties. Amin et al. stated that the durian seed gum is stable at pH levels between 2.0 and 10.0. This pH is similar to the pH of xanthan gum (2.0 to 12.0) and further supports their application in a wide range of products [13].

In addition to this, the three primary sugars in durian seed gum are rhamnose, D-galactose, and glucose. Amin et al. found that the ratio of these sugars (i.e., glucose, rhamnose, and D-galactose) is 9:3:1, respectively [13]. The primary component in the formation of gum in durian seeds is L-rhamnose, which is also known as C-5 polysaccharide. When rhamnose sugar comes into contact with water, polysaccharides form a structure to prevent water molecules from joining. As a result, a thicker gel is formed after the detraction of water molecules by C-5 polysaccharide [14]. Therefore, the presence of sugar in the polysaccharide is important in enhancing the rheological properties of the gum, which are dependent on the soaking and purification process [15]. Moreover, the durian seed gum is comparable to guar gum in terms of colour, solubility, water, and oil-holding capacity [2]. The study revealed that the solubility of durian seed gum is higher than that of guar gum due to its active interaction between protein and monosaccharide fractions. Apparently, the colour of durian seed gum is slightly darker compared to the colour of guar gum (Figure 2), but it is acceptable.

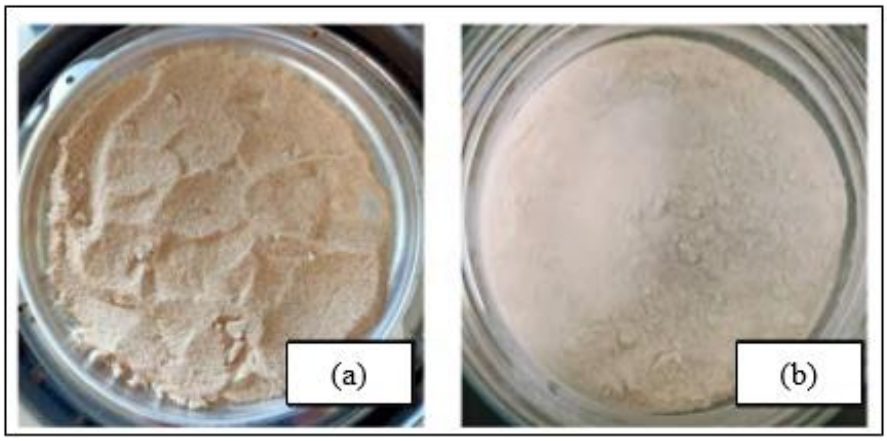

Figure 2. (a) Durian seed gum; (b) guar gum [2]

In another study, Cornelia et al. described that the use of durian seed gum as an emulsifier in vegan mayonnaise results in the same texture as commercial vegan mayonnaise [11]. Furthermore, there is no significant cream helps to improve the consistency and texture of the ice cream. This is proven when the overrun of the ice cream at a low concentration (0.1%) of durian seed gum difference in terms of aroma in vegan mayonnaise made from durian seed gum. The application of durian seed gum in ice cream was investigated by Sawasdikarn et al. and found that the use of durian seed gum in sherbet ice was higher (30.26%) compared to the overrun of ice cream without any durian seed gum (25.36%) [16].

Effects of extraction parameters on the properties of durian seed gum

The processing steps involved in producing durian seed gum include extraction and purification phases. As shown in Table 1, different researchers have used different ranges of extraction parameters (soaking time, soaking temperature, decolouring time, and concentration of acid and pH). Sompie et al. reported that prolonging the soaking time in the presence of heat during the extraction process opens up the bonds of gelation molecules, thus resulting in a higher yield [17]. This finding is supported by Veira et al. that a temperature of 60°C produced a high yield of flaxseed gum [18].

Besides that, the hydration properties of the gum also depend on the water-holding capacity (WHC), solubility, and swelling capacity [5]. The interaction of soaking time and soaking temperature represents the most significant effect on the WHC of the gum as compared to the decolourisation process. The WHC of gum is determined by the conformational structure, pore size, and capillary of the molecule that are associated with the hydration molecule with polar compound and hydrophilic interaction [19]. According to Mirhosseini and Amid, gum extracted below 85°C with an alkaline pH has a higher WHC [6]. Besides, the interaction of soaking time and soaking temperature represents the most significant effect on the WHC of the gum compared to the decolourisation process. This is because the swelling properties of the gum generally depend on the ratio between the solvent and matrix, soaking time, and soaking temperature. The longer soaking time results in lower WHC properties because it has a poor affinity for absorbing water. Therefore, a shorter soaking process is required as it leads to a smaller pore size of the gum and thus increases the WHC. In contrast to the WHC, the lower soaking temperature and longer decolourisation produce a gum with a higher oil-holding capacity (OHC). High OHC is associated with a hydrophobic character and the presence of non-polar amino acids. According to Mirhosseini and Amid, purified gum has lower OHC than crude gum due to the presence of hydrophobic fractions and non-polar side chains in the crude durian seed gum that may bind the hydrocarbon units of oil [6].

Generally, gum exhibits high solubility and relatively low viscosity. Sompie et al. reported that the presence of heat during the soaking process may help in forming gum with higher viscosity properties, but eventually reduces them at higher temperatures [17]. According to Viera et al., the soaking process at 60 °C is sufficient to produce gum with a high viscosity. This is because the heat opens up the bonds between molecules and free-flowing liquids that are initially trapped inside the structure, thus forming a viscous gel [18].

Besides that, the solubility of a polymer in a solution depends on the size and weight of molecules as well as the concentration of the polymer in the solution. A study found that gum soaked for 4 to 8 hours has low solubility properties [5], but the finding is contradictory. A study conducted by Akdowa et al. found that the gum undergoes a one-to-three-hour soaking process to have better solubility properties [20], while the study by Batal and Hasib reported that one hour of the soaking process is sufficient to produce gum with high solubility properties [21]. The study found that the longer the soaking process, the larger the particle size of gum. Figure 3 shows a simple illustration of the effects of soaking time on the particle size of gum produced. A shorter soaking process results in a smaller particle size due to the lower absorption of insoluble matter into the final extract.

According to Mirhosseini and Amid, gum with high impurities and larger molecules has lower solubility properties [5]. This is because coarser and larger particles require a longer time to be dissolved due to the longer time required to penetrate water into the sample matrix. Therefore, the soaking time is crucial in producing a high-quality durian seed gum as it helps to reduce the protein content, ash content, and insoluble impurities. Generally, a shorter soaking process is preferable as it results in the presence of small gum particles and better solubility of gum.

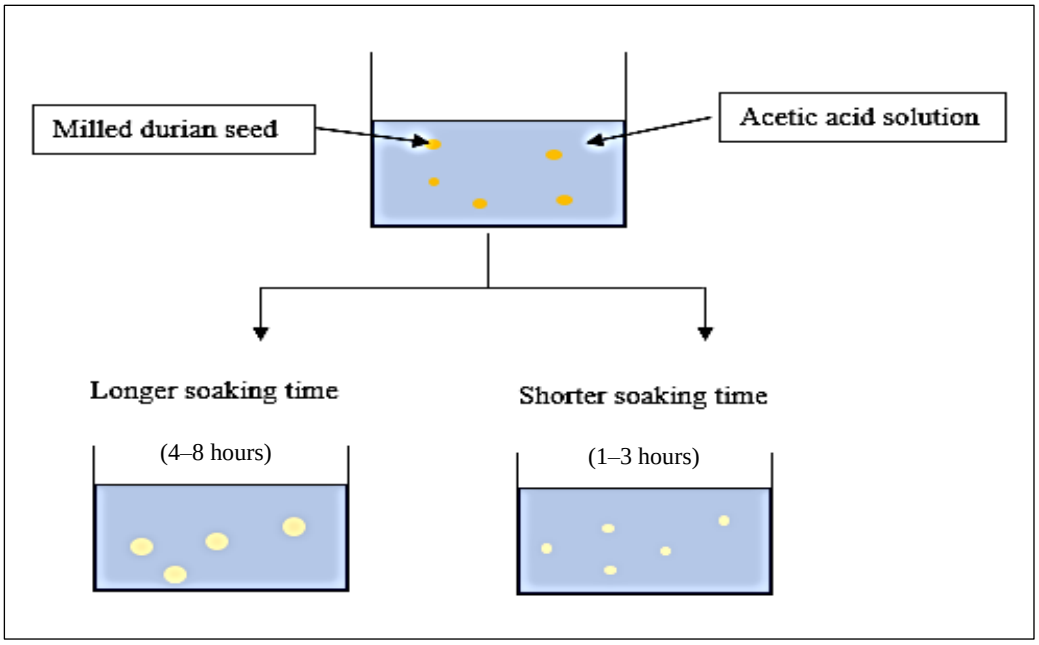

Figure 3. Illustration on the effects of soaking time on the particle size of gum produced

Apart from that, protein content in gum is also a known factor in affecting the purity of the gum. Gum with large amounts of protein is more flexible and has good adsorption capacity at the interface. Therefore, the protein content of the gum is highly critical toward achieving a good emulsifier property. According to Sompie et al., the acid concentration used during extraction influences the protein content of the gum produced [17]. The study showed that 4% of acid is good for producing gum with excellent emulsifying properties. Meanwhile, a high concentration of acid used reduces the viscosity of the gum due to the destruction of protein structures (hydrolysation of the peptide bond). Another work by Akdowa et al., which employed 1% of acetic acid, was also able to produce viscous gum coupled with a proper soaking process during the chemical extraction [20]. The suitable range of acetic acid concentration is between 1% and 4%, because at these concentrations, the peptide bond in the molecules cannot be broken down. Thus, high viscosity gum can be produced. However, a 1% concentration of acetic acid is preferable as it is less acidic and toxic.

Table 1. Different ranges of extraction parameters for durian seed gum.

Ref.	Parameters					Findings / Properties of Gum Obtained
	Temperature (℃)	Soaking Time (hr)	Decolouring Time (hr)	Concentration of Acid (%)	pH	
[5]	25℃ – 55℃	4 hrs – 8 hrs	1 hr – 3 hrs	1%	N/A	• Low solubility and WHC properties • Soaking time should be considered as the most critical extraction variable
[17]	50℃ – 60℃	N/A	N/A	2% – 6%	N/A	• Strong gel strength • Higher concentration causes a decrease in viscosity • Optimum condition: 4% of acetic acid at 55℃
[20]	N/A	1 hr – 3 hrs	N/A	1%	4 – 10	• Good solubility properties • Optimum condition: 1 hour; pH 7
[21]	70℃ – 100℃	20 mins – 60 mins	N/A	1%	N/A	• Maximum yield of gum • Optimum condition: 95℃ for 60 minutes

Challenges of durian seeds as food gum

Despite the merits of durian seeds as food gum, some challenges still arise. First, the amount of anti-nutrients in durian-derived seed gum is higher compared to that of other types of gum. According to Marina et al., the amount of anti-nutrients such as tannins, saponins, phytates, and oxalates was 232.19±4.92 mg/100g, 60.22±1.27 mg/100g, 181.32±4.46 mg/100g, and 105.55±13.07 mg/100g, respectively, after the durian seed underwent the boiling process [22]. These values were much higher than the amounts found in acacia seeds and karaya (3.0 mg/100g and 3.5 mg/100g) [4].

Next, food products require more durian seed gum than other commercial gums. For example, vegan mayonnaise requires at least 4% of durian seed gum to achieve a preferable texture [11]. Apart from that, additional usage of other commercial gums such as Arabic gum or xanthan gum is required if the concentration of durian seed gum used is lower than 4%. As a result, if manufacturers are forced to double or triple the quantities of stabilisers used in their products, production costs may rise. Besides that, research on the sensory properties of food using durian seed gum is less reported and lacking. To date, there have only been two available studies that focused on mayonnaise [11] and ice cream [16]. Inadequate sources of information are a limitation for further studies on the application of durian seed gum as a potential food ingredient.

Finally, the nature of the durian's growth, which belongs to the seasonal fruit category, might be a drawback to its continuous production. Commonly, the fruiting season of durian in Malaysia is from June to July. In order to ensure the availability of durian seed gum, the seeds must be handled with extra care during the fruiting season. Improper storage of the seeds may result in the loss of viability, which may reduce their moisture content and their overall quality [23].

Conclusion

To sum up, the soaking process has a significant impact on the properties of durian seed gum compared to the concentration of acid used during the extraction process. This is because the soaking time affects the quantity of impurities present in the gum and the particle size of the gum extracted, which have a direct impact on the solubility and water-holding capacity of the gum. Nevertheless, the selection of the extraction parameters depends on the purpose of the extracted gum. If the physicochemical and functional properties of the gum are targeted, a soaking time of 1 to 2 hours is sufficient. Meanwhile, a longer soaking time is needed if the gum yield is targeted. The ideal range of soaking temperatures is between 55°C and 95°C. Further research on anti-nutrient content and sensory evaluation of durian seed gum in food products is needed for safety purposes. It is also beneficial to analyse the nanoparticles of durian seed gum to improve its solubility, thus producing food gum of better quality.

Abstract

Dispersive micro-solid-phase extraction (D-µ-SPE) method using polypyrrole-graphene oxide (PPy-GO) nanocomposite sorbent has been developed for the extraction and pre-concentration of tetracycline antibiotics (TCs) residues, namely oxytetracycline (OTC), tetracycline (TC), chlortetracycline (CTC), demeclocycline (DMC) and doxycycline (DOC) in water samples prior to high-performance liquid chromatography-ultraviolet/diode array detector (HPLC-UV/DAD). The PPy-GO nanocomposite was prepared by *in situ* oxidative chemical polymerization. The effects of sample pH, a mass of sorbent, desorption solvent, extraction time and desorption time on the extraction of analytes were evaluated and optimized. Under the optimum conditions, the method demonstrated good linearity (R^2=0.9989-0.9995) over a concentration range of 10-1000 µg L^{-1}. The limit of detection (LOD) was in the range of 4.9-8.7 µg L^{-1} with satisfactory relative recoveries (80 – 105 %) and a good relative standard deviation (RSD) of ⩽ 2.3 % (n = 3) was obtained. The method was successfully applied to river water and tap water samples. Results obtained using the developed method were compared with results previously reported using other SPE-based methods.

Keywords: tetracycline antibiotics, PPy-GO, dispersive micro-solid-phase extraction, liquid chromatography, water samples

Abstrak

Kaedah pengekstrakan fasa-pepejal-mikro secara serakan (D-µ-SPE) menggunakan penjerap nanokomposit polipirol- grafin oksida (PPy-GO) telah dibangunkan untuk pengekstrakan dan pra-pemekatan sisa antibiotik tetrasiklin (TCs), iaitu oksitetrasiklin (OTC), tetrasiklin (TC), klortetrasiklin (CTC), demeklosiklin (DMC) dan doksisiklin (DOC) di dalam sampel air sebelum kromatografi cecair berprestasi tinggi-pengesan tatasusunan ultraungu/diod (HPLC-UV/DAD). Nanokomposit PPy-GO telah disediakan melalui pempolimeran oksidatif kimia *in situ*. Kesan pH sampel, jisim penjerap, pelarut nyahjerapan, masa pengekstrakan dan masa nyahjerapan pada pengekstrakan analit telah dinilai dan dioptimumkan. Di bawah keadaan optimum, kaedah menunjukkan kelinearan yang baik (R^2=0.9989-0.9995) dalam julat kepekatan 10-1000 µg L^{-1}. Had pengesanan (LOD) adalah dalam julat 4.9-8.7 µg L^{-1} dengan pemulihan relatif yang memuaskan (80-105%) dan sisihan piawai relatif (RSD) yang baik sebanyak ≤ 2.3% (n = 3) telah diperoleh. Kaedah tersebut berjaya diaplikasikan pada sampel air sungai dan air paip. Keputusan yang diperoleh menggunakan kaedah yang dibangunkan dibandingkan dengan keputusan yang dilaporkan sebelum ini menggunakan kaedah berasaskan SPE yang lain.

Kata kunci: antibiotik tetrasiklin, Ppy-GO, pengekstrakan fasa-pepejal-mikro secara dispersif, kromatografi cecair, sampel air

Introduction

The discovery of antibiotics in the 1940s has witnessed traditional medicine and herbal therapies being replaced by a more effective remedy for treating bacterial infections [1-2]. Since then, antibiotics have become essential in medicine and are critical components of the modern healthcare systems. Tetracycline, for example, is a group of broad-spectrum antibiotics active against several Gram-positive and Gram-negative bacteria [3]. Since their discovery, tetracycline antibiotics have played a prominent role in veterinary and human medicine, specifically for treating and preventing microbial infections and as additives in animal feed [4]. Although the role of antibiotics in fighting harmful bacteria cannot be neglected, the mishandling of antibiotics can adversely affect public health.

Tetracycline antibiotics (Figure 1) can be discharged from industrial production, animal foodstuff and human medicine into rivers and local groundwater [5]. The occurrence of these antibiotic residues in water samples in high concentrations will cause harmful effects on public health, including allergic reactions in humans, liver damage, accumulative toxicity, yellowing of teeth, the transfer of drug-resistant bacteria from food to humans, and gastrointestinal disturbance [6]. There is also growing concerned that antimicrobials are affecting water quality because they can accelerate the evolution of antimicrobial-resistant bacteria [7]. Hence, it is critical to develop reliable analytical methods for routine monitoring of tetracycline in the environment. The method should be rapid, precise, economical, less time-consuming, and environmentally friendly.

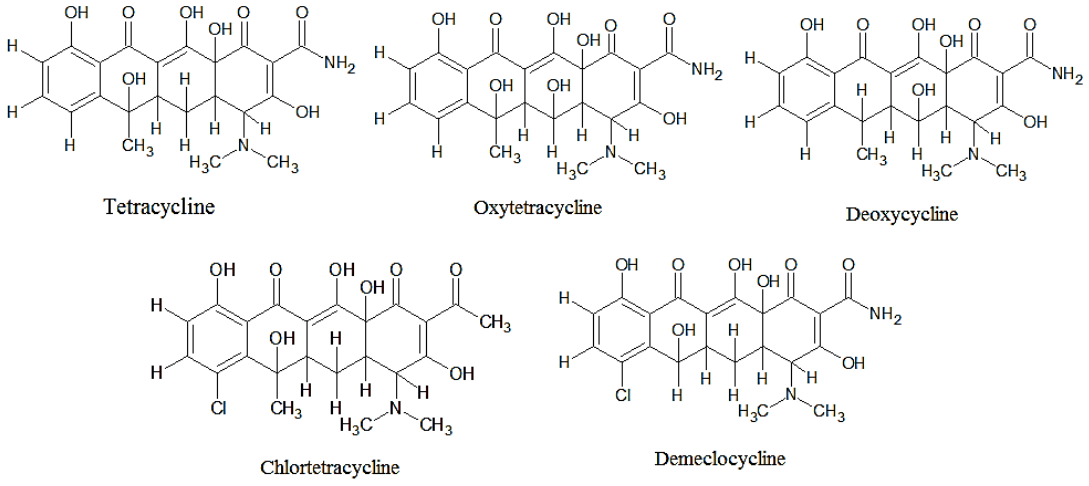

Figure 1. Chemical structure of some commonly used tetracycline antibiotics

In recent years, numerous analytical methods have been developed for the detection of tetracycline in complex environmental matrices such as swine wastewater and manure [8, 9], livestock tissues [10], milk [11], honey [12], and soils [13]. Several extraction techniques have been reported mainly for the extraction and pre-concentration of tetracycline antibiotics in aqueous matrices. These include solid-phase extraction (SPE) [14], solid-phase microextraction (SPME) [15], liquid-liquid extraction [16] and pressurized liquid extraction [17].

SPE is the most common sample isolation and pre-concentration technique for the extraction of pharmaceuticals, including tetracycline in water samples [18]. Yang et al. [19] developed an analytical method for the determination of 11 tetracyclines using solid-phase extraction and liquid chromatography-electrospray ionization tandem mass spectrometry in the influent and effluent of domestic wastewater. Dzomba et al. [20] have reported a comparative study of ultrasonic coupling to the modern SPE method, such as tandem solid-phase extraction (TSPE), dispersive solid-phase extraction (DSPE) and matrix solid-phase dispersion (MSPD) for the extraction of tetracycline in river water.

Trapping media in SPE have aroused increasing interest in research on sample preparation as they have a key role in obtaining high clean-up and enrichment efficiency for trace analysis in complex matrices. In recent years, there have been many successful works on the use of varieties of commercialized sorbent materials for an efficient SPE technique [21]. Apart from commercially available sorbents, researchers are devoted and have been passionate on developing new sorbents to enhance the extraction process. In the past few decades, various type of solid sorbent has been developed for the determination of environmental decontamination, including carbon-based [22], molecularly imprinted polymers [23], nano-fibres [24] and carbon nanotubes [25].

Graphene has been extensively employed in a wide range of applications since its discovery by Novoselov et al. in 2004 [26]. Graphene oxide performs well as sorbent, with high porosity, chemical stability, unique surface structure, large specific surface area and hydrophilicity due to its richness in oxygenated groups [27]. However, because they tend to agglomerate easily due to the strong Van der Waals interaction between molecules and have low selectivity, their usage as extraction sorbent is restricted [28]. To address the aforementioned issues, varieties of graphene-based composite materials have recently been developed. Polypyrrole-graphene oxide (Ppy-GO) composites have been utilized as supercapacitor electrodes and biosensors due to their remarkable electrical and optical properties [29-30]. Nonetheless, the efficacy of PPy-GO as sorbent has not been explored much, especially in the detection of pharmaceutical residues in complex matrices.

Hence, this research aimed to investigate the use of PPy-GO as a promising material for the determination of tetracycline antibiotics in water samples with the aid of D-μ-SPE, which is believed to be a simple, rapid, selective and efficient alternative method compared to the traditional SPE.

Materials and Methods

Chemicals and materials

Five (5) tetracycline antibiotics, namely oxytetracycline (OTC), tetracycline (TC), demeclocycline (DMC), chlortetracycline (CTC), and doxycycline (DC) with purity assay in range of 98-101% were purchased from Sigma-Aldrich. Acetonitrile (ACN), methanol (MeOH), formic acid (of HPLC grade), sodium hydroxide (NaOH) and hydrochloric acid (HCl) were purchased from Merck (Darmstadt, Germany). Pyrrole monomer and ferric chloride crystal ($FeCl_3.6H_2O$, 99.0%) were procured from Xian, China. Graphene oxide powder and methane sulfonic acid (MSA) were purchased from Sigma-Aldrich (St. Louis, USA). Ultrapure water was produced by Barnstead Nanopure (Thermo Scientific).

Preparation of standard and sample solutions

The individual stock solutions of OTC, TC, DMC, CTC, and DOC were prepared separately in HPLC grade methanol to a final concentration of 1000 mg L^{-1}. All standard solutions were stored in amber glass bottles at 4 °C when not in use. A series of working standard solutions were prepared in methanol by dilution before

analysis to prevent the decomposition of analytes. Tap water samples were collected from a laboratory in Universiti Teknologi MARA (UiTM) Shah Alam, Selangor, Malaysia, while river water samples were collected from Hulu Langat, Selangor, Malaysia. The collected samples were filtered through 0.45 µm nylon filter paper to remove any suspended particles. Samples were kept in polyethene bottles pre-cleaned with acetone and stored at 4 ºC prior to the analysis process. For accuracy and precision studies, the river and tap water samples (10 mL, pH 3) were spiked with the standard mixture of five tetracycline antibiotics to give a final concentration of 1 mg L^{-1} for each analyte.

Preparation of PPy-GO nanocomposite material

The method of synthesis was adapted from literature [31]. The synthesis of PPy-GO nanocomposite material was prepared by in situ chemical polymerization of pyrrole. About 0.05 g GO was dispersed in distilled water and sonicated to form a 2 mg mL^{-1} homogeneous suspension. Then, 25 µL pyrrole monomer was slowly added to the yellowish-brown GO solution under ultrasonication for 40 min. Approximately 0.3 g $FeCl_3.6H_2O$ was dissolved in 10 mL distilled water, introduced into the mixture dropwise and followed by ultrasonication for another 0.5 h. After that, the black-colored PPy-GO composites were collected by centrifugation and washed with distilled water and ethanol several times, followed by vacuum drying at 45 ºC for 12 h.

Dispersive micro-solid-phase extraction procedure by using PPy-GO nanocomposite material

The extraction method of D-µ-SPE was adopted from Othman et al. [32]. About 50 mg of PPy-GO nanocomposite material was dispersed into the aqueous sample (10 mL, pH 3). The mixture was vigorously stirred with a magnetic stirrer to trap the analytes for 15 min. Subsequently, the PPy-GO nanocomposite material was isolated from the solution by centrifugation (4000 r min^{-1}, for 5 min). The supernatant was discarded. About 1 mL of desorption solvent was added, and then the mixture was sonicated for 10 min to desorb the analytes. The mixture was then centrifuged at 4000 rpm for 5 min. The solvent was collected and evaporated until dry under a soft stream of nitrogen gas. Finally, 10 µL of the extract was injected into the HPLC system for analysis. The workflow of this method is illustrated in Figure 2. The PPy-GO nanocomposite material can be reused several times after washing with 2 mL of methanol and water, respectively. Several optimization parameters for D-µ-SPE were optimized by changing one variable at a time.

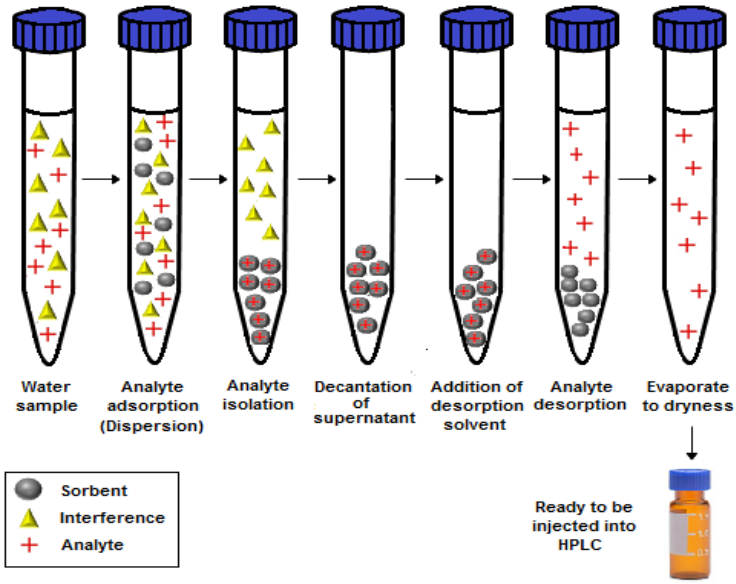

Figure 2. Dispersive micro-solid-phase extraction (D-µ-SPE) procedure by using Ppy-GO as sorbent

Chromatographic conditions

All analyses were performed using an automated high-performance liquid chromatography (HPLC) Dionex Ultimate 3000 (Sunnyvale, CA, USA) system, using an Acclaim Polar Advantage II (5 µm, 120 Å, 4.6×150 mm) (Dionex USA) as the analytical column. A gradient elution consisting of acetonitrile, methanol and formic acid was applied. The flow rate was programmed at 1 mL min^{-1}. For initialization of the LC analysis, the chromatographic system was cleaned and stabilized for 1 h. The quantification of TCs was performed by measuring the peak area of the chromatogram. TCs were detected using an ultraviolet/diode array detector (UV/DAD) at a selected wavelength of 270 nm.

Validation of the analytical method

The extraction method was assessed for linearity (R^2), the limit of detection (LOD), the limit of quantification (LOQ), precision (% RSD), and accuracy (% relative recovery) prior to sample analysis. Linearity was measured by plotting the calibration curve of five (5) different concentration levels for the standard mixture of TCs. The same calibration graph was used for the determination of LOD and LOQ. Method precision was measured using three (3) different extractions of the calibration standard at the lowest concentration.

Results and Discussion

Optimization of extraction parameter

The oxytetracycline (OTC), tetracycline (TC), demeclocycline (DMC), chlortetracycline (CTC), and doxycycline (DC) were selected as model analytes in this study as they are among the most commonly used TCs. To determine the optimum conditions for the extraction of TCs from aqueous samples, many parameters that can affect the extraction efficiency were investigated, namely the extraction time, desorption time, sample pH, extraction solvent and mass of sorbent. The optimization was carried out using one variable at a time while other parameters were kept constant. Optimization was carried out using deionized water samples spiked with each TC to give a final concentration of 1 mg L^{-1} in 10 mL of water samples. About 1 mL of acetonitrile was used as the desorption solvent. Triplicate extractions were carried out for each parameter optimized in this study.

Effect of sample pH on the extraction of TCs

The experiment was carried out by varying the pH value of the spiked sample solution from pH 3 to pH 11 to determine the effect of sample pH on the extraction of TCs. It was observed that the peak area slightly increased with increasing pH from pH 3 to pH 7 and highest at pH 7. This is shown in Figure 3(a). The peak area starts to decrease after pH 7.

The effect of sample pH on the adsorption of analytes can be explained based on its amphoteric characteristics under varied pH conditions [33]. Tetracycline is an amphoteric compound with various ionizable functional groups and will form different ionic species in an aqueous solution at different pHs. Thus, in the analysis of TCs, pH adjustment is a very crucial step [34]. TCs have three pKa values ($pKa_1 \approx 3$, $pKa_2 \approx 7$, $pKa_3 \approx 9$) [35].

Throughout the range of pH, tetracycline occurs as cationic in strong acid solution approximately at pH 3, zwitterionic at pH 4 to 7.7 and anionic at pH > 7.7 [36]. The adsorption of TCs onto Ppy-GO nanocomposite sorbent is strongly affected by either the acidity or basicity of the sorbent surface and the tetracycline speciation. At pH 4 - 7.7, TCs are mainly in their molecular form and are less protonated. Meanwhile, the sorbent surface had an increasing negative charge. Hence, the TCs exhibited increasing hydrophobicity with increasing pH, resulting in better adsorption on the sorbent. From the experiment carried out, the extraction of TCs was observed to be highest at pH 7. After pH 7, the adsorption became less efficient due to the electrostatic repulsion between anionic TCs and the negatively charged sorbent surface. Therefore, pH 7 was selected as the pH value used in subsequent experiments.

Effect of extraction time

The influence of extraction time on the peak area of analytes was studied in the range of 5 to 25 min. The effect of contact time between sorbent and analytes is shown in Figure 3(b). It was observed that the adsorption capacity of TCs rapidly increased from 5 to 15 min of extraction time. The highest extraction efficiency was obtained after 15 min of extraction time.

After 15 min, the adsorption of analytes became practically constant. This could be due to the long duration of extraction time, whereby all the active sites on the surface area of sorbent were fully saturated with the analyte as time progressed [37]. Therefore, 15 min was selected as the optimal extraction time and was used in further experiments.

Effect of desorption time

The effect of desorption time was studied in the range of 5-25 min of sonication. The sonication method was used for the desorption solvent to desorb TCs from the PPy-GO sorbent as this technique is suitable to be applied for reversible adsorption [38]. The maximum desorption time for the analytes was achieved within 10 min of sonication (Figure 3(c)). However, beyond 10 min of sonication, the peak area of analytes was constant. This was probably due to the analytes being fully desorbed from the sorbent into the desorption solvent. Therefore, a desorption time of 10 min of sonication was chosen for subsequent experiments.

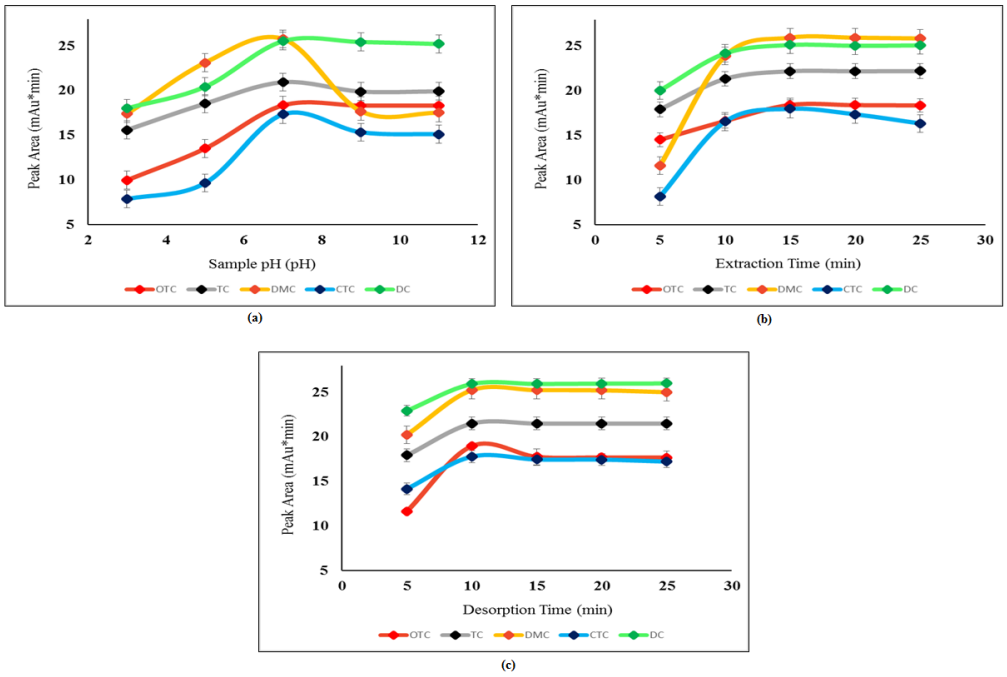

Figure 3. Optimization for the extraction performance of PPy-GO using D-μ-SPE. (a) Effect of sample pH, (b) extraction time and (c) desorption time on PPy-GO-D-μ-SPE of TCs in water samples. (Error bars represent standard deviations of results, n = 3)

Effect of desorption solvent

A complete back extraction process depends on the time of sonication and the strength of the desorption solvent [39]. The selection of a suitable organic solvent is crucial to ensure the complete elution of trapped analytes from the surface of the PPy-GO nanocomposite. In this study, the influence of different types of organic solvents was investigated to enhance the recovery of analytes. The solvents used in this study were acetone, acetonitrile, ethanol, and methanol, according to the increasing order of polarity. The experimental results depicted in Figure 4(a) demonstrate that the use of acetone as a desorption solvent yielded the lowest recovery and was therefore not sufficiently powerful for desorption of the targeted TCs. The data also showed that the best efficiency (expressed as peak area) was obtained when methanol was used as a desorption solvent. This can be related to its polar characteristic. Methanol has a stronger hydrogen bond and dipole-dipole intermolecular interactions with the targeted TCs, thus enabling effective desorption of TCs from the sorbent surface. Therefore, methanol was

selected as the desorption solvent in all subsequent experiments.

Effect of mass of sorbent

For the optimization of the mass of sorbent, about 5 mg to 100 mg of PPy-GO powder was used. The result showed that the lowest proposed mass of sorbent (5 mg) produced the lowest peak area (Figure 4(b)). On the other hand, 50 mg of sorbent gave the highest peak area of analytes. No significant increase in the peak area was observed with a further increase in sorbent mass. This was probably due to all the analytes having been fully adsorbed by the sorbent while there were still a lot of active sites available for surface adsorption [40].

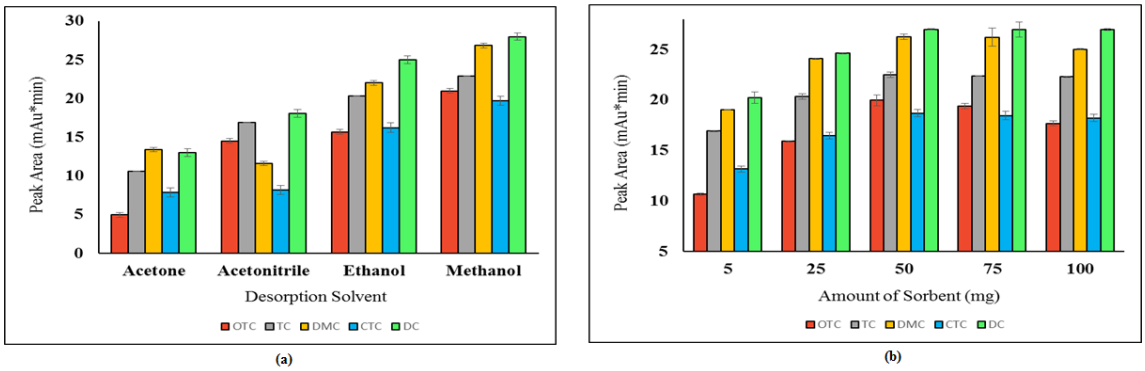

Figure 4. Optimization for the extraction performance of PPy-GO using D-μ-SPE. (a) Desorption solvent and (b) sorbent amount on PPy-GO-D-μ-SPE of TCs in water samples. (Error bars represent standard deviations of results, n = 3).

Optimum extraction conditions

The final adopted PPy-GO-D-μ-SPE conditions were: sample pH, pH 7; extraction time, 15 min; desorption time, 10 min; desorption solvent, methanol; sorbent mass, 50 mg. Hence, these optimum extraction conditions were applied for subsequent studies.

Reusability of sorbent

The reusability of the sorbent was tested by rinsing the sorbent five times with 2 mL methanol with sonication after each extraction. Then, the sorbent was dried at 60 °C for 1 hour before further use in the next D-μ-SPE procedure. The result showed that the sorbent could be conveniently reused up to fifteen times without any significant loss in the extraction recovery (> 80%) for TCs before the recovery starts to decrease slowly. This was probably due to the loss of carboxyl groups from the surface of the sorbent after repeated use.

Method validation and analytical performance of D-μ-SPE

The optimization of D-μ-SPE was then validated for relative recoveries, sample calibration and LOD. From the linearity range of 10-1000 μg $L^{-1,}$ good linearity was obtained for the four analytes, where the coefficients of determination (R^2) were in the range of 0.9989-0.9995. The LODs and LOQs were calculated at a signal-to-noise ratio of 3, and the results were in the range of 4.9 - 8.7 μg L^{-1} for LODs. The precision of the method was measured by the relative standard deviation (RSD), and the results obtained were between 1.4-3.0 %. Table 1 shows the validation data for D-μ-SPE of TCs from water samples.

Table 1. Quantitative results of DSPE-LC of TCs in tap and river water samples

Sample	Analyte	Linear Range (μg L^{-1})	Coefficient of Determination (R^2)	LOD (μg L^{-1})	RSD (%, n = 3)
Tap water	OTC	10-1000	0.9991	8.6	2.5
	TC	10-1000	0.9994	5.6	1.4
	DMC	10-1000	0.9992	8.1	3.0
	CTC	10-1000	0.9995	7.4	2.0
	DC	10-1000	0.9990	5.9	1.9
River water	OTC	10-1000	0.9992	8.7	2.3
	TC	10-1000	0.9989	4.9	2.0
	DMC	10-1000	0.9993	8.6	2.1
	CTC	10-1000	0.9995	7.4	1.6
	DC	10-1000	0.9991	6.6	2.2

Application of D-μ-SPE on river and tap water samples

The developed PPy-GO-D-μ-SPE method was successfully applied to river and tap water samples. Relative recovery studies were conducted by spiking the water samples to give a final concentration of 50 and 500 μg L^{-1}. The results are presented in Table 2. It shows that good relative recoveries were obtained in the range of 80% to 105%. The results suggest that dispersive micro-solid-phase extraction is an efficient technique for extracting drugs in aqueous matrices. Figure 5 shows HPLC chromatograms of the OTC, TC, DMC, CTC and DC in river and tap water samples.

Table 2. Relative recovery studies of DSPE-LC of TCs from different spiked water samples (n = 3)

Analyte	Spiked concentration (μg L^{-1})	Tap water		River water	
		Relative Recovery (%)	RSD (%)	Relative Recovery (%)	RSD (%)
OTC	50	95	4.8	98	2.3
	500	103	3.9	98	0.8
TC	50	99	0.4	85	1.9

Comparison with other reported methods

The efficiency of the proposed D-μ-SPE method for TCs was compared with other reported methods in terms of analysis method, extraction sorbent, linear range and LODs. The comparative results are summarized in Table 3. As can be seen, the method developed in this study achieved a comparable LOD with other prior reported methods, which also used graphene-based nanocomposite. Furthermore, compared with other developed nanocomposite sorbents, Ppy-GO is easy to prepare and can be reused fifteen times. On the other hand, extraction of tetracycline using conventional SPE involves high consumption of organic solvents and sorbents, which is laborious, somewhat costly, and time-consuming [44]. On the other hand, D-μ-SPE only requires a small amount of organic solvent and sorbent for every single analysis. In addition, since D-μ-SPE requires simple devices such as a sonicator and centrifuge, it can be considered relatively inexpensive, simple, rapid and suitable for routine analyses.

Table 3. Comparison of Ppy-GO-D-μ-SPE with other published methods for the determination of TCs.

Analysis Method	Sorbent	Type of Sample	Linear Range (μg L^{-1})	LOD (μg L^{-1})	Recoveries (%)	Ref.
μ-SPE- HPLC-UV	PET-GO nano-fiber	Honey	10–5000	15.3	89–94	[24]
MSPE-DLLME	Fe_3O_4@SiO_2@GO-β-CD	Milk, Water	10–200	1.8–2.9	71-122	[41]
SPE-HPLC	Graphene	Milk	20–1000	10-20	82-104	[42]
MSPE- UPLC–TUV	Fe_3O_4@SiO_2@FeO	Tap, river	0.133–333	0.027-0.107	91-105	[43]
D-μ-SPE-HPLC-UV	Ppy-GO	Tap, river	10-1000	4.9-8.7	80-105	This work

μ-SPE- HPLC-UV: micro-solid-phase extraction high-performance liquid chromatography
MSPE-DLLME: magnetic solid-phase extraction dispersive liquid-liquid microextraction
SPE-HPLC: solid-phase extraction high-performance liquid chromatography
MSPE-UPLC-TUV: magnetic solid-phase extraction ultra-performance liquid chromatography tunable ultra-violet
D-μ-SPE-HPLC-UV: dispersive micro solid-phase extraction high-performance liquid chromatography ultra-violet

Conclusion

This paper reports the use of polypyrrole incorporated with graphene oxide for the extraction of tetracycline antibiotics using dispersive micro solid-phase extraction combined with HPLC-UV/DAD. Several parameters were optimized in the D-μ-SPE method. The optimum

parameters were used to analyse real samples for successful extraction of oxytetracycline, tetracycline, demeclocycline, chlortetracycline, and doxycycline from river and water samples. Good linearities were achieved for the analytes with coefficients of determination R^2, in the range of 0.9989-0.9995. The method was successfully applied to the analysis of river and tap water samples, with good relative recoveries in the 80-105 % range. Compared with other previously reported methods that employed graphene-based nanocomposites, the D-μ-SPE method proved to be a simple, sensitive, selective and green extraction method that could potentially be used in the chemical laboratory for routine analysis of water samples.

Abstract

Bisphenol A (BPA) is a derivative of phenol that has been identified as a pollutant in water. This work aimed to evaluate the experimental and molecular docking findings on the adsorption of BPA using porous material metal–organic frameworks (MOFs) of zeolitic imidazolate frameworks (ZIF–8 (Zn)). The commercial ZIF–8 (Zn) was characterized by field emission scanning electron microscopy (FESEM), scanning electron microscopy (SEM), and energy dispersive X–ray (EDX). The surface morphology of ZIF–8 (Zn) showed cubic particles and zinc components (18.70 %) detected by EDX. The adsorption of endocrine–disruptive chemicals of BPA was performed by batch adsorption experiments and measured using ultraviolet–visible (UV–Vis) spectrophotometry. ZIF–8 (Zn) was shown to achieve adsorption at BPA dosage (0.4 g), and pH 6 (25 ^{o}C) with high BPA removal (98.84%). Molecular docking simulation represented that BPA was bound to ZIF–8 (Zn) via the inner pores. The mechanism interaction of BPA and ZIF–8 (Zn) was via van der Waals interaction. The adsorption of BPA onto ZIF–8 (Zn) fitted the Langmuir isotherm and the pseudo–second–order model. The possible regeneration and reusability of ZIF–8 (Zn) show good suitability for reusable adsorbent in BPA adsorption application from environmental water.

Keywords: bisphenol A, adsorption, ZIF–8, water pollutants, metal–organic frameworks

Abstrak

Bisfenol A (BPA) adalah terbitan fenol yang telah dikenal pasti sebagai bahan pencemar di dalam air. Kerja kajian ini bertujuan untuk menilai ekperimen dan kajian penambatan molekul pada penjerapan BPA menggunakan kerangka kerja logam–organik (MOFs) bahan berliang iaitu kerangka besi zeolitik imidazolat (ZIF–8 (Zn)). ZIF–8 (Zn) secara komersil dicirikan oleh mikroskopi electron imbasan pancaran medan (FESEM), mikroskopi electron elektron imbasan (SEM), dan sinar–X serakan tenaga (EDX). Morfologi permukaan ZIF–8 (Zn) oleh EDX menunjukkan zarah padu partikel kubik dan komponen zink (18.70 %) dikesan oleh

EDX. Penjerapan BPA yang mengganggu bahan kimia endokrin telah dilakukan oleh secara eksperimen penjerapan kelompok dan diukur menggunakan spektrofotometer ultraungu tampak (UV–Vis). ZIF–8 (Zn) yang ditunjukkan mencapai penjerapan pada dos BPA (0.4 g), pH 6 (25 ºC) dengan penyingkiran BPA yang tinggi (98.84%). Simulasi penambatan molekul menunjukkan bahawa BPA terikat kepada ZIF–8 (Zn) melalui liang dalam. Mekanisma BPA dan ZIF–8 (Zn) adalah melalui interaksi van der Waals. Penjerapan BPA ke atas ZIF–8 (Zn) adalah sepadan dengan model Langmuir dan pseudo–tertib–kedua. Kemungkinan penjanaan dan kebolehgunaan semula untuk ZIF–8 (Zn) menunjukkan kesesuaian yang baik untuk bahan penjerap yang boleh diguna semula dalam aplikasi penjerapan BPA daripada air persekitaran.

Kata kunci: bisfenol A, penjerapan, ZIF–8, pencemaran air, kerangka besi logam–organik

Introduction

Toxic organic compound contamination of water has remained an issue for ecosystems. Endocrine–disrupting compounds of bisphenol A (BPA) and bisphenol S (BPS) have been frequently detected in industrial and environmental water [1]. BPA is widely used in the manufacturing of storage containers, such as plastics [1], water supply pipes [2], reusable water bottles [3–5], and food containers [6–7]. A phenolic molecule with two phenol moieties [8], low vapor pressure, moderate water solubility, and low volatility [9] are some of the characteristics of BPA. BPA is a solid at room temperature and very toxic to aquatic life at concentrations of 1,000 to 10,000 mg/L in freshwater [10–11].

Multiple wastewater treatment strategies have been shown to effectively remove BPA from water [8–10]. Adsorption is one of the promising techniques to remove organic and inorganic pollutants from wastewater [8]. The most commonly used adsorbent is activated carbon and multi–walled carbon nanotubes at both laboratory and industrial scales. However, it has several disadvantages, such as problems with hydrophilic substances, the selective performance of the carbon used, high cost, and the need for complexing agents [2]. Thus, an alternative reusable adsorbent has been proposed to treat BPA wastewater so that the discharged water can comply with environmental regulations.

Metal–organic frameworks (MOFs) are suggested as one of the most advanced materials that can effectively remove toxic pollutants from wastewater. MOFs are organic–inorganic hybrid crystalline porous substances with positively charged metal ions next to organic linker molecules [12]. The compounds offer many advantages, such as ultra–porous structure for the surface area [13], high pore volume [14], uniform particle size [15–18], good thermal and chemical stability [19], and the flexibility of geometrical structures to impart different shapes for the frameworks [10]. These advantages of MOFs have the potential for effective BPA adsorption in wastewater. ZIFs, or zeolitic imidazolate frameworks, are a subclass of MOFs that are primarily composed of tetrahedrally coordinated transition metals such as cobalt, zinc, and imidazolate linkers. They are assembled through the process of self–assembly. With the strong and small bonds of the metal ions–imidazolate, ZIFs are associated with great characteristics as universal adsorbents for adsorption of BPA [19].

According to the findings that were published by Peng et al. [20], the elimination of BPA by employing chitosan–modified zeolite (Ch–Z) in the absence and presence of sodium cholate (NaC) was examined. It was discovered that the elimination of BPA by adsorption onto Ch–Z with NaC was over nine times higher than when there was no NaC present in the experiment. The research conducted by Genc et al. [21] utilized surfactant–modified natural zeolite to remove BPA from aqueous solutions. The robust design technique developed was applied in order to maximize the adsorption of BPA, and the maximum adsorption capacity was reported to be 6.90 mg/g. The adsorption of BPA by modified zeolites containing cetyltrimethyl ammonium bromide (CTAB) and cetylpyridinium bromide (CPB) was investigated by Wang et al. [22]. The most effective modified zeolite for the removal of BPA was found to be one that combined 10% CTAB with pre-treated zeolite and was carried out at a temperature of 25℃ for thirty-six hours. Other research found that the ZIF-8@SBA-15 adsorbent, which was made by modifying the ZIF-8 coating layers using the

coordination method, has a maximum adsorption capacity of 123.4 mg/g for 200 mg/L BPA. More than a twofold increase in adsorption capacity was seen with the ZIF-8@SBA-15 adsorbent, and an almost twentyfold increase in adsorption rate constant was observed [23]. Synthetic zeolite with a NaX structural type was modified with cyclodextrin (CD) in the study conducted by Bandura et al. [24] to improve the adsorption of BPA from aqueous solutions. The adsorption of BPA was consistent with a monolayer model, and it suggested the creation of host–guest complexes along with hydrogen bond formation. The highest adsorption capabilities for the removal of BPA were measured at 32.7 mg/g. According to the adsorption behavior of ZIFs, they can function as an effective adsorbent for the removal of BPA from aqueous media.

In this work, ZIF–8 (Zn) was chosen as the adsorbent in this investigation of the BPA removal from an aqueous solution. There has been no previously published work for ZIF–8 (Zn) utilizing ultraviolet–visible (UV–Vis) spectroscopy that studied regeneration and reusability. The reusable ZIF–8 (Zn) may help in the development of a green adsorbent that will offer a high yield whilst having very low operational expenses. The batch adsorption experiments were measured using scanning electron microscopy (SEM), energy–dispersive X–ray spectroscopy (EDX), field emission scanning electron microscopy (FESEM), and UV–Vis spectrophotometer for absorbance measurement. The effects of parameters were studied for effective BPA adsorption. The thermodynamics, kinetics, and isotherm of the process were also determined, and possible mechanisms step and molecular docking for the BPA adsorption were proposed. By considering reusable adsorbent, ZIF–8 (Zn) could reduce the maintenance cost and be environmentally friendly in the removal of BPA.

Materials and Methods

Chemicals Reagents

The chemicals used in this experiment were analytical grade and had no purification before use. BPA analytical standard (> 99% purity), and Basolite Z1200@ZIF–8 (Zn) (99% purity) was obtained from Sigma–Aldrich (USA). Sodium hydroxide (NaOH), and hydrochloric acid (HCl) were obtained from Avantis Laboratory, Malaysia.

Characterization of ZIF–8 (Zn)

The surface morphology of ZIF–8 (Zn) was determined using FESEM–EDX (Zeiss Supra 55 VP, the United Kingdom). Meanwhile, the equipment was operated at 200 kV and the samples were sputtered–coated with Au metal. EDX was conducted to detect the elemental composition of the ZIF–8 (Zn).

Batch adsorption studies

The experiments were carried out using ZIF–8 (Zn) that was added to 200 mL of BPA solutions. Fig. S1 represents typical calibration curves for the BPA solution. The conical flasks were sealed and placed in a shaker and mixed using an orbital shaker (Daihan Scientific, China). The samples were withdrawn at a certain time interval using a syringe and the residual BPA concentration was analyzed spectrophotometrically by observing the absorbance at the maximum wavelength of absorption (276 nm) using a UV–vis spectrophotometer (Shimadzu, UV–1800). The parameters that affect the adsorption, such as the MOF dosage, temperature, and pH were systematically studied using one parameter at a time (OFAT).

The % BPA removal is stated by the formula below [17]:

$$\%R = \frac{C_o - C_e}{C_o} \times 100\% \quad (1)$$

And the BPA quantity adsorbed at a time (q_t) and equilibrium (q_e) is calculated as:

$$q_t = \frac{(C_o - C_t)V}{w} \quad (2)$$

$$q_e = \frac{(C_o - C_e)V}{w} \quad (3)$$

where C_t is the equilibrium concentration of the BPA (mg/L), C_o is the initial BPA concentration (mg/L), V is the volume of the water (L) and w is the mass of BPA (g).

The adsorption isotherms for BPA were obtained via adsorption for 60 minutes, which is sufficient for

equilibrium. The effect of the ZIF–8 (Zn) dosage (0.05–0.4 g) was investigated and maintained at 90 mg/L. For BPA adsorption under a range of pH (2–12), the pH of the BPA solution (90 mg/L) with 0.4 g of ZIF–8 (Zn) was adjusted, before adsorption, by using 0.10 M HCl or 0.10 M NaOH solution. The effect of changing the BPA removal temperature was also investigated at temperatures ranging from 25 to 45 °C. The results obtained from the effect of adsorption temperatures were used to analyse the thermodynamic values using $\Delta G^{\theta} = -RTInK_C$ where ΔG^{θ} (kJ/mol) is the change in Gibbs free energy, R is gas constant, T is the temperature (K) and K_C is a ratio of the amount of BPA adsorbed onto the ZIF–8 (Zn) to the concentration of BPA at equilibrium. The equation explains the extent of the spontaneity of the removal process.

For thermodynamic calculation, the value Kc represents the distribution coefficient, which refers to the ratio of the amount of BPA adsorbed onto the MOFs (C_{ads}) to the concentration of BPA at equilibrium (C_e). Equation 4 can also be rewritten as [17]:

$$InK_C = \frac{\Delta H^{\theta}}{R} - \frac{\Delta S^{\theta}}{RT} \quad (4)$$

where ΔH^{θ} (kJ/mol) is the enthalpy change and ΔS^{θ} ($Jmol^{-1}K^{-1}$) is the entropy change of the adsorption process.

The regeneration and reusability of ZIF–8 (Zn) was also investigated. Using 100 mL of ethanol solution, the ZIF–8 (Zn) was regenerated by discharging the filtrate and washing the leftover particles away. Following that, the MOFs were vacuum dried at 100 ° C for 3 hours. For stability studies, the samples were stored in a desiccator and remained unaltered during the long–term storage.

Molecular docking simulation

The molecular docking study of the 1:1 ratio of BPA with ZIF–8 (Zn) molecules was conducted using AutoDock Tools version 1.5.6. The docking process was studied by the macromolecule (ZIF–8 (Zn)) and ligand (BPA) into the system. After that, the Autogrid tool in the AutoDock program was used to generate a grid box of 120 × 120 × 120 Å cubic with 0.375 Å spacing points. It was installed wider than ZIF–8 (Zn) and attached to the middle of ZIF–8 (Zn) molecules to verify that the box encompassed the whole surface of ZIF–8 (Zn). Cambridge Crystallographic Data Centre (CCDC) and ChemTube3D (University of Liverpool, ChemTube3D) [25] were also used to achieve the crystallographic parameter of one unit cell of ZIF–8 (Zn). BPA's original structure was obtained via the Automated Topology Builder (ATB) service [25], and it was then optimized that use the DFT technique at the B3LYP/631G* level of theory. The BPA compounds were then presented into the cavity of ZIF–8's macromolecular receptor (Zn). To estimate the potential dock framework of BPA with ZIF–8 (Zn) complex and evaluate the binding energy (ΔG_{bind}), the Lamarckian genetic algorithm (LGA) has been used [17].

$$\Delta G_{bind} = \Delta G_{VDW} + \Delta G_{electrostatic} + \Delta G_{H°bond} + \Delta G_{desolv} + \Delta G_{tor} \quad (5)$$

ΔG_{VDW} represents van der Waal energy, $\Delta G_{H°bond}$ represents hydrogen bonding energy, $\Delta G_{electrostatic}$ refers to electrostatic energy, ΔG_{tor} is torsional free energy and ΔG_{desolv} represents desolvation energy.

Results and Discussion

ZIF–8 (Zn) Characterization

The surface morphology of ZIF–8 (Zn) was determined by FESEM analysis, as depicted in Figure 1(a). From the FESEM images, it is observed that the external surfaces of ZIF–8 (Zn) are relatively smooth with fine pores in a cubic structure (yellow arrows). The particle size of ZIF–8 (Zn) was estimated in the range of 219.2 to 572.1 nm which showed a smaller particle size that could contribute to the high surface area. The porosity of ZIF–8 (Zn) was described by the nitrogen (N_2) adsorption–desorption analysis. ZIF–8 (Zn) showed good BET surface area and pore volume, as highlighted in Mahmad et al. [26] studies, which are the characteristics of a highly porous material. It shows the typical nature of porous materials with ZIF–8 (Zn) having a surface area and pore volume of 1299 m^2/g and 0.6 m^3/g,

respectively. ZIF–8 (Zn) showed a high BET surface area due to the flexible amine group pendants [17]. The pore size of the ZIF–8 (Zn) was determined using Barrett–Joyner–Halenda (BJH) analysis as shown in Fig. 1 (d). Also, the surface elemental composition from the EDX analysis of ZIF–8 (Zn) (Figure 1(b)) proved that the surface elemental compositions consisted of carbon (45.55 %), nitrogen (30.34 %), oxygen (5.41 %), and zinc (18.70 %).

In addition, the ZIF–8 (Zn) with good chemical, thermal, and moisture stability was synthesized and characterized. The ZIF–8 (Zn) is described by the cubic–like particles, indicating the good stability of the MOFs as emphasized in the works of literature [17–18]. To further ascertain the stability of the adsorbents for the *in vivo* application, the ZIF–8 (Zn) had aged in a strong acidic condition (pH 1) for a period of one week. However, the SEM analysis has shown no defect in the structural morphology of the ZIF–8 (Zn) as shown by the images in Fig. 1 (c). The detail on the good stability of the ZIF–8 (Zn) is in the same agreement as previously reported by Molavi et al. [27] and Oveisi et al. [28].

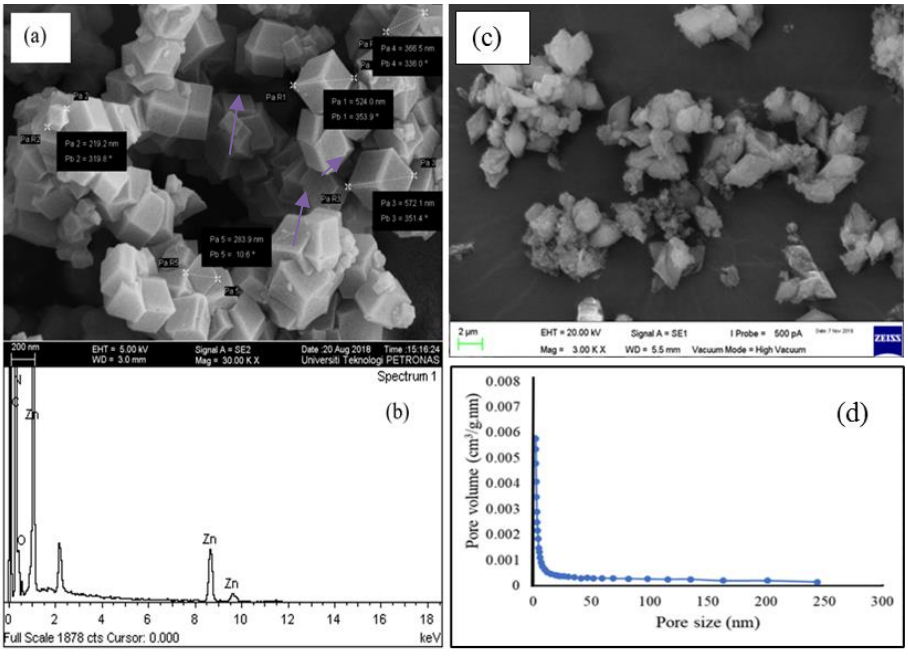

Figure 1. (a) FESEM and (c) SEM images at 30,000× magnification, (b) EDX spectra, and (d) the image of the pore size distribution of ZIF–8 (Zn)

BPA adsorption study

The effect of different dosages of ZIF–8 (Zn) on BPA adsorption was analyzed and the data are shown in Figure 2(a). ZIF–8 (Zn) achieved the highest percentage of BPA removal (98.84 %) at a 0.4 g dosage, which is exactly equivalent to the work done by Zango et al. [17–18]. The mass transfer increased as the dosage of ZIF–8 (Zn) increased, which was determined based on the increase in BPA adsorption capacity. This is because increasing the ZIF–8 (Zn) dosage, increases the number of active pore sites on the surface of ZIF–8 (Zn) for BPA adsorption to occur [29]. At higher dosage, BPA molecules acquired higher equilibrium adsorption capacity due to the increase in the diffusion gradient as the driving force for adsorption [30].

As the pH increased, the removal percentage of BPA decreased (Figure 2 (b)). At the acidic phase, the optimum removal of BPA was 94.68% (pH 6) using ZIF–8 (Zn). Fundamentally, pH affects the electrostatic attraction between ZIF–8 and BPA molecules in an aqueous solution. Based on the results, the adsorption

between ZIF–8 (Zn) and BPA molecules is promoted in an acidic medium. The H^+ ions in the BPA solution are present in an acidic medium, which produced positively charged BPA [17–18]. The BPA removal increased in the presence of acids compared to bases because the negative charge of ZIF–8 (Zn) increases as pH decreases [17]. Hence, there is more electrostatic attraction between ZIF–8 (Zn) and BPA molecules, leading to higher BPA uptake.

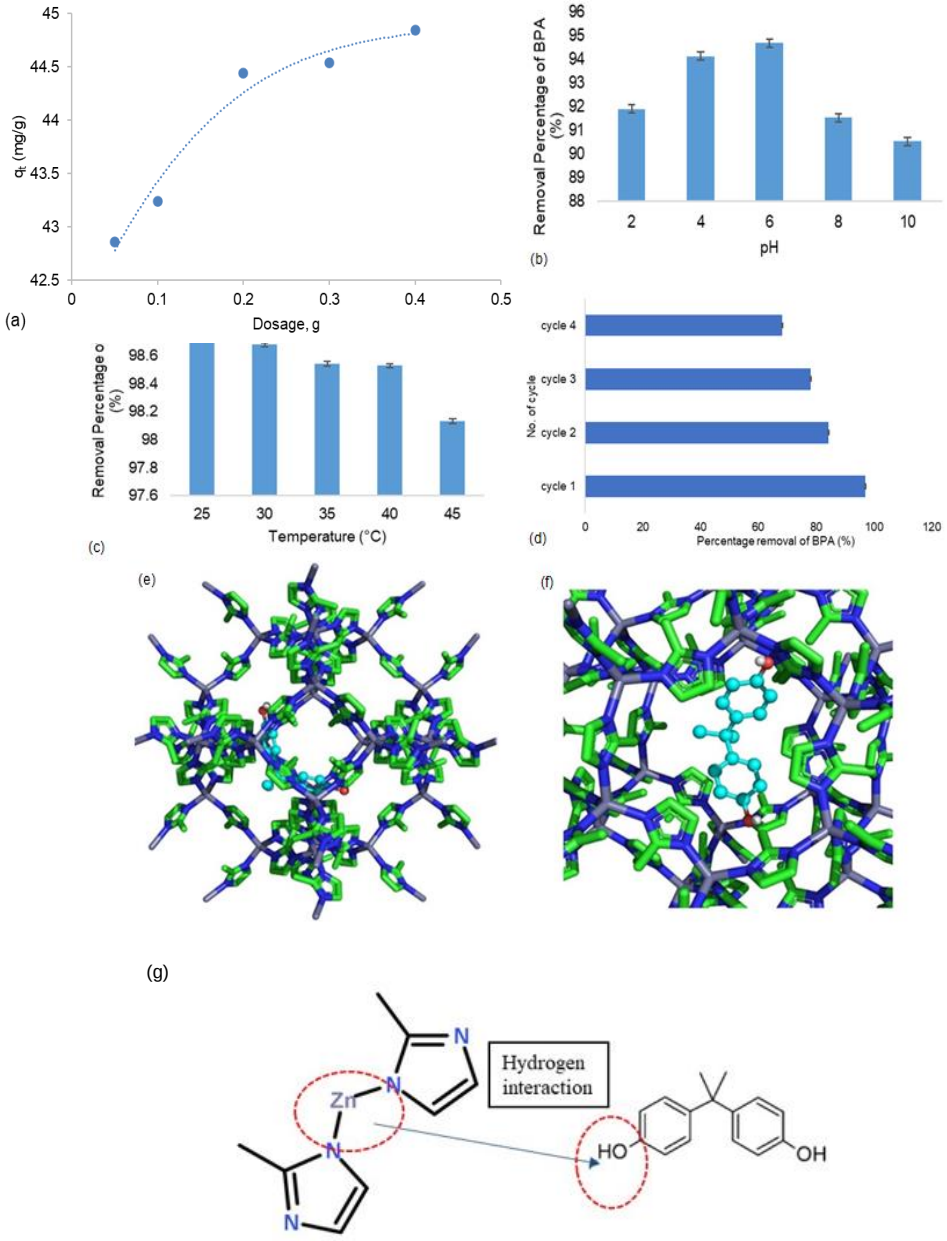

Figure 2. The graph for effect of (a) dosage, (b) pH, (c) temperature, (d) reusability for BPA adsorption onto ZIF–8 (Zn), molecular structure of (e) ZIF–8 (Zn)(BPA) (full view), (f) ZIF–8 (Zn)(BPA) (zoom view) and (g) possible mechanism of ZIF–8 (Zn)(BPA). BPA was colored light blue.

On the other hand, the removal efficiency for ZIF–8 (Zn) at a particular temperature is presented in Figure 1(c). A decrease in the removal percentage of BPA was recorded at accumulated temperatures. As the temperature rises, the mass transfer rate from the bulk solution to the boundary layer near ZIF–8 (Zn) decreases. The increased BPA solubility reveals a lower tendency to the surface of ZIF–8 (Zn) [17–18]. To determine the thermodynamics of the adsorption, Van't Hoff equation was applied and the corresponding enthalpy (ΔH^{θ}), Gibbs free energy (ΔG^{θ}), and entropy changes (ΔS^{θ}) were deduced [17–18] (Table 1). The ΔG^{θ} values were reported to be negative and decreased at high temperatures, indicating a spontaneous and unfavorable nature of the process as the temperature increases [17–18]. The ΔH^{θ} value was 9.957 kJ/mol for ZIF–8 (Zn). This further shows the exothermic and endothermic nature of the BPA adsorption. The rate of diffusion of ZIF–8 (Zn) molecules through the external boundary layers and interior pores of ZIF–8 (Zn) increased as the temperature rises, representing an endothermic adsorption mechanism. The value of ΔS^{θ} was 0.0142 J/mol/K for ZIF–8 (Zn), which showed a high degree of randomness in the ZIF–8 (Zn) adsorption system. In addition, according to Mahmad et al. [26], the adsorption of BPA onto ZIF–8 (Zn) fitted the Langmuir isotherm and the pseudo–second–order model.

Table 1. Thermodynamic parameters for the adsorption of BPA onto ZIF–8 (Zn)

Temp (°C)	ΔG^{θ}(kJ/mol)	ΔH^{θ}(kJ/mol)	ΔS^{θ}(J/mol/K)
25	−14.241		
30	−14.222		
35	−14.424	9.957	0.0142
40	−14.852		
45	−14.632		

After the batch adsorption tests, the regeneration and reusability of ZIF–8 (Zn) demonstrate remarkable potential as adsorbents for BPA removal. The BPA removal percentage obtained by ZIF–8 (Zn) in the 4th cycle was 68.2% (Figure 1 (d)). This finding shows that ZIF–8 (Zn) has good reusability features with good removal performance [17–18]. Zango et al. [17] reported that MOF has the possibility to be regenerated and reused until the 5th cycle with a good percentage of pollutant removal. A significant *p*–value is vital for determining the fit of the model. In other words, a *p*–value < 0.05 indicates the significance of the model for the regression analysis under the influence of independent variables. The temperature and dosage of ZIF–8 (Zn) were considered significant for BPA adsorption. Thus, these values proved that the alternative hypothesis is accepted and there is a difference between the means of the parameters. Meanwhile, the pH of ZIF–8 (Zn) was not statistically significant. This shows that the null hypothesis is accepted and there is no difference between the means of the parameters.

Molecular docking of adsorption of BPA onto ZIF–8 (Zn)

Docking simulation was also performed to analyze the molecular interaction for the BPA removal onto ZIF–8 (Zn). The binding conformers for the complex formation are shown in Figure 1 (e–f) for ZIF–8 (Zn). It was observed that BPA molecules prefer to bind with the internal pores of ZIF–8 (Zn) due to their smaller size [17–18]. The stability of the docking conformers is determined by the binding energy of the inclusion complex formed. It represents the strength and stability of the interaction of ZIF–8 (Zn) with BPA. The result of molecular docking for the interaction of ZIF–8 (Zn) with

BPA was supported by the calculated equilibrium adsorption capacities obtained from the contact time optimization studies with ZIF–8 (Zn) adsorption, where the q_e value was 43.82 ±0.17 mg/g [31]. The BPA adsorption onto ZIF–8 (Zn) exhibited the ΔG_{bind} of −4.21 kcal mol^{-1} [31]. The docking findings follow a pattern that is comparable to that seen in the experimental data collected for the adsorption capacity of ZIF–8 (Zn). More stable physisorption interaction is associated with lower free energy values [32], as opposed to higher free energy values. ZIF–8 (Zn) models were established with BPA and also exhibit van der Waals interactions with the adsorbing contaminants. Table 2 lists the van der Waals as well as electrostatic energies associated with the inclusion complexes, as well as the values of interaction energies. The distance of the hydrogen bond was reported as 3.6 Å. However, the hydrogen bond of ZIF–8 (Zn) was insignificant due to the large average distance (more than 3 Å) from the experimentally determined geometry, which can be due to wrong orientation or displacement (Figure 2 (g)) [32–33]. Hence, due to the lowest ΔG_{bind}, ZIF–8 (Zn) was predicted to have van der Waals interaction with BPA in adsorption studies. Thus, the information obtained from the docking simulation is relevant.

Table 2. The interaction energy of ZIF–8 (Zn) with BPA inclusion complex obtained from molecular docking simulation

Interaction Energy (kcal/mol)					
$\Delta G_{binding}$	$\Delta G_{\text{vdw + HBond + desolv}}$	ΔG_{elec}	ΔG_{total}	$\Delta G_{unbound}$	ΔG_{tor}
−4.21	−5.38	−0.02	−0.50	−0.50	+1.19

Comparison with other adsorbents

Table 3 shows the key features of adsorbents for the removal of BPA from wastewater that have been reported. Based on the reported studies, it is clear that ZIF–8 (Zn) has a higher BPA removal percentage (% R = 98.84 %). The optimum contact time was also rapid (30 minutes) [26], and the ZIF–8 (Zn) was reported with good reusability and regeneration. In contrast to the adsorbents given in Table 3, the listed adsorbents have not undergone any studies on their potential to be regenerated and reused. Because ZIF–8 (Zn) has the capacity to regenerate itself and is reusable, it has the potential to reduce costs, has a high level of efficiency, and is kind to the environment. Despite this, when compared to the other adsorbents, the ZIF–8 (Zn) demonstrated the shortest amount of time necessary for the adsorption of BPA to attain the optimal result. When compared to the other adsorbents, the surface area of ZIF–8 (Zn) was reported as having the greatest value; as a result, ZIF–8 (Zn) has a high potential for future research into the maximum adsorption capacity based on the impact of a high concentration of BPA. As a result of these findings, ZIF–8 (Zn) has the possibility to be a future alternative reusable adsorbent for the removal of BPA.

Table 3. Comparison of reported adsorbents with MOFs used for BPA removal

Adsorbents	Surface Area (m^2/g)	Maximum Adsorption Capacity (mg/g)	Initial Concentration, Solid/Liquid Ratio	Isotherm Models	Kinetic Models	Removal of BPA (%R)	Equilibrium Time	References
Commercial powdered activated carbon	1027	307.00	5–70 mg/L, 10 mg/100 mL	Langmuir	Ps2	>99.00	>90 min	[34]

Conclusion

The BPA removal onto the commercial ZIF–8 (Zn) has been studied. The high BPA removal percentage was successfully achieved with ZIF–8 (Zn). For the regeneration and reusability studies of ZIF–8 (Zn) for BPA adsorption, the removal percentage achieved 68.2% in the 4th cycle. The van der Waals interaction could occur in the adsorption of BPA, as determined using molecular docking simulation. The Langmuir isotherm and the pseudo–second order model were also compatible with the findings. Molecular docking simulation predicted better interaction between ZIF–8 (Zn) and BPA molecules, which agreed well with the experimental findings. Based on the comparison of previously used adsorbents, ZIF–8 (Zn) was shown to be superior in terms of rapid equilibration (30 min), highest BPA removal, and reusable features. Thus, ZIF–8 (Zn) as a future reusable adsorbent can achieve good results in the removal of BPA from wastewater.

Abstract

Palm oil industry is among the most important commodities industry in Malaysia where Malaysia dominates 39% and 44% of global palm oil production and exports respectively. Most of the palm oil exports to various countries are done via sea-shipping which increases the risk towards marine pollution in form of oil spillage from vessels. Microbial degradation studies are important in establishing baseline data which is instrumental for mitigation planning and policy making. Degradation of palm oil derivatives was investigated using natural seawater collected from Klang Port and isolated bacteria *Pseudomonas aeruginosa* UMTKB-5 based on modified shake flask method as described by OECD Guidelines for Testing Chemicals, OECD TG 306 (Biodegradability in Seawater). Analytical method for determination of CPO and CPKO degradation comprises of measurement of dissolved organic carbon (DOC), colony forming unit (CFU), bacterial diversity using 16S rDNA gene based metagenomic analysis, and fatty acid measurements. Degradation of CPO and CPKO in seawater collected from Klang Port show increase in bacterial population which peaked in day 7 and 21 before declining indicating that palm oil is being used as substrate for bacterial growth in tandem with degradation which is aided by lipase enzyme produced by selected bacteria. Similar growth pattern observed in *P. aeruginosa* UKTKB-5 cultivated sample. DOC removal in sample showed negative value showing that carbon input from CPO and CPKO degradation is higher than consumption by bacteria. Fatty acid measurement shows changes in composition where bacterial degradation and utilisation of oil. The metagenomic analysis revealed diverse bacteria population in the different sampling locations and four lipase-producing bacterial strains were isolated at the end of the biodegradation experiment. The study has shown the biodegradability of palm oil in seawater and able to provide baseline data to understand and formulate the action plan in the event of spill in marine environment.

Keywords: palm oil, bacteria diversity, microbial degradation, fatty acids

Abstrak

Industri minyak sawit adalah antara industri komoditi terpenting di Malaysia di mana Malaysia menguasai 39% dan 44% pengeluaran dan eksport minyak sawit secara global masing-masing. Kebanyakan eksport minyak sawit ke pelbagai negara dilakukan melalui perkapalan laut yang meningkatkan risiko pencemaran marin dalam bentuk tumpahan minyak dari kapal. Kajian degradasi mikrob yang mampan adalah penting dalam mengesahkan data asas yang memainkan peranan penting untuk perancangan mitigasi dan pembuatan dasar dan polisi. Degradasi minyak sawit tidak ditapis (CPO) dan minyak isirong sawit tidak ditapis (CPKO) dalam air laut semula jadi yang dikumpul dari Pelabuhan Klang and bakteria *Pseudomonas aeruginosa* UMTKB-5 telah dikaji menggunakan kaedah kelalang goncang yang diubah suai seperti yang diterangkan oleh garis panduan OECD untuk pengujian bahan kimia, OECD TG 306 (kebolehbiodegradan dalam air laut). Analisa process degradasi CPO and CPKO melibatkan pengukuran karbon organik terlarut (DOC), kiraan unit pembentuk koloni (CFU), analisis metagenomik berasaskan gen 16S rDNA untuk kepelbagaian bakteria, dan perubahan acid lemak bebas. Keputusan menunjukkan peningkatan dalam kiraan CFU apabila bilangan hari meningkat dan kiraan CFU berada pada tahap tertinggi pada hari ke-7 dan 21 sebelum menurun. Situasi ini menunjukkan penggunaan minyak sawit sebagai substrat oleh bakteria. Peningkatan populasi bakteria yang sama ditunjukkan oleh bakteri *P. aeruginosa* UMTKB-5. Perubahan nilai penyingkiran DOC kepada nilai negatif mendedahkan kemasukan karbon melalui process degradasi CPO and CPKO pada tahap yang melebihi penggunaan oleh bakteria. Perubahan komposisi asid lemak penggunaan substrat oleh bakteria. Analisis metagenomik mendedahkan populasi bakteria yang pelbagai di lokasi persampelan yang berbeza dan lebih daripada empat strain bakteria telah diasingkan pada akhir eksperimen biodegradasi. Strain positif juga diuji untuk aktiviti lipolitik. Kajian ini telah mendedahkan kebolehbiodegradasian minyak sawit dalam air laut dan dijangka dapat membekalkan maklumat asas kepada pihak berkuasa berkaitan minyak sawit, pengangkutan dan agensi alam sekitar untuk memahami dan merangka pelan tindakan sekiranya berlaku tumpahan dalam persekitaran marin.

Kata kunci: minyak sawit, kepelbagaian bakteria, bakteria pendegradasi, asid lemak

Introduction

The demand for vegetable oil for food and as alternative fuel has fuelled the rapid production of oilseed [1]. The vegetable oil production is estimated to be around 187 million tonnes for 2016/2017 and is expected to grow to 195 million tonnes in the following year [2]. Four types of vegetable oil namely palm oil, soyabean oil, rapeseed oil and sunflower oil dominated the global vegetable oil market [1,3]. The major vegetable oil produced are palm oil (PO) and palm kernel oil (PKO) which accounts for 70.3 million tonnes (37.6%) of global production and followed by soybean oil where 55 million tonnes (30%) are produced [1].

The major producer of PO and PKO are Indonesia and Malaysia where nearly 86.5% of oil is produced. Malaysia is the second largest producer of palm oil where it accounts for 39% of global palm oil production and 44% of exports [4]. The oil palm tree *Elaeis guineensis* of tenera (thin shelled) variety is commonly planted in Malaysia due to its high oil yield [5]. Oil palm of tenera variety has higher palm oil content where it yields about four to five tonnes of crude palm oil (CPO) and one ton of crude palm kernel oil (CPKO) per hectare per year which made it as suitable planting material for commercialisation approach.

Significant portions of export and import activities of palm oil and its derivatives are conducted via sea shipping [6]. Malaysia exports palm oil to countries such as People's Republic of China, European Union, India, and United States via sea-shipping through major ports such as Johor Port, Klang Port, and Sandakan Port. This mode of transportation has led to pollution of marine environment where spillage of palm oil and its derivatives has occurred. There are several reported incidents of palm oil, and the most recent incident is the oil spill that occurred in Chinese waters where 9000 tonnes of palm stearin spilled from vessel collision [7] as well as dumping of palm oil by ships at the North Sea, Great Britain [8]. Vegetable oil spill incidents can negatively impact the exposed ecosystem where exposed organisms suffer oxygen depletion, toxicity effects, and smothering of surface-dwelling organisms causing fatal effects.

The United States Environmental Protection Agency (USEPA) has classified environmental impact of

vegetable oil spill as similar to hydrocarbon oil spills [9]. However, there are limited studies on the degradation of vegetable oil especially palm oil in marine environment. A study into natural palm oil degradation process and the role microbes play in the degradation process is necessary to understand the potential short and long-term impact of vegetable oil spills. This study aims to investigate the utilisation of different palm oil derivates by naturally occurring bacteria and cultivated marine bacteria to assess the degradability of oil via assessment of bacterial population, carbon removal, and fatty acid profile.

Materials and Methods

Degradation of crude palm oil and crude palm kernel oil using natural seawater: Study area

The sampling site chosen for natural seawater collection was Klang Port where the sample was collected at the coordinates for Site A: 2.999119°N, 101.379022°E and Site B: 3.004477°N, 101.354947°E (Figure 1). The seawater was collected based on the methods by American Public Health Association (APHA) [10]. Furthermore, the physical parameters such were measured and recorded *in situ* using portable Hydrolab Quanta Multiprobe meter. The sample was stored in ice until further analysis.

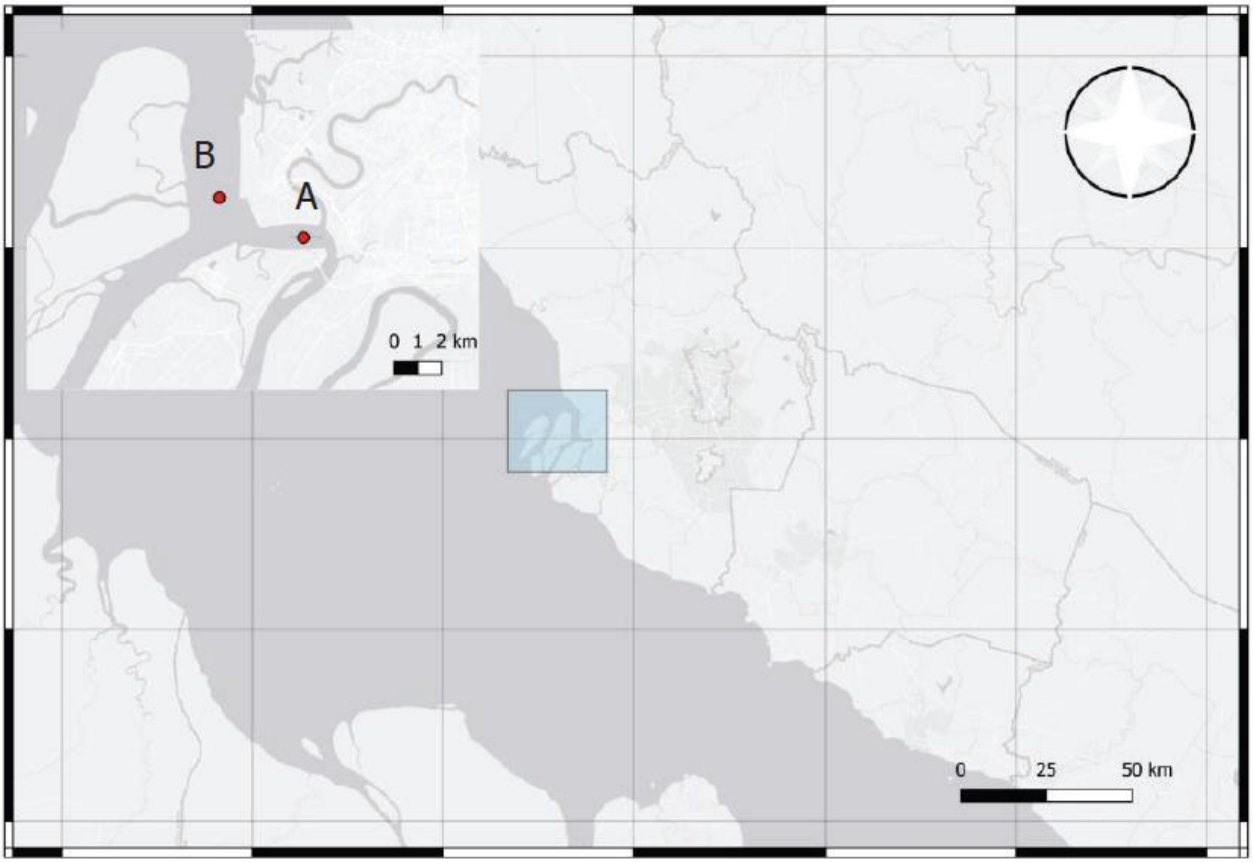

Figure 1. Map indicating the seawater sampling location at Klang Port, Selangor

Degradation of palm oil

The degradation of crude palm oil (CPO) and crude palm kernel oil (CPKO) that were obtained courtesy of MPOB were investigated using OECD Guidelines for Testing Chemicals, OECD TG 306: Biodegradability in Seawater with some modifications [11]. Shaken flask culture method was used in this study. The seawater was enriched with 1 mL litre^{-1} of each mineral nutrients that were prepared according to OECD guideline. The degradation study included blank, which is enriched

seawater without any test substance, test substance at two loading rate (1 g L^{-1} and 10 g L^{-1}) and aniline as reference substance. The degradation study was carried out for a period of 42 days at room temperature and was incubated at 150 rpm using Protech Orbital Shaker 721 ambient shaker. Samples were taken at selected interval for colony forming unit (CFU) determination using Zobell Marine Agar 2216 (HiMedia, India) and dissolved organic carbon (DOC) measurement. Furthermore, formation of floating and precipitate particles, oil droplets and dispersion were observed. Experiment was conducted in triplicates.

Determination of DOC

The DOC levels in culture medium were determined on samples from day 0, 7, 14, 21 and 28. The collected water samples were filtered using 0.45-µm polyether sulfone syringe filter (Sartorius, Germany) [12]. The DOC was measured using high-temperature catalytic oxidation (HTCO) method with a Shimadzu TOC-L & SSM 5000A (Shimadzu, Japan) total organic carbon equipped with non-dispersive infrared gas analyser (NDIR) detector [13]. The sample were acidified to pH then the samples were then sparged for 5 min before being analysed. Calibration of the instrument was done using freshly prepared standards [14]. Based on the DOC data obtained, degradation value was calculated based on formula provided in the guidelines [11].

Identification of bacterial consortium

The bacterial population of water sample before and after cultivation period were identified. The water sample collected during sampling was outsourced to Apical Scientific Sdn. Bhd. immediately after sample for metagenomic assessment of bacterial population. Meanwhile, phenotypically different bacterial colonies obtained at the end of degradation experiment was identified using 16S rDNA sequencing. Polymerase chain reaction (PCR) amplification was performed under the conditions: 3 min initial denaturation at 95°C; 34 cycles of denaturation (30 s at 95°C), annealing (45 s at 55°C) and extension (90 s at 72°C); and final extension at 72°C for 5 min [15,16]. The primer sets used were 63F (5'-CAGGCCTAACACATGCAAGTC-3') and 1389R (5'-ACGGGCGGTGTGTACAAG-3') [15,16]. The PCR products were sent to Apical Scientific Sdn. Bhd. for purification and sequencing. The obtained sequences obtained were compared with Basic Local Alignment Search Tool (BLAST) databases using Standard Nucleotide BLAST (BLASTn) to identify the bacteria.

Degradation of crude palm oil and crude palm kernel oil using natural seawater: Bacterial strain and utilisation test

P. aeruginosa UMTKB-5 (GenBank accession number: KT194193.1) was obtained from the culture collection of Institute of Marine Biotechnology, Universiti Malaysia Terengganu (Terengganu, Malaysia) [17]. The strain was isolated from marine sediment of Pulau Bidong. The strain was maintained on Zobell Marine Agar 2216 (HiMedia, India). The utilisation test was conducted using modified OECD TG 306 method based on previous study [15]. Test substance which are aniline, CPO, CPKO refined bleached and deodorised palm oil (RBDPO) and refined, bleached and deodorised palm olein (RBDPL) were added at concentration of 1 g L^{-1} into 100 mL working volume of artificial seawater. The utilisation study was carried out for a period of 8 days at room temperature and was incubated at 150 rpm using Protech Orbital Shaker 721 ambient shaker. The utilisation of different palm oil derivatives by *P. aeruginosa* UMTKB-5 was determined by CFU count determination, residual oil measurement, emulsification test [18] and free fatty acid determination.

Residual oil measurement

The residual oil was extracted using 30 mL of hexane on the culture broth [10,19]. The mixture was shaken vigorously, and 5 mL of hexane layer is transferred onto pre-weighted container and air-dried until complete evaporation of hexane before weighing.

Fatty acid determination via gas chromatography-flame ionisation detector (GC-FID)

The acid-catalysed ethylation of sample was done according to a methodology described by Anuar et al. [20] and some modifications based on Bhubalan et al. [15]. Total 1 mg of sample was mixed with 1% H2SO4 (1 mL) in a test tube. The mixture was then added into 2 mL of methanol followed by 1 mL of toluene (C_8H_8) before leaving the mixtures overnight at 50°C. Then the

samples were washed with 5 mL of 5% sodium chloride (NaCl) in distilled water using pipette. After washing, 5 mL of hexane was used to extract the fatty acid methyl ester (FAME). The extraction was performed twice to ensure all the FAMEs were extracted. The hexane layer was washed using 2 mL of 2% NaHCO3 solution and dried with anhydrous sodium sulphate (Na_2SO_4). Prior to GC analysis, samples were weighed and diluted with hexane. The GC-FID parameter setting is done according to previous study as reported by Bhubalan et al [15].

Results and Discussion

Degradation of CPO and CPKO using natural seawater collected from Klang Port

Based on Figure 2, it can be noted that, the bacterial counts were increasing over the 42 day of experiment excluding the sudden drop at day 14. The colony count with aniline (AR, BR) as test substance dropped sharply from day 28 compared to other test substances. Table 1 shows the degradation of test substances in percentage of DOC removal where 70% DOC removal is needed for a substance to be concluded to have potential biodegradation ability in marine environment. Based on the results obtained, only aniline (1 g L^{-1}) [AR, BR] achieved more than 70% DOC removal. The CPO (1 g L^{-1}) [A1C1 B1C1] CPO (10 g L^{-1}) [A1C2, B1C2], CPKO (1 g L^{-1}) [A2C1, B2C1] and CPKO (10 g L^{-1}) [A2C2, B2C2] showed a negative trajectory on regards of DOC removal which is an interesting observation.

The metagenomic results of bacterial population at the start of the experiment shows a diverse bacterial population compared to the bacteria isolated at the end of 42 days of experiment (Figure 3). The genus of isolated bacteria was present in the metagenomic results indicating their presence in the beginning of the experiment. A total of four phenotypically different bacteria were isolated. Table 2 shows the nucleotide BLAST results of these bacteria. The isolated bacteria were *Microbacterium* sp. 1204, *Vibrio fluvialis* NCTC 11327, *Oceanobacter* sp., and *Thalassospira profundimaris* WP0211.

Table 2. BLAST matches against NCBI-database of 16S rRNA sequences obtained from bacterial sequences

Bacterial Isolate	Accession No.	Identification Result	Similarity (%)	Query Cover (%)

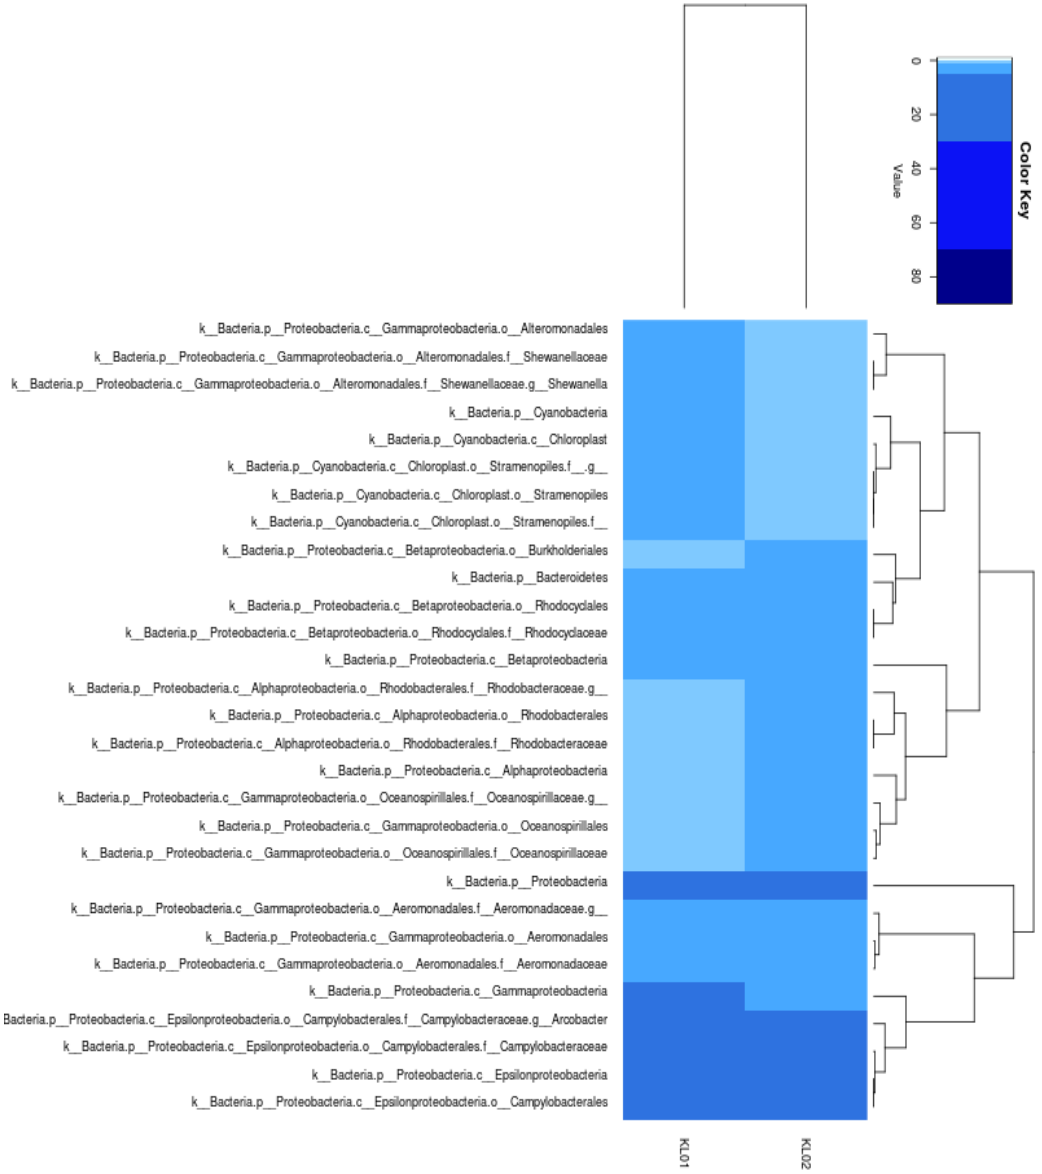

Figure 3. Metagenomic result of bacterial population at genus level of water sample collected at Klang Port

Degradation of palm oil and its derivatives using cultivated marine bacteria *P. aeruginosa* UMTKB-5

Figure 4 shows the CFU (log CFU/mL) count of *P. aeruginosa* UMTKB-5 supplemented with different substrate. The bacterial growth generally increased from day 0 to day 4 but decreased at day 8. The CPO and CPKO were the only two carbon substrates showing highest log CFU/mL on Day 4 (9.426 ± 0.6703 and 9.434 ± 0.7358, respectively) but by comparing Day 0 log CFU/mL between CPO and CPKO, it was clear that bacteria showed more growth in CPO to achieve similar log CFU/mL to CPKO at Day 4. The RBDPO and RBDPL had very little bacterial growth where log CFU/mL at Day 4 was 8.236 ± 0.2386 and 8.297 ± 0.9197 respectively.

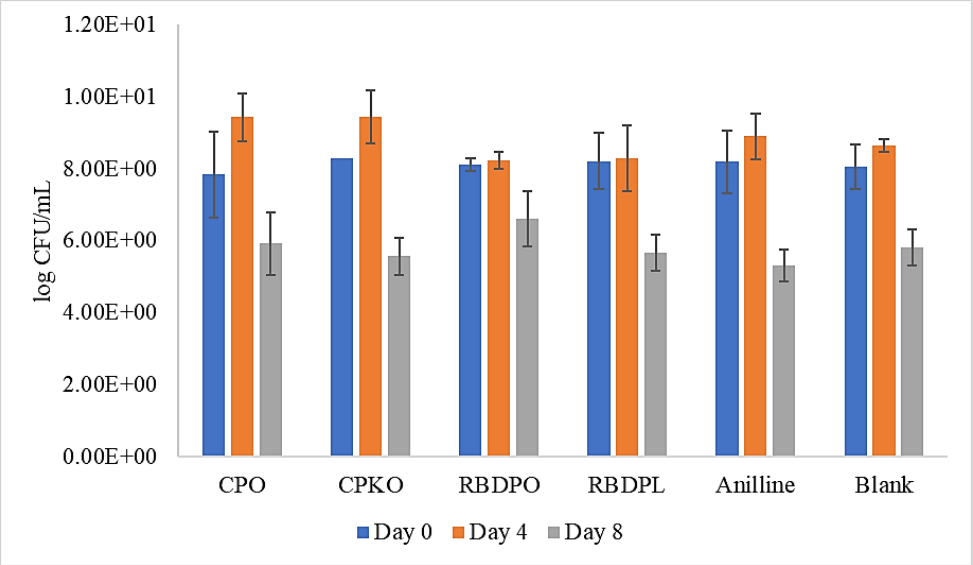

Figure 4. CFU count of *P. aeruginosa* UMTKB-5 cultured in test substances for Day 0, 4 and 8

Based on Figure 5, it can be noted that all the palm oil substrates tested were utilised. However, among all the substrate CPO was utilised the most where 83.37% of CPO initial weight added is lost. CPKO had the most of amount of residual oil remaining (69.3%) indicating lesser utilisation by *P. aeruginosa* UMTKB-5.

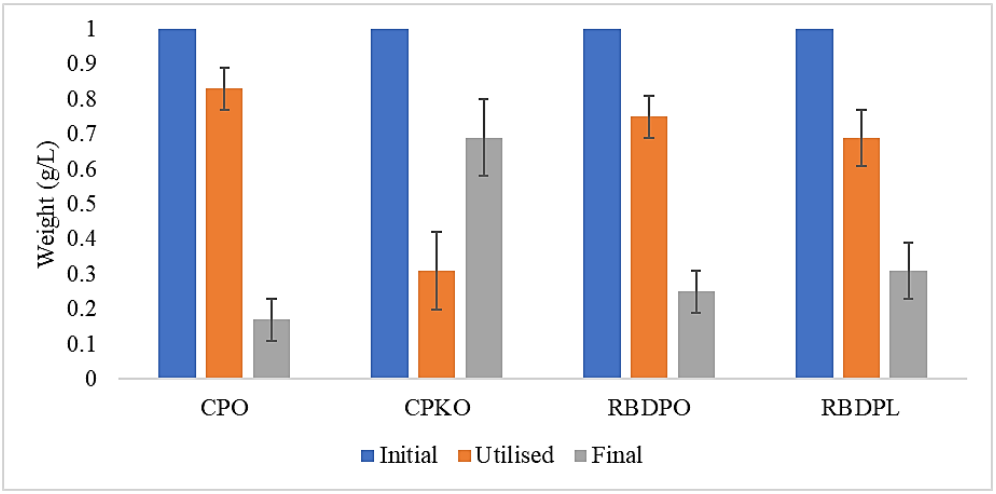

Figure 5. Residual oil measurement of carbon substrate left after the eight-day utilisation

Palmitic acid (C16:0) was detected in all the carbon substrate (Figure 6). Meanwhile, capric acid (C10:0), caprylic acid (C8:0) and caproic acid (C6:0) was found exclusively in CPKO. Palmitic acid in RBDPO and RBDPL were not detected after the utilisation. Concentration of palmitic acid in CPO decreased by 21.6%. Capric acid in CPKO was observed only before utilisation. After the 8-day incubation, both caprylic acid and caproic acid showed a decrease in concentration (37.1% and 6.98%, respectively).

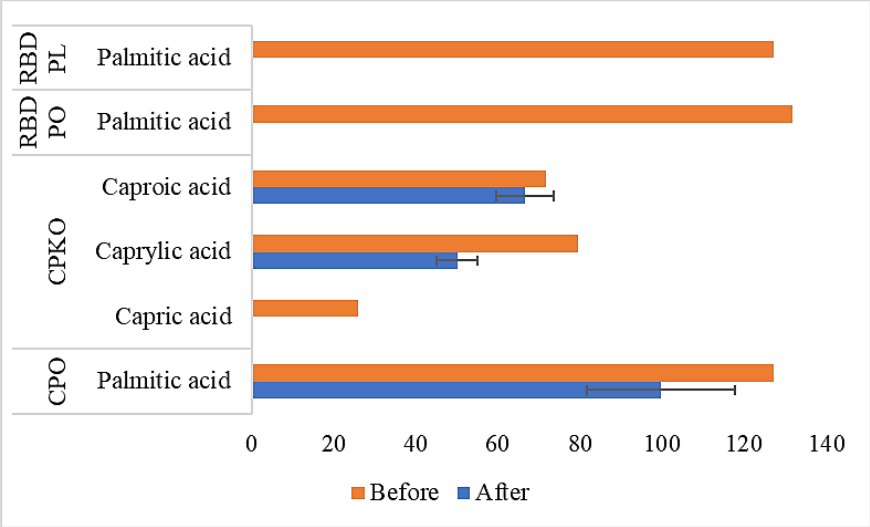

Figure 6. Fatty acid composition of all carbon substrates before and after utilisation by *P. aeruginosa* UMTKB-5

All the culture broth where palm oil derivatives supplemented as carbon substrate to *P. aeruginosa* UMTKB-5 able to exhibit emulsification activity (Figure 7). The CPO containing culture broth was able to exhibit emulsification activity at day 1,4 and 8. However, CPKO, RBDPL and RBDPO containing culture broth was able to exhibit emulsification activity only once. Furthermore, at day 4, RBDPL exhibited the highest emulsification index (E24) [12.28 ± 1.75%] compared to other palm oil derivatives tested.

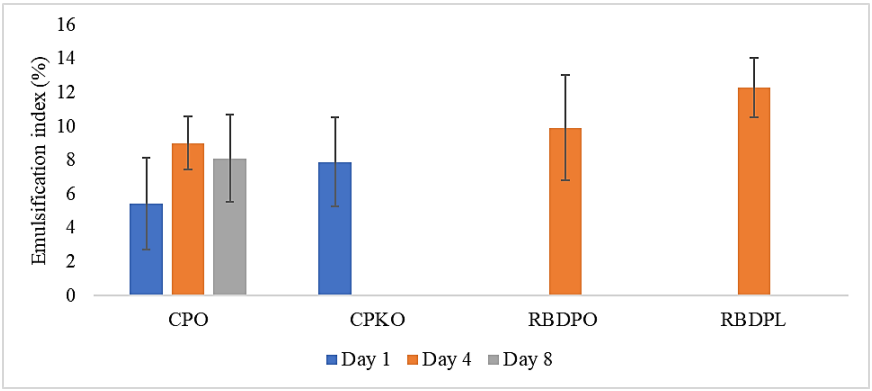

Figure 7. Emulsification index (E24) of selected carbon substrates test substances for Day 1, 4 and 8

Vegetable oil spill in the marine environment has been reported as early as 1975 where palm oil and coconut spilled near coral reef area of Fanning Atoll, Kiribati [21]. Since then, more incidents of vegetable oil spill have been reported and their environmental impacts were investigated. Mudge reported that vegetable oil spilled in the marine environment could pose lethal and sub-lethal effects towards organisms [22]. However, Mudge further reported that naturally occurring marine bacteria can degrade the vegetable oil whilst being in an unpolymerized state [22].

The assessment of ex-situ degradation of CPO and CPKO using Klang Port water showed some interesting

results where the bacterial count increased over the 42 days of experiment but the DOC removal (%) showing a negative trend. This modified experimental design based on OECD TG 306 method was intended to observe the degradation pattern in cases of large amount of oil spill where 1 g L^{-1} and 10 g L^{-1} of test substance was supplemented instead of 5 to 40 mg L^{-1} range proposed by the OECD method [11]. However, the fluctuations in DOC removal rate (%) along with bacterial counts indicates that there is utilisation of CPO and CPKO as carbon substrate and degradation of those palm oil is occurring. Despite not achieving 70% of DOC removal as set by OECD guideline, the negative result does not indicate that the substance is non-biodegradable but a more sophisticated confirmatory is needed [23].

The research by Al-Darbi et al. studied the biodegradation of natural oils namely canola oil, mustard oil, and olive oil in seawater [24]. In regard to the bacterial counts, they reported similar observation where bacterial counted increased over time in oil contaminated samples. However, the bacterial counts differed based on the type of oil tested. Canola oil had the highest bacterial count (500 000 CFU/mL) in fortified seawater at day 15 compared to other oil type. Thus, they concluded that canola oil degraded easily followed by mustard, cod and olive oil. The structure of oil in terms of length of carbon chain and number and location of double bond influences the degradation process [24].

Formation of white and yellow particles were noticed during the degradation study. According to Al-Darbi and colleagues [24], the white particles are saponified oil that reacted with sodium, potassium and calcium that are present in seawater to produce fatty acid salts. Similar observations are made by previous studies when seawater interacted with sunflower oil, canola oil and palm olein to form solid white polymer [15,24,25]. Furthermore, Mudge added that polymerised oils will reduce the natural biodegradation rate [22].

The presence of the isolated bacteria before and after the 42 days of experimentation shows their ability of survive, utilise CPO and CPKO as carbon substrate and to degrade them. Different bacteria species of the same genus were obtained in this study as from study conducted by Bhubalan et al., where *Vibrio fluvialis* was isolated in this study while *V. harveyi* and *V. alginolyticus* was isolated by Bhubalan et al. [15]. Variation and concentration of microbial communities due to origin of water sample influences the biodegradation process as presence of competent degrader is essential [23,26].

P. aeruginosa UMTKB-5 is a rhamnolipid biosurfactant-producing bacteria that was isolated from marine sediment. Previously, different *P. aeruginosa* strains were reported being able to utilise palm oil as substrate for growth and to produce biosurfactant. Palm oil were supplemented as carbon source for *P. aeruginosa* IFO3924 and *P. aeruginosa* A41 to produce rhamnolipid [27,28]. The ability of biosurfactant-producing bacteria is crucial is bioremediation effort of oil spill. Rhamnolipid application can be useful in degradation of oil due to their emulsifying property. In the presence of biosurfactant the rate of biodegradation of organic compounds is increased due to increased solubility [29]. The increased solubility enables microorganisms to be more accessible to the compounds. In the utilisation study of different palm oil derivatives by *P. aeruginosa* UMTKB-5, the increased bacterial counts were reflected by the reduced residual oil obtained at the end of day 8 of experiment as well as the emulsification index (E_{24}) value obtained. Furthermore, the changes in the concentration of fatty acid (ppm) composition indicates the utilisation of palm oil by *P. aeruginosa* UMTKB-5.

The utilisation of palm oil derivatives by bacteria as carbon substrate fuelled the population growth. Studies by Bhubalan et al. [15] along with Al-Darbi et al. [24] reported the similar trends where the bacterial counts increased over time when supplemented with RDB palm olein and canola oil respectively. However, the bioremediation of oil spill using biosurfactant producing bacteria is more focused on hydrocarbon-based oil spill [29]. The summary of findings of this study and other comparable literature is summarised in Table 3 below.

Table 3. Summary of research findings and comparison with other literature

Oil Type	Findings	Reference
CPO and CPKO	• Bacterial population increased over 42 days with population number peaking on day 7 and 21. • Increase in DOC level thorough input of carbon from bacterial degradation of oil.	This study
CPO, CPKO, RBDPO, RBDPL	• Degradation by rhamnolipid-producing bacteria increased the bacterial population. • Presence of rhamnolipid increased the degradation process and decrease in fatty acid concentration indicted the utilisation of palm oil as substrate by bacteria.	
Canola Oil, Mustard Oil, Olive Oil	• Increase in bacterial population in oil exposed seawater with population count highest on day 15. • Chemical structure of oil influences the degradability of oil with shorter chain oil more susceptible to degradation. • Formation of white and yellow particles that are saponified oil due to polymerisation.	[24]
RBD Palm Olein	• Growth of bacterial population in oil exposed sample. • Decreased in fatty acid composition of palmitic acid (C16:0), stearic acid (C18:0) and oleic acid (C18:1)	[15]
Palm oil (commercial product)	• *P. aeruginosa* IFO3924 utilised palm oil for bacterial growth and synthesis of rhamnolipid.	[27]
Palm oil	• Rhamnolipid production by *P. aeruginosa* A41 by utilisation of palm oil as carbon feedstock.	[28]

This study serves as preliminary study into the potential application of biosurfactant in bioremediation of vegetable oil thus more detailed study in needed.

Conclusion

As the increasing demand for palm oil increases the potential risk of spillage occurring in the marine environment, there is a need to understand the degradation potential of the palm oil. This study shows that naturally occurring marine bacteria can utilise different palm oil derivatives as substrates for growth and subsequently degrade them. Furthermore, the isolated bacteria were able to survive for an extended period in palm oil enriched environment indicating their potential as degrader. *P. aeruginosa* UMTKB-5 a biosurfactant-producing oil-degrading bacteria is able to exhibit emulsifying activity in palm oil-exposed water as well as using palm oil as carbon substrate. The emulsifying property could be helpful in bioremediation of oily contamination. However, it is important to investigate the optimum method of deployment.

Acknowledgement

This study was supported by Fundamental Research Grant Scheme [FRGS] [FRGS/1/2017/WAB09/UMT/02/2] awarded by Ministry of Higher Education, Malaysia. The authors would like to acknowledge MPOB for providing the palm oil that was used in this study. Furthermore, we would like to thank Jabatan Laut for providing us support in accessing the port area. The authors thank Tan Suet May Amelia for proofreading and formatting the manuscript.

Abstract

Palm oil is one of the potential renewable resources in biolubricant production. However, the direct application of palm oil as a biolubricant base stock is restricted due to some performance limitations such as low oxidative stability. It is due to the presence of oxidation active site β-hydrogen in a glycerol backbone structure. This oxidative drawback can be overcome by molecule structural redesign through a chemical modification process such as esterification with polyhydric alcohol. The esterification of palm oil fatty acids (POFAs) with neopentylglycol (NPG) was carried out in a mole ratio of 2:1, 1% of sulphuric acid, reaction temperature of 145 °C and reaction time of 4.56 hours. Gas Chromatography equipped with a Flame Ionization Detector (GC-FID) was used to determine the ester composition in Neopentylglycol Diester (NPGDE). The structure of NPGDE was confirmed by Fourier Transformation Infra-Red (FTIR), proton and carbon Nuclear Magnetic Resonance (^{1}H-NMR and ^{13}C-NMR) spectroscopy. Results showed that the percentage yield of NPGDE was 90% and NPGDE existed in liquid form at room temperature. NPGDE was successfully synthesised with 100% composition of diesters. The existence of the ester functional group is evidenced by FTIR at 1738 cm^{-1}, the chemical shift of ^{1}H NMR at 2.29-2.33 ppm and ^{13}C NMR at 173.71 ppm. Physicochemical properties analysis showed that NPGDE has oxidative stability at 184 °C, pour point at 10 °C, flash point at 235 °C and 160-viscosity index which makes NPGDE plausible to be used in lubrication applications.

Keywords: esterification, neopentylglycol, oxidative stability, palm oil fatty acids

Abstrak

Minyak sawit merupakan salah satu sumber boleh diperbaharui yang berpotensi untuk digunakan dalam penghasilan biopelincir. Walau bagaimanapun, penggunaan minyak sawit secara terus sebagai stok asas biopelincir adalah terhad disebabkan oleh had prestasi seperti kestabilan oksidatif yang rendah. Ini disebabkan oleh kehadiran tapak aktif pengoksidaan β-hidrogen dalam struktur

tulang belakang gliserol. Kelemahan oksidatif ini boleh diatasi dengan melakukan ubahsuai struktur molekul melalui proses pengubahsuaian kimia seperti pengesteran dengan alkohol polihidrik. Pengesteran asid lemak minyak sawit (POFAs) dengan neopentilglikol (NPG) telah dijalankan pada nisbah mol 2:1, 1% asid sulfurik, suhu tindak balas 145 °C dan masa tindak balas 4.56 jam. Kromatografi gas dengan pengesan nyala pengionan (GC-FID) digunakan untuk menentukan komposisi ester dalam Diester Neopentilglikol (NPGDE). Struktur NPGDE disahkan dengan menggunakan spektroskopi infra-merah transformasi Fourier (FTIR), resonans magnetik nuklear proton dan karbon (^{1}H-NMR dan ^{13}C-NMR). Keputusan menunjukkan bahawa peratusan hasil NPGDE ialah 90% dan NPGDE wujud dalam bentuk cecair pada suhu bilik. NPGDE telah berjaya disintesis dengan 100% komposisi diester. Kehadiran kumpulan berfungsi ester dibuktikan melalui FTIR pada 1738 cm^{-1}, anjakan kimia ^{1}H NMR pada 2.29-2.33 ppm dan ^{13}C NMR pada 173.71 ppm. Analisis sifat fizikokimia menunjukkan bahawa NPGDE mempunyai kestabilan oksidatif pada 184 °C, takat tuang pada 10 °C, takat kilat pada 235 °C dan indeks kelikatan 160 yang menjadikan NPGDE sesuai untuk digunakan dalam aplikasi pelinciran.

Kata kunci: pengesteran, neopentilglikol, kestabilan oksidatif, asid lemak minyak sawit

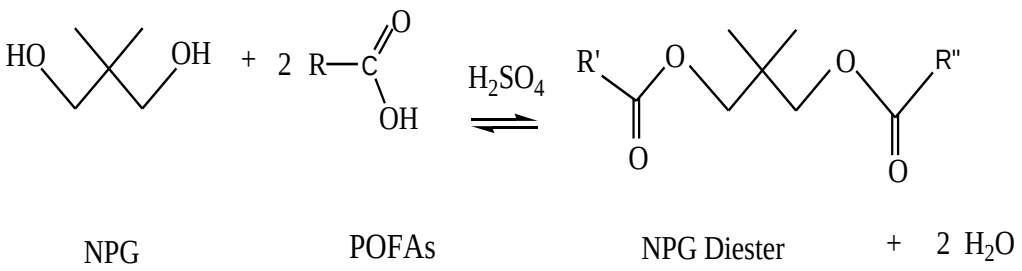
Introduction

In the field of lubricants, there are wide ranges of lubricant base oils used which include mineral oils, synthetic oils, re-refined oils and plant oils. Among these, mineral oils are the most commonly used [1]. Mineral oil is stable, readily available and exists in a wider range of viscosities [2]. However, they pose a constant threat to ecology and vast groundwater reserves due to their inherent toxicity and non-biodegradable nature [1, 3]. The reduction of petroleum oil resources and increasing greenhouse gas emissions give a clear picture of the importance of the move towards sustainable development [4]. The use of renewable sources in the industry is vital to ensure sustainable development. These include studies on plant oils as feedstock in the manufacture of products for daily use.

Plant oils are not only renewable resources but also cheaper, biodegradable and non-toxic, unlike conventional mineral-based oils [1, 5]. As a lubricant, they also exhibit excellent lubricity and high viscosity index, which are being more closely examined as base stock for lubricants and functional fluids [6-8]. Biolubricants hold great potential for environmental conservation as an alternative lubricant. The global market size for biolubricants was USD 2.20 billion in 2019 and is projected to reach USD 2.46 billion by 2025, at a compound annual growth rate (CAGR) of 4.1% between 2020 and 2025 [9, 10]. Stringent regulations and the growing acceptance among end-users are projected to drive the biolubricants market [9, 10].

However, plant oils have some drawbacks such as poor thermal and oxidative stability which restrict their direct application as a lubricant [2, 8, 11, 12]. It is because of the existence of oxidation active sites β-hydrogen in glycerol backbone structure and double bonds in the unsaturated fatty acid structure that will make palm oil becomes easily damaged at high temperature. The β-hydrogen is easily removed from triacylglycerol molecules and it will form acid and olefin (unsaturated compounds). The resulting unsaturated compounds will undergo polymerization and will cause the formation of precipitate that will increase the viscosity of plant oil [13].

Chemical modification of plant oils becomes one of the attractive ways to solve these problems by replacing glycerol with polyhydric alcohols such as neopentylglycol (NPG), trimethylolpropane (TMP) and pentaerythritol (PE) through esterification. The advantage of using polyhydric alcohol is the absence of β-hydrogen which enhances the thermal and oxidative stability of the lubricant at high temperatures [14-16]. Recently, palm oil which is abundantly available all over Malaysia become one of the potential plant oils that can be used as biolubricant base stock [17, 18]. There are many studies reported on the production of biolubricant from palm oil and polyhydric alcohols.



The production of biolubricant via transesterification of palm oil methyl ester (POME) with trimethylolpropane (TMP) was reported by Yunus et al. [19]. TMP is polyhydric alcohol that has three hydroxyl groups. The transesterification of POME and TMP was carried out in a mole ratio of 3.9:1, a reaction temperature of 120 °C, a reaction time of 1 hour, 20 mbar of pressure and 0.8%

of sodium methoxide catalyst has successfully produced 98% palm oil TMP triesters. Sulaiman et al. [20] also reported the optimization of transesterification of POME and TMP. The optimum conditions obtained were a 3.8:1 mole ratio, a reaction temperature of 120 °C, a reaction time of 2 hours, 20 mbar of pressure and 0.9% of sodium methoxide catalyst. At these optimum conditions, 86% of palm oil TMP triesters were successfully synthesised. In 2013, Salih et al. [21] reported the esterification between palm kernel oil fatty acids (PKOs) with TMP in a mole ratio of 4:1, a reaction temperature of 150 °C, a reaction time of 5 hours and 1% of sulphuric acid as catalyst. Results showed that a 68% yield of TMP ester was successfully synthesised with good lubrication properties such as high flash point (over 300 °C), low pour point (3 °C) and high viscosity index (157).

In 2014, Aziz et al. [22] reported the production of biolubricant through transesterification between POME and pentaerythritol (PE). PE is polyhydric alcohol with four hydroxyl groups. The transesterification process was carried out in a mole ratio of 4.5:1, reaction temperature of 158 °C, reaction time of 1 hour and 1.19% of sodium methoxide catalyst. The transesterification has produced a 40% yield of PE ester which has a flash point at 302 °C and 12.7 cSt viscosity at 100 °C.

Other than TMP and PE, there was also a study using neopentylglycol (NPG) in the production of biolubricant. NPG is a polyhydric alcohol with two hydroxyl groups. Synthesis of neopentylglycol (NPG) ester was reported by Vanitah et al. [23]. Synthesis of NPG ester was carried out via esterification of NPG and oleic acid in a mole ratio of 1:2, reaction temperature of 130 °C, reaction time of 4 hours and 2% sulphuric acid as catalyst. Results showed that an 80% yield of NPG ester was successfully synthesised with oxidative stability at 177 °C, high flash point (200 °C), low pour point (-44 °C) and high viscosity index (227).

In this study, the esterification of palm oil fatty acids (POFAs) with NPG to produce NPG Diester (NPGDE) as shown in Figure 1 is reported. Fatty acid composition of POFAs and NPGDE, as well as ester composition in NPGDE, were analysed by GC-FID, while the structure of NPGDE was confirmed by FTIR and NMR spectroscopy. Physicochemical properties of NPGDE were examined by using several tests such as oxidative stability, pour point, flash point and viscosity index.

R= Mixed palm oil fatty acids (myristic, stearic, palmitic, oleic and linoleic acid)

Figure 1. Esterification of palm oil fatty acids (POFAs) with neopentylglycol

Materials and Methods

Materials

Palm oil was obtained from Jomalina Refinery, Teluk Panglima Garang, Selangor, Malaysia. Neopentylglycol was purchased from Sigma Aldrich. Sulphuric acid, toluene, ethyl acetate, sodium bicarbonate, sodium chloride, sodium sulphate, hydrochloric acid, n-hexane, potassium hydroxide and ethanol were purchased from Systerm.

Hydrolysis of palm oil

The hydrolysis process was conducted by mixing 50 g of palm oil with alkaline ethanol and heated at 60 °C for 2 hours [24]. Then, the mixture was washed with 150 mL of 6N hydrochloric acid, 200 mL of distilled water

and 100 mL of *n*-hexane. The washing process was continued with 100 mL of hexane followed by 50 mL of distilled water until the pH became neutral. The product, palm oil fatty acids (POFAs), was kept overnight by adding anhydrous sodium sulphate. The product was filtered by Whatmann No. 1 filter paper and the solvent used was isolated by rotary evaporator at 70 °C. The product (POFAs) was analysed using GC-FID.

Esterification of POFAs and NPG

The esterification process was conducted by mixing POFAs and NPG at a 2:1 molar ratio. 1% of sulphuric acid and 100 mL toluene were added to the mixture and then heated at 145 °C for 4.56 hours. The product, NPG Diester (NPGDE) was neutralised with sodium hydrogen carbonate solution, sodium chloride solution and ethyl acetate. The product was kept overnight by adding anhydrous sodium sulphate. The product was filtered by Whatmann No. 1 filter paper and the solvent used was isolated by a rotary evaporator at 70 °C. The NPGDE was analysed using Gas Chromatography equipped with a Flame Ionization Detector (GC-FID), Fourier Transformation Infra-Red (FTIR), and proton and carbon Nuclear Magnetic Resonance (^{1}H-NMR and ^{13}C-NMR).

Fatty acid composition analysis

Fatty acid composition of palm oil, POFAs and NPGDE were analysed using GC-FID (column BPX-70). Fatty acid methyl esters (FAMEs) were prepared using two methods: acid-catalysed for POFAs and base-catalysed for palm oil and NPGDE. For acid-catalysed, 1 g of POFAs was weighed into a 250 mL three-neck round bottom flask equipped with a mechanical stirrer, thermometer and reflux condenser. 3.75 mL methanol was added with 0.75 mL reagent mixture (5 mL methanol and 1.25 mL concentrated hydrochloric acid (36.5%)), followed by 0.75 mL of toluene. The mixture was heated at 65 °C for 1.5 hours. The mixture was transferred into a separation funnel. 7.5 mL of hexane and 5 mL of distilled water were added to the mixture. The mixture was allowed to stand to separate two layers. The upper layer was slowly collected and dried using anhydrous sodium sulphate overnight. The sample was filtered and injected into GC for analysis. For base-catalysed, FAME was prepared by mixing 0.1 mL of the palm oil or NPGDE with 1 mL of hexane. 1 mL of sodium methoxide solution (1.55 g NaOH and 50 mL of methanol) was added to the solution and the solution was stirred vigorously using a Vortex stirrer for 10 seconds. The solution was allowed to stand for 10 minutes to separate the clear solution of FAMEs from the cloudy aqueous layer. The upper FAMEs layer was slowly collected and injected into GC for analysis.

NPGDE analysis

Ester composition in NPGDE was determined using GC-FID (column DB-5HT). The sample was prepared by mixing 0.3 µL of NPGDE with 1mL of ethyl acetate. The structure of NPGDE was confirmed using FTIR and NMR analysis. FTIR spectra were recorded on a Perkin Elmer Infrared Spectrophotometer in the range of 500-4000cm^{-1}. ^{1}H and ^{13}C NMR were recorded on JEOL-ECP 400 spectrometer (400 MHz ^{1}H/100.61 MHz^{13}C) using $CDCl_3$ as solvent.

Physicochemical properties tests of NPGDE

The American Society for Testing Materials standards such as ASTM D-6186, ASTM D-5853, ASTM D-92 and ASTM D-2270 were used to measure oxidative stability, pour point, flash point and viscosity index [25]. The oxidative stability test was conducted using Differential Scanning Calorimetry (DSC). 1.5 mg of NPGDE was placed into an aluminium pan with a pinhole cover to allow interaction between ester product and oxygen gas which acted as a reaction gas. Then, the aluminium pan was put into DSC and heated for 20 minutes up to temperatures of 250 °C by using nitrogen gas. Onset temperature was recorded to determine oxidative stability.

In the pour point test, the NPGDE was filled into a U-shaped glass tube until it reached a height of 4 cm. The thermometer was placed at one end of the U-shaped tube and both ends of the U-shaped tube were covered with parafilm. The U-shaped tube containing the sample was placed in the refrigerator (minimum temperature -80 °C) for 24 hours to ensure that the sample froze completely. After being left overnight, the U tube was removed and flipped upside down. The lowest temperature at which movement of the sample was observed was recorded as the pour point.

For flash point testing, 2 mL of NPGDE was placed in a crucible and heated on a heating plate. A thermometer with a maximum reading temperature of 360 °C was placed on the sample to measure the sample's temperature. The temperature was rapidly increased at first and then at a slow constant rate as the flash point was approached. The lowest temperature at which the vapours above the surface of the liquid ignited was taken as the flash point.

For the viscosity index test, the Rheometer Anton Paar (Physica MCR 301 model) was used to measure the viscosity and viscosity index of NPGDE. The diameter used was 0.051 mm. The viscosity of NPGDE was tested at 40 °C and 100 °C. The NPGDE viscosity index was calculated based on the formula below:

$$\text{Viscosity index} = (L-U)/(L-H)\times 100 \quad (1)$$

Where: U = oil's kinematic viscosity at 40 °C. L and H = values based on the oil's kinematic viscosity at 100 °C.

Results and Discussion

Palm oil is golden yellow and exists in the semi-solid form at room temperature. The hydrolysis process has successfully separated 95% of the fatty acids from the glycerol backbone. Figure 2 shows a GC-FID chromatogram of fatty acid compositions in palm oil (a-before hydrolysis) and POFAs (b-after hydrolysis). The percentage composition of fatty acids has been simplified in Table 1. The major fatty acids in POFAs were oleic acid with 43.5%, followed by palmitic acid (42.5%), linoleic acid (9.5%), stearic acid (3.7%) and myristic acid (0.8%). The fatty acid composition of both samples is approximately close to the value of the fatty acid composition of palm oil reported by Chowdhury et al. [26].

The esterification process between POFAs and NPG has successfully produced a 90% yield of NPGDE. Fatty acid compositions in NPGDE are shown in Figure 2(c) and the percentage composition of fatty acids also has been simplified in Table 1. The GC result showed that NPGDE contains 54.2% of saturated fatty acid and 45.8% unsaturated fatty acid. It means that saturated fatty acid which has a straight-chain structure has a higher tendency to react with NPG compared to the bent structure of unsaturated fatty acid due to less steric hindrance.

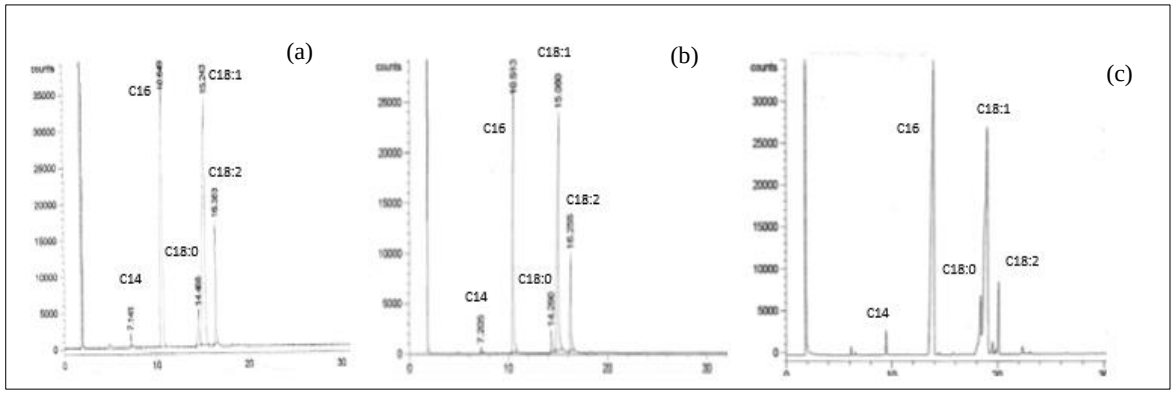


Figure 2. GC-FID chromatogram a) palm oil; b) POFAs; c) NPGDE

Table 1. Fatty acid composition (percentage) of palm oil, POFAs and NPGDE

Fatty Acid Composition	Palm Oil	POFAs	NPGDE	Reference [26]
Myristic acid (C14)	0.6	0.8	1	1.23
Palmitic acid (C16)	41.9	42.5	47	41.78
Stearic acid (C18)	3.6	3.7	6.2	3.39
Oleic acid (C18:1)	44.8	43.5	41.4	41.9
Linoleic acid (C18:2)	9.1	9.5	4.4	11.03

The percentage of ester composition was also determined by GC-FID as shown in Figure 3. In esterification, two types of esters will be produced which are monoesters and diesters. Monoesters will be formed as intermediate products towards the completion of the reaction producing NPGDE diesters. Figure 3 shows that 100% of diesters were produced in NPGDE. It means all hydroxyl groups in NPG were successfully esterified with POFAs. This result was supported by the low hydroxyl value of NPGDE which was 24.68 mgKOH/g compared to the hydroxyl value of NPG which was 1075 mgKOH/g.

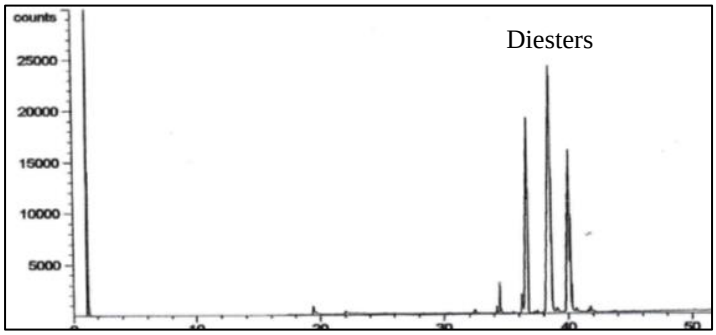

Figure 3. GC-FID chromatogram of NPGDE

FTIR analysis

The formation of ester was confirmed by FTIR analysis. The comparison between FTIR spectra of POFAs (before esterification) and NPGDE (after esterification) is shown in Figure 4. In the FTIR spectrum of NPGDE, there are appearances of the stretching of the C=O ester peak at 1738 cm^{-1} and the stretching of the C-O ester peak at 1161 cm^{-1} and 1241 cm^{-1}. On the other hand, the FTIR spectrum of POFAs shows the stretching of the C=O group of carboxylic acid at 1696 cm^{-1} and the stretching of C-O carboxylic acid at 1291 cm^{-1} and 1247 cm^{-1}. The shift in wavenumbers for both spectra showed that POFAs have been successfully esterified with NPG to form NPGDE. In addition, the -OH peak which initially exists in the POFAs spectrum (2400-3400 cm^{-1}) is no longer visible in the NPGDE spectrum.

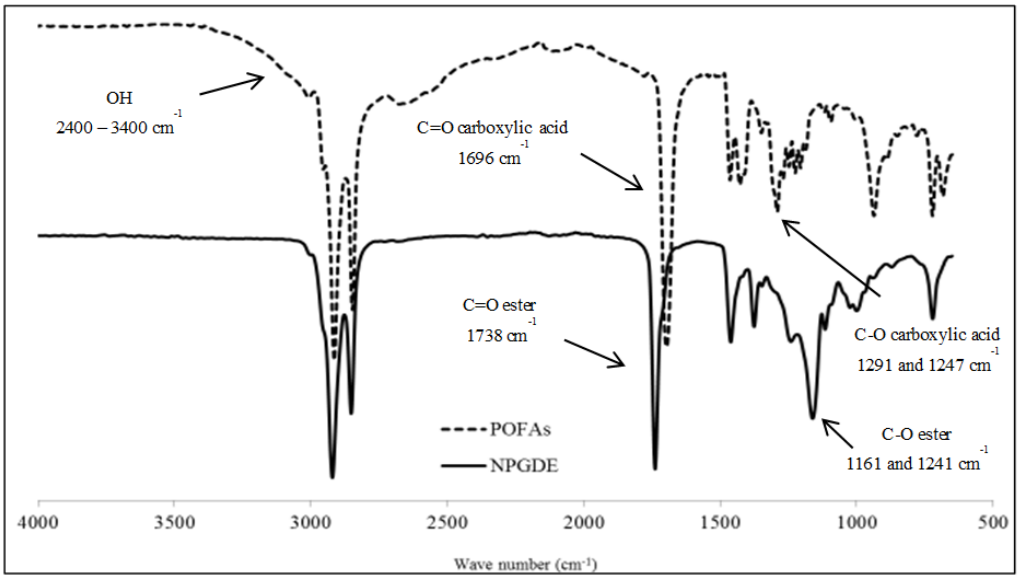

Figure 4. FTIR spectra of POFAs and NPGDE

NMR spectroscopy

NPGDE structure was also analysed using NMR spectroscopy. Figure 5 shows the ^{1}H NMR spectrum of NPGDE. In the ester structure, there are two types of protons which are the proton of C**H**$_2$-O and the proton of C**H**$_2$-C=O. The proton of C**H**$_2$-O for NPGDE was detected at 3.88 ppm and the proton of C**H**$_2$C=O was detected at 2.29-2.33 ppm. These values are in agreement with the reference which is a chemical shift for proton C**H**$_2$-O is 3.5- 4.8 ppm, while the chemical shift for proton C**H**$_2$C=O is at 2.1- 2.5 [27]. NPGDE consists of a mixture of acyl groups such as myristate, palmitate, stearate, oleate and linoleate. The presence of unsaturated fatty acids was determined by the identification of the alkene group. In the alkene group, there are two types of protons which are protons of double bond (-C=C-**H**) at chemical shift 4.5-6.5 ppm and proton of methylene group which bound to double bond (-C=C-C-**H**) at chemical shift 1.6-2.6 ppm [25]. Figure 5 shows the existence of both protons at chemical shifts 5.32-5.37 ppm (-C=C-**H**) and 1.95-2.03 ppm (-C=C-C-**H**). This spectrum also shows there is no signal detected for the hydroxyl group which means all hydroxyl groups have reacted with fatty acids.

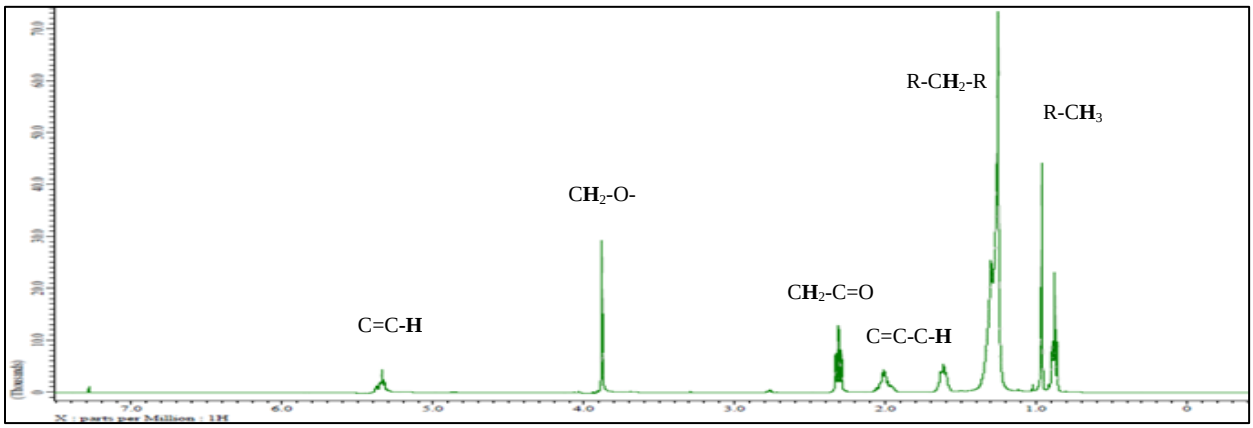

Figure 5. ^{1}H NMR spectrum of NPGDE

Figure 6 shows the ^{13}C NMR spectrum of NPGDE. The existence of ester carbon carbonyl (**C**=O) in NPGDE was detected at a chemical shift of 173.71 ppm. This value was in agreement with Pavia et al. [27] who showed that the chemical shift for carbon carbonyl ester (**C**=O) was in the range of 155-185 ppm. The signal peak for carbon **C**-O which bound fatty acid to NPG was detected at a chemical shift of 68.96 ppm. The presence of both carbons indicates the presence of an ester bond between POFAs and NPG which forms NPGDE. The quaternary carbon for NPGDE $(CH_3)_2$-**C**-$(CH_2OCOR)_2$ was detected at 34.59 ppm and this value was in agreement with the reference which was 20-60 ppm [27]. The alkene group (**C**=**C**) in NPGDE was detected at chemical shift 127.87-130.51ppm and this value was in agreement with the reference which was 100-150 ppm [27]. This spectrum also shows there is no signal detected for the hydroxyl group.

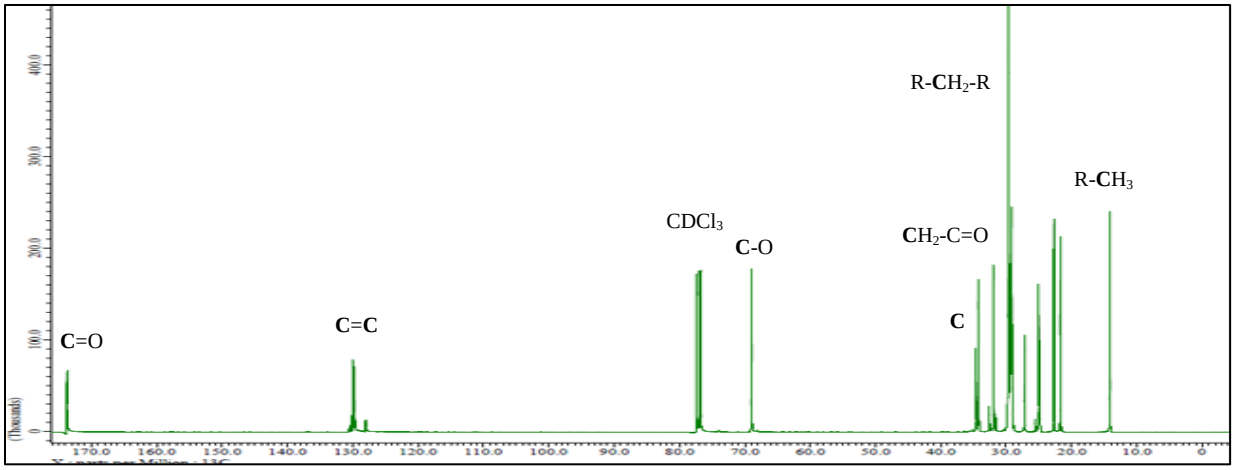

Figure 6. ^{13}C NMR spectrum of NPGDE

Physicochemical properties of NPGDE

The quality of biolubricant depends on various physicochemical properties such as oxidative stability, pour point, flash point, viscosity and viscosity index. Modification of the oil structure has influenced the properties of biolubricant. The physicochemical properties results obtained are shown in Table 2.

The ability of a substance to resist oxidative degradation is an important property of biolubricant. NPGDE was analysed using Differential Scanning Calorimetry (DSC) to measure its oxidative stability by determination of onset temperature (OT). A higher onset temperature indicates that the lubricant has high oxidation stability [2]. In this study, NPGDE possesses good oxidative stability with a high onset temperature at 184 °C. It is due to its high percentage of saturated fatty acid (54.2%). Reduction of unsaturated fatty acid will reduce oxidation active site; thus it will make NPGDE more stable in high temperatures.

Pour point is one of the important quality parameters to determine the cold flow properties of the lubricant. NPGDE has a high pour point (10 °C) due to the high saturated fatty acid content. High saturated fatty acids content has caused lubricant tends to form macrocrystalline structures through uniform precipitation at low temperatures. Flash point is often used as a descriptive characteristic of fuel oil and it is also used to describe oils that are not used as fuels such as a lubricant. NPGDE ester showed a high flash point at 235 °C. A high flash point value is important to ensure that the biolubricant is not burned in the engine during its operation [2].

Viscosity has also become one of the most important quality parameters for lubricating oils. The efficiency of the biolubricant in reducing friction and wear is greatly influenced by its viscosity. The least viscous biolubricant which still forces the two moving surfaces apart is desired. If the biolubricant is too viscous, it will require a large amount of energy to move and if is too thin, the surfaces will rub each other and friction will increase [2]. The viscosity of NPGDE was in the medium range which was 50.07 centistokes (cSt) at 40 °C and decreased to 11.47 cSt at 100 °C. The viscosity of oils decreases as temperature increases [2]. The viscosity index highlights how the viscosity of biolubricant changes with variations in temperature [2]. NPGDE has high viscosity index which is 160 compared to palm oil (130). It shows the viscosity of NPGDE is less affected by temperature changes and does not drastically change when the temperature varies. This is a good indicator and suggests its suitability for use in a large temperature range.

Table 2 also shows a comparison of lubrication properties between the biolubricant base stock produced (NPGDE) with commercial lubricants in the market. The selected commercial lubricants are ISO VG 100 grade lubricants, namely Denicol Compressor Oil

(100A) [28] and SubsTech Hydraulic Oil (100B) [29]. Based on the comparison made, NPGDE has a higher viscosity index compared to 100A and 100B lubricants.

Table 2. Physicochemical properties of palm oil and NPGDE.

Physicochemical properties	Palm oil	NPGDE	100A[a]	100B[b]
Oxidative stability (°C)	181	184	n/a	n/a
Pour point (°C)	7	10	-19	-27
Flash point (°C)	240	235	276	254
Kinematic viscosity at 40 °C	56.97	50.07	96	96.7
Kinematic viscosity at 100 °C	9.24	11.47	10.9	11
Viscosity index (VI)	130	160	97	100
ISO viscosity grade	46	46	100	100

a: 100A: Denicol Compressor Oil ISO VG 100 [28], b: SubsTech Hydraulic Oil ISO 100 [29]

Conclusion

Neopentylglycol Diester (NPGDE) was successfully synthesised from palm oil fatty acids and neopentylglycol with 90% of yield and 100% of diesters composition. NPGDE showed good lubrication properties which are having high oxidative stability and high viscosity index compared to palm oil. The removal of β-hydrogen in palm oil and replacing polyhydric alcohol in NPGDE has successfully increased the lubricity properties. This makes NPGDE plausible to be used as a biolubricant.

Abstract

Tea (*Camellia sinensis*) is among the most popular non-alcoholic beverages consumed daily in the world due to its unique taste and flavor. Tea leaves and their products have obtained significant attention because of their high antioxidant capacities. In this study, the analytical methods based on the molecular absorption spectrophotometric principle were evaluated for determining the Trolox equivalent antioxidant capacities (TEACs), including 2,2'-Azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) radical scavenging activity, ferric reducing antioxidant power (FRAP), and cupric reducing antioxidant capacity (CUPRAC) in several commercial dried tea products originated from Lam Dong Province (Vietnam). Double liquid extraction in a water bath at 70 ℃ (10 min for each extraction cycle) was employed to obtain the extracts for further colorimetric reactions. The results demonstrate low limits of detection and quantification (12.3-37.3 µmol TE/L, 9.9-30.1 µmol TE/L, and 11.8-35.7 µmol TE/L for ABTS, FRAP, and CUPRAC, respectively), wide working ranges (100-700 µmol TE/L), favorable repeatability (RSD_r of 1.03-1.52%), reproducibility (RSD_R of 1.26-1.55%), and acceptable recoveries (98.0-101%) according to Appendix F of AOAC (2016). The Shewhart charts were also constructed based on the UV-Vis 1800 Shimadzu (Japan) from 21 separate working days to control the accuracy and precision of the analytical results. For tea products in Lam Dong, the TEACs of all samples in the descending order were determined as green tea > oolong tea > black tea, which could be mainly due to the differences in the oxidation levels during the fermentation. In addition, strong correlation was recorded for pairs of FRAP-CUPRAC (R^2 = 0.8579), ABTS-FRAP (R^2 = 0.8453), and ABTS-CUPRAC (R^2 = 0.710).

Keywords: tea, antioxidant capacities, 2,2'-Azino-bis(3-ethylbenzothiazoline)-6-sulphonic acid radical scavenging activity, ferric reducing antioxidant power, cupric reducing antioxidant capacity

Abstrak

Teh (*Camellia sinensis*) merupakan minuman tak beralkohol popular yang diambil setiap hari di seluruh dunia kerana keunikkan rasanya. Daun teh dan produknya mendapat perhatian penting kerana mempunyai kapasiti antioksida yang tinggi. Dalam kajian

ini, kaedah analisis berasaskan prinsip spektrofotometrik serapan molekul telah dinilai bagi penentuan kapasiti antioksida setara Trolox (TEACs), termasuk cerakin pemerangkapan radikal 2,2'-Azino-bis(3-etilbenzothiazolin-6-asid sulfonik) (ABTS), kuasa antioksida penurunan ferik (FRAP) dan kapasiti antioksida penurunan kuprik (CUPRAC) di dalam pelbagai produk teh komersial berasal dari wilayah Lam Dong (Vietnam). Pengekstrakan cecair cecair di dalam rendaman air pada suhu 70 °C (10 min bagi setiap kitaran pengekstrakan) telah dibangunkan bagi tujuan memperolehi hasil ekstrak sebelum tindak balas kolorimetrik. Hasil menunjukkan had pengesanan dan pengkuantitian rendah (12.3-37.3 µmol TE/L, 9.9-30.1 µmol TE/L,dan 11.8-35.7 µmol TE/L masing-masing bagi ABTS, FRAP, dan CUPRAC), julat kelinearan (100-700 µmol TE/L), kebolehulangan (RSD_r of 1.03-1.52%), kebolehasilan semula (RSD_R of 1.26-1.55%), dan perolehan semula (98.0-101%) berdasarkan Appendix F AOAC (2016). Carta Shewhart telah dibangunkan berdasarkan UV-Vis 1800 Shimadzu (Jepun) dari 21 hari bekerja berbeza bagi mengawal ketepatan dan kejituan hasil analisis. Bagi produk teh Lam Dong, nilai TEACs semua sampel di susun tertib menurun iaitu teh hijau > teh oolong > teh hitam, disebabkan oleh perbezaan tahap pengoksidaan semasa penapaian. Tambahan lagi, hubungkait yang kuat direkodkan bagi pasangan FRAP-CUPRAC (R^2 = 0.8579), ABTS-FRAP (R^2 = 0.8453), dan ABTS-CUPRAC (R^2 = 0.710).

Kata kunci: teh, keupayaan antioksida, ,2'-Azino-bis(3-etilbenzothiazolin-6-asid sulfonik), kuasa antioksida penurunan ferik, kapasiti antioksida penurunan kuprik

Introduction

Antioxidants are known as any substances capable of slowing or preventing the oxidation of easily oxidized components [1]. In addition, they have been commonly used in food production to limit the deterioration in food quality and maintain nutritional values, in which the antioxidants can slow lipid oxidation by inhibiting the initial free radical formation or preventing the generation of free radicals [2]. Plants and food products containing high contents of antioxidants perform great biological benefits since they are reported to have the ability to protect the animals' and humans' bodies against oxidizing agents, such as reactive oxygen, nitrogen, and chlorine species [3]. Dietary antioxidants generally belong to the family of phenolic and polyphenolic compounds. The phenolic compounds occurring in foods are in the phenylpropanoid (C6-C3) family and are also the derivatives of cinnamic acid. The condensation of C6–C3 compounds through the participation of malonyl coenzyme A leads to the formation of chalcones, which can then cyclize under acidic conditions to produce flavonoids and isoflavonoids. The antioxidant activity of flavonoids is significantly dependent on the number and position of hydroxyl groups in the molecule structures [2]. In tea leaves and their products, the antioxidant activity is mainly due to the combination of aromatic rings and hydroxyl groups incorporating their chemical structures, thereby binding and neutralizing lipid free radicals basically by these hydroxyl groups. The antioxidant compounds in tea, including catechins, inhibit the formation of lipid peroxides by binding lipid alkoxyl radicals. Such activity depends on the structure of the molecules, and the number and position of the hydroxyl groups in the molecule. Specifically, the –OH groups at the 3'-, 4'-, and 5'- positions in the B-ring of flavonoids would increase the value of the measured antioxidant capacities. Sample matrices containing the vast majority of simple phenolic compounds with only one hydroxyl group exhibit lower antioxidant activity [4, 5]. The catechin compounds in green tea also exhibit antioxidant capacities through the inhibition of pro-oxidant enzymes and the formation of antioxidant enzymes. The antioxidant capacities generally show a general trend as follows: green tea > oolong tea > black tea [2].

Food contains macronutrients such as carbohydrates, proteins, and lipids as well as trace elements such as minerals and vitamins. These components with the potential to interact with antioxidant compounds are present at various concentrations in the sample matrices and performed different activity behaviors. Therefore, the antioxidant capacities of food products obtained from a single chemical reaction mechanism do not provide adequate information due to the diversity of the chemical compositions in different samples, which may influence the results [2, 6, 7]. Moreover, there have been no officially published standardized methods for determining the antioxidant capacities of any food in general, and tea products in specific. Thus, there are discrepancies in the extraction and analytical methods presented in different papers. The performance of the analytical method in determining the antioxidant capacities based on different mechanisms of chemical

reaction in a specific food product should be evaluated to be applied in routine analysis and research activities. The determination of antioxidant capacities based on molecular absorption spectrophotometry is considered as one of the most effective approaches to assess and compare the general information about the antioxidant activity in various foods and drinks. Particularly, the changes in antioxidant capacities can occur when foods undergo processing and storage periods [2, 7, 8]. However, the antioxidant activity should be interpreted specifically based on the chemical nature of the applied methods and the chemical compositions of the analyzed samples. The chemical nature of the method used is determined based on the types of reagents used and the reaction mechanisms between the agents and the antioxidant components present in the sample matrices. The antioxidant activity was evaluated by various methods, both in vitro and/or in vivo. Based on the chemical nature of the in vitro process, the methods for the determination of antioxidant activity can be classified into different mechanisms such as single electron transfer (SET), hydrogen atom transfer (hydrogen atom transfer-HAT), and association mechanisms. The single-electron transfer methods are known as the most popular method, which is based on free radical scavenging reaction, ferric reducing antioxidant power (FRAP) [7], 2,2-diphenyl-1-picrylhydrazyl radical (DPPH) radical neutralizing/scavenging activity [9], 2,2'-Azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) free radical neutralizing/scavenging activity [5], cupric-reducing antioxidant capacity (CUPRAC) [7]. For tea leaves and their products, most of the published studies have focused on 1 and/or 2 determination assays to assess antioxidant capacities. The combination of two or more assays assists to perform a more adequate reflection of the antioxidant activity behavior [10, 11].

The objectives of this current study are to evaluate the performance of the analytical method for determining the Trolox equivalent antioxidant capacities (TEACs) via three different in vitro assays, namely ABTS, FRAP, and CUPRAC in dried tea products. The evaluation included the estimation of the limit of detection and quantification (LOD and LOQ), the establishment of calibration curves, the assessment of repeatability (intra-day precision) and reproducibility (inter-day precision), method accuracy through the recovery test, and the construction of the quality control charts. Then, the analytical methods were applied for the determination and assessment of TEACs of several commercial dried tea products belonging to different types of green, oolong, and black teas originating from Lam Dong Province, one of the prominent tea plantation regions located in the South of the Vietnam.

Materials and Methods

Sampling and pretreatment

To evaluate the analytical methods for determining the Trolox equivalent antioxidant capacities (TEACs) based on the three different assays of ABTS, FRAP, and CUPRAC in dried tea products. The commercial black tea product, called "investigated sample", was used to carry out the analytical method evaluation. Then, the evaluated methods were applied to 15 commercial dried tea products collected from the local supermarkets in Ho Chi Minh City (Vietnam). The tea products belong to three different types of green, oolong, and black tea, representing the non-fermented, partially fermented, and fully fermented tea types, respectively. As displayed on the tea product labels, these products originated from Lam Dong Province, one of the prominent tea plantation regions in the southern part of Vietnam. The tea products were packed in non-permeable bags (250 g per bag) and sealed under a vacuum. The purchased samples were transferred to the laboratory in Ho Chi Minh City and stored at −10 ℃ until pre-treatment and further use. The tea samples underwent a pre-treatment procedure [12] which involved homogenization in the for determination of TEACs. The homogenized tea samples were put in non-permeable bags sealed under a vacuum, stored at 25 ℃ with 70% humidity, away from direct sunlight.

Extracts were obtained from the well-homogenized tea products via the extraction procedure performed in ISO 14502-1:2005 [13] with some modifications. Shortly, 0.2 ($\pm$0.001) g of dried tea product was subjected to solid-liquid extraction using the 7:3 v/v mixture of methanol ($\geq$ 99.9%, Merck, Germany) and deionized water (MeOH:DIW) as the extraction solvent. The extraction was carried out in duplicate within 20 min (i.e., 10.00 mL solvent and 10 min for each extraction

cycle) at 70 ℃ in a water bath. All extracts were collected and transferred to a 50-mL volumetric flask. The extraction solvent with a ratio of MeOH:DIW (7:3 v/v) was used to generate the calibration mark. The extracts were then filtered through a 0.45 µm PTFE membrane, and further diluted 20 times by DIW before being subjected to colorimetric assays and spectrophotometric measurement on the UV-Vis 1800 Shimadzu (Japan).

ABTS assay

For the ABTS free radical scavenging activity, the reagent of 2,2'-Azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) or ABTS (≥ 98%, Merck, Germany) was used and the assay was carried out according to the method reported by Abdullahi et al. [14]. The ABTS radical cation was generated through the reaction between aqueous stock solutions of ABTS and $K_2S_2O_8$ for 12 to 16 hours in the dark at the ambient temperature to reach the final concentrations of 7.0 mmol/L and 2.45 mmol/L, respectively. Before use, the ABTS stock solution was diluted using acetate buffer solution of pH = 4.5 (0.3 mol/L) to obtain an absorbance of 0.74 ± 0.03 at 734 nm (working ABTS solution). In the presence of Trolox as the standard or an antioxidant in the sample matrices that are capable of giving hydrogen, the nitrogen atoms can quench the hydrogen atom in the ABTS reagent, resulting in the decolorization of the reaction solutions [15, 16]. In this current study, 200 µL of the diluted tea extract was mixed with 4000 µL of working ABTS solution. The mixture was shaken gently and protected from direct light for 7 minutes. The absorbance was measured at 734 nm for quantification purposes.

FRAP assay

The ferric reducing antioxidant power or FRAP was utilized to evaluate the reducing ability of the antioxidants present in dried tea products. The FRAP procedure was carried out according to the publication of Pellegrini et al. [7], which is based on the reduction reaction of Fe^{3+}–TPTZ (2,4,6-tris(2-pyridyl)-1,3,5-triazine, ≥ 98%, Merck, Germany) with antioxidant compounds in the sample matrices, forming Fe^{2+}–TPTZ. Briefly, a volume of 100 µL of the diluted tea extract was reacted with 3900 µL of working FRAP solution, comprising 300 mmol/L sodium acetate-acetic acid buffer of pH = 3.6, 10 mmol/L TPTZ solution, and 20 mmol/L ferric chloride solution at a volume ratio of 10:1:1. The binding of Fe^{2+} to the ligands from the reduction reaction creates a color of deeply intense navy blue, which absorption values at 593 nm were measured to determine the concentrations of antioxidants that correlates with the amount of iron reduced [7].

CUPRAC assay

For the analysis of cupric reducing antioxidant capacity or CUPRAC of tea products, the tea extract was mixed with $CuCl_2$ and neocuproine (Nc, ≥ 98%, Merck, Germany) working solutions, in which Cu(II) was reduced to Cu(I) through the action of electron-donating antioxidants. The procedure was briefly described as follows: 4.00 mL of the diluted tea extract was mixed with 1.00 mL of 10^{-2} mol/L $CuCl_2$; 1.00 mL of 7.5×10^{-3} mol/L neocuproine was diluted in ethanol; and 1.00 mL ammonium acetate buffer (pH = 7.0) was prepared by dissolving 19.27 g ammonium acetate in 250 mL DIW. After 1 hour of reaction, the absorbance was measured at 450 nm for the quantification of antioxidants that wer present in the tea products [7].

Analytical method evaluation

Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid, 97%, Merck, Germany) was used as the standard for all criteria of interest. The quantification was carried out according to the calibration curves, which were established based on the linear relationship (y = ax + b) between the analyte concentrations (µmol TE/L) and the respective absorption. The calibration curves of FRAP and CUPRAC (reducing power) were constructed based on the linear relationship between the Trolox concentrations and the absorption signal of each standard solution after subtracting the signal of the blank solution ($Abs_{std} - Abs_{blk}$). For ABTS (radical scavenging activity), the calibration curve was built up according to the linear relationship between the Trolox concentrations and the values derived from the subtraction of absorbances (Abs) between the blank solution (blk) as the control sample and the signal of each standard (std) point ($Abs_{blk} - Abs_{std}$). The bias values for each standard point of the calibration curves

(calculated in percentage) were calculated by the equation 1 [17]:

$$\text{bias } (\%) = \frac{C_{cal.} - C_{std}}{C_{std}} \times 100 \quad (1)$$

where $C_{cal.}$ and C_{std} stand for the concentration of the standard solutions calculated from the established calibration curves and from the practical preparation (concentration values used to establish the calibration curves), respectively.

The limit of detection (LOD) and quantification (LOQ) of the analytical methods was estimated by simultaneously analyzing 11 separate blank solutions (containing only the extraction solvents and colorimetric reagents). Next, the estimated average concentrations ($\bar{x}$) and their standard deviation value (SD) were calculated to apply in the following relationships [18]:

$$LOD = \bar{x} + 3SD \text{ and } LOQ = 3LOD \quad (2)$$

The black tea (as the "investigated sample") was used for the repeatability assessment (intra-day precision) within one day (six replicates, n = 6) and reproducibility assessment (inter-day precision) for three separate days (six replicates per day) through the calculation of relative standard deviations, RSD_r and RSD_R, respectively, at the significance level of 0.05. In addition, the standard solution was spiked into this sample at three different levels ($0.5C_x$, $1C_x$, and $1.5C_x$, where C_x is the estimated analyte concentration in the investigated sample for the recovery test to evaluate the method accuracy.

The Shewhart charts were constructed for quality control by analyzing the investigated sample in successive runs along with "warning" and "action" limits employed to detect the arisen problems in different measurements on the UV-Vis 1800 Shimadzu (Japan) [18].

The evaluated analytical methods for determining ABTS, FRAP, and CUPRAC were applied to the collected dried tea products (performed in dried weight). All the analytical data were carried out in triplicate and analyzed by Microsoft Office Excel 2016 (version 16.54, Microsoft 365 Subscription), expressed as mean value ± standard deviation (SD). For potential correlation assessment of the measurements, the correlation analysis was performed using the statistical package software of SPSS (version 23).

Results and discussion

Calibration curves

Trolox, a derivative of vitamin E, is the most commonly used chemical standard for quantifying the antioxidant capacities from different sample matrices, including the reducing power, e.g., FRAP and CUPRAC, and free radical scavenging ability, e.g., ABTS. In addition, Trolox is soluble in polar solvents [19], thus compatible with the extraction solvent used in this study, i.e., 70% v/v MeOH in DIW.

For the analysis of ABTS, FRAP, and CUPRAC in dried tea products, the calibration curves were established for quantification purposes. Table 1 shows the parameters of the established calibration curves, which performed the goodness of linearity ($R^2 > 0.995$) according to the Appendix F of AOAC (2016) [20]. The working ranges for all TEAC detection methods were wide (from 100 to 700 µmol TE/L), which was suitable for different tea types with varying analyte concentrations, prepared through the same sample preparation procedure and dilution factor. The bias values obtained from all standard points were from 0.010 to 14.2% (Table 1), which are in agreement with the recommended value (< 15%) published in "Method validation for chemical and microbiological analysis" published by Vietnam National Institute for Food Control [17].

Table 1. Parameters of the calibration curves

	ABTS	FRAP	CUPRAC
Working range (μmol TE/L)	100-700	100-700	100-700
Slope (a)	0.0009	0.0011	0.0011
Intercept (b)	−0.0111	0.0113	0.0127
R^2	0.9985	0.9982	0.9979
Bias range (%)	0.20-10.5	0.010-14.2	0.42-9.6

Limit of detection and quantification

The results in Table 2 indicate that the LODs and LOQs of ABTS, FRAP, and CUPRAC (LOD-LOQ) were low (in the range from 9.9 to 37.3 μmol TE/L) compared to the remarkably high concentrations of antioxidants (up to thousands of μmol TE/g dried weight) in tea products due to the rich phenolic contents [21-25]. Therefore, the obtained LOD and LOQ values were suitable for tea matrices, and it is not necessary to lower these values for analytical method development.

Table 2. LODs, LOQs, intra-day precision (RSD_r), inter-day precision (RSD_R), and recoveries

Criteria	LOD (μmol TE/L)	LOQ (μmol TE/L)	RSD_r (%)	RSD_R (%)	Recovery (%)		
					$0.5C_x$	$1C_x$	$1.5C_x$
ABTS	12.3	37.3	1.37	1.48	99.3-99.6	98.7-99.8	99.7-101
FRAP	9.9	30.1	1.03	1.26	98.7-98.9	99.6-100	99.1-99.9
CUPRAC	11.8	35.7	1.52	1.55	98.0-100	98.5-99.5	98.9-99.6

Repeatability and reproducibility

In this current study, the precision (intra- and inter-day) of the analytical methods for TEACs was evaluated through the repeatability and reproducibility tests. The results in Table 2 indicate the favorable repeatability (RSD_r from 1.03 to 1.52%) regarding the Appendix F of AOAC (2016) [20]. The calculation of one-way ANOVA was carried out to evaluate the reproducibility in three separate working days (6 replicates/day) at the confidence level of 95%. The results of RSD_R ranged from 1.26 to 1.55%, consistent with the requirements of AOAC (2016) [20] for the analyte concentrations of 10-100% in Appendix F.

Recovery test

In this study, the accuracy of the analytical methods for ABTS, FRAP, and CUPRAC was assessed by the recovery test. Typically, the Trolox standard solution was spiked into the investigated sample in different concentrations, i.e., $0.5C_x$, $1C_x$, and $1.5C_x$, where C_x is the estimated analyte concentration of the corresponding investigated sample. The results in Table 2 demonstrate the high recoveries (98.0-101% for all spiked samples), favorable to the requirements of AOAC (2016) [20] for method validation in Appendix F. The analytical methods can be applied for the quantification of the antioxidant capacities of dried tea products with proper precision and accuracy. The extraction was performed once to obtain the sample liquids for the measurement of ABTS, FRAP, and CUPRAC, as well as for better comparison and assessment. Moreover, the analytical methods are simple, inexpensive, and suitable for both research and routine analysis of tea products and potentially, tea-related matrices.

Shewhart quality control chart

To control the sensitivity and stability of the analytical system, the Shewhart quality control charts were constructed based on the analysis of the investigated sample (black tea) within 21 days. The black tea product, representing the fully fermented tea type, was used to generate the quality control chart to ensure consistent results under proper preservation conditions during the analysis period. In this situation, the investigated black tea sample plays the role of quality control or QC sample. Figure 1 demonstrates the Shewhart charts for ABTS, FRAP, and CUPRAC, including the mean concentration (C_{mean}) and warning values listed as upper warning limit

(UWL), lower warning limit (LWL), upper action limit (UAL), and lower action limit (LAL). These limits were calculated following the principles of ± 2SD and ± 3SD (SD: standard deviations of three replicates within one day) for warning and action limits, respectively. For each working day, the QC sample can be analyzed to examine the stability and robustness of the measurement system, in which the analyzed results of the QC sample should be between the LWL and UWL to ensure the accuracy of the analytical results [18]. However, during the analytical period, there could be a different emerging situation that needs to be solved based on the QC results. Typically, the analysis should be temporarily stopped and the obtained results and the measurement system need to be carefully checked if one of the following situations happens: (i) any QC results that are beyond the range of LAL-UAL, (ii) the values of more than two in three continuous QC samples are beyond the range of LWL-UWL, (iii) the QC results tend to be located at the same side of the mean line, which it is not acceptable if more than nine continuous points are located at the same side (above or under the mean line), and (iv) the QC results has the tendency to increase or decrease, which it is not acceptable if there are six continuous points tend to go up or down [26]. The results in Figure 1 indicate that the measurement system was stable, i.e., all the values of UAL, UWL, LWL, and LAL were close to C_{mean}, the obtained results are in the range of LWL-UWL and none of the nine continuous points were located at the same side of the mean line. Therefore, the evaluated analytical method meets the proper stability, and robustness for long-term analysis and could be applied in the analysis of dried tea products both for research activities and routine approaches. Moreover, tea products belonging to other types and different geographical origins could be analyzed for their TEACs by employing the evaluated analytical methods due to the favorable adaptability of the operating conditions for diverse tea matrices.

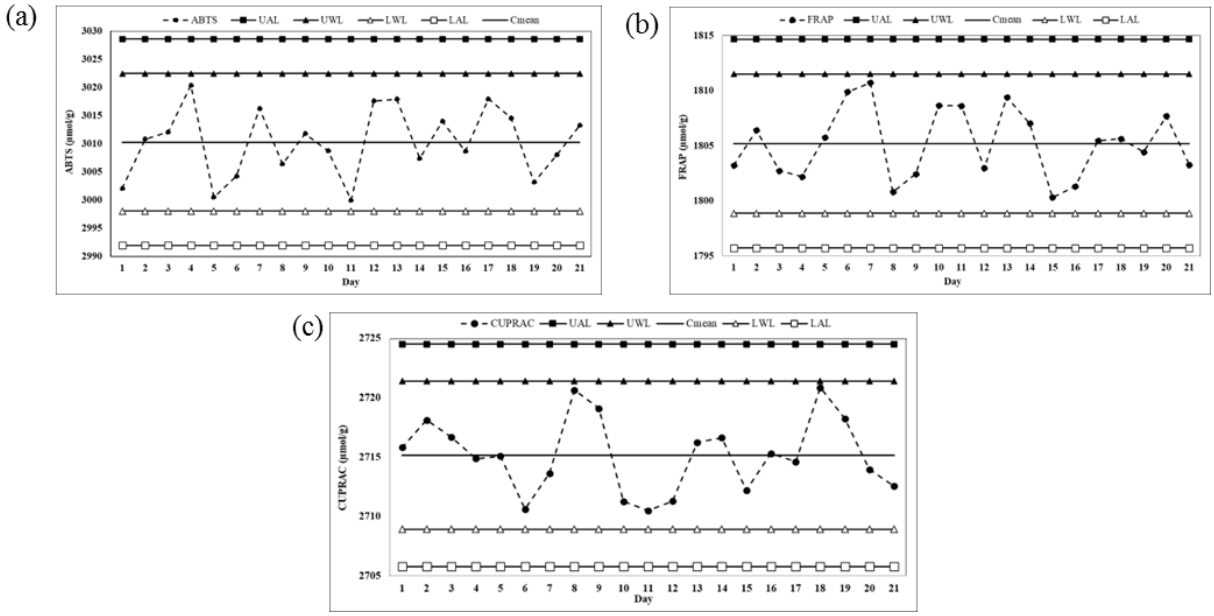

Figure 1. Quality control charts of (a) ABTS, (b) FRAP, and (c) CUPRAC

Application of the evaluated analytical methods for dried tea products

The evaluated analytical methods were applied to determine ABTS, FRAP, and CUPRAC in several commercial dried tea products originating from Lam Dong Province (Vietnam). The results in Figure 2 indicate the TEACs of the tea products in descending order: green tea > oolong tea > black tea. For ABTS, Green-05 and Black-05 exhibited the highest (4006 ± 31 μmol TE/g) and lowest values (3593 ± 41 μmol TE/g), respectively. A similar observation for ABTS in dried tea products was published in Carloni et al. [23], which

reported the highest ABTS values for green tea samples, followed by white and black tea products. Another study by Qian et al. [27] employed a liquid chromatography system coupled with a reaction compartment containing the ABTS reagents after the column, which also demonstrated an ABTS radical scavenging activity of different tea products in descending order: green tea > oolong tea > black tea. Generally, green tea products exhibit significant antioxidant capacities due to the high contents of phenolic and flavonoid compounds [2, 28-30]. The antioxidant capacities of black and dark tea products may be decreased by the activity of polyphenol oxidase enzymes and bacteria during the fermentation period, which could lead to the degradation of simple catechins and other phenolic compounds, as well as formation of more complicated dimers and/or polymers [31-33]. These large molecular compounds could be less reactive with the ABTS reagents, leading to lower ABTS readings [8, 27]. Moreover, the oxidation of catechins to produce the theaflavins during fermentation may also contribute to the intense color and characteristic flavor of oolong and black tea [34, 35].

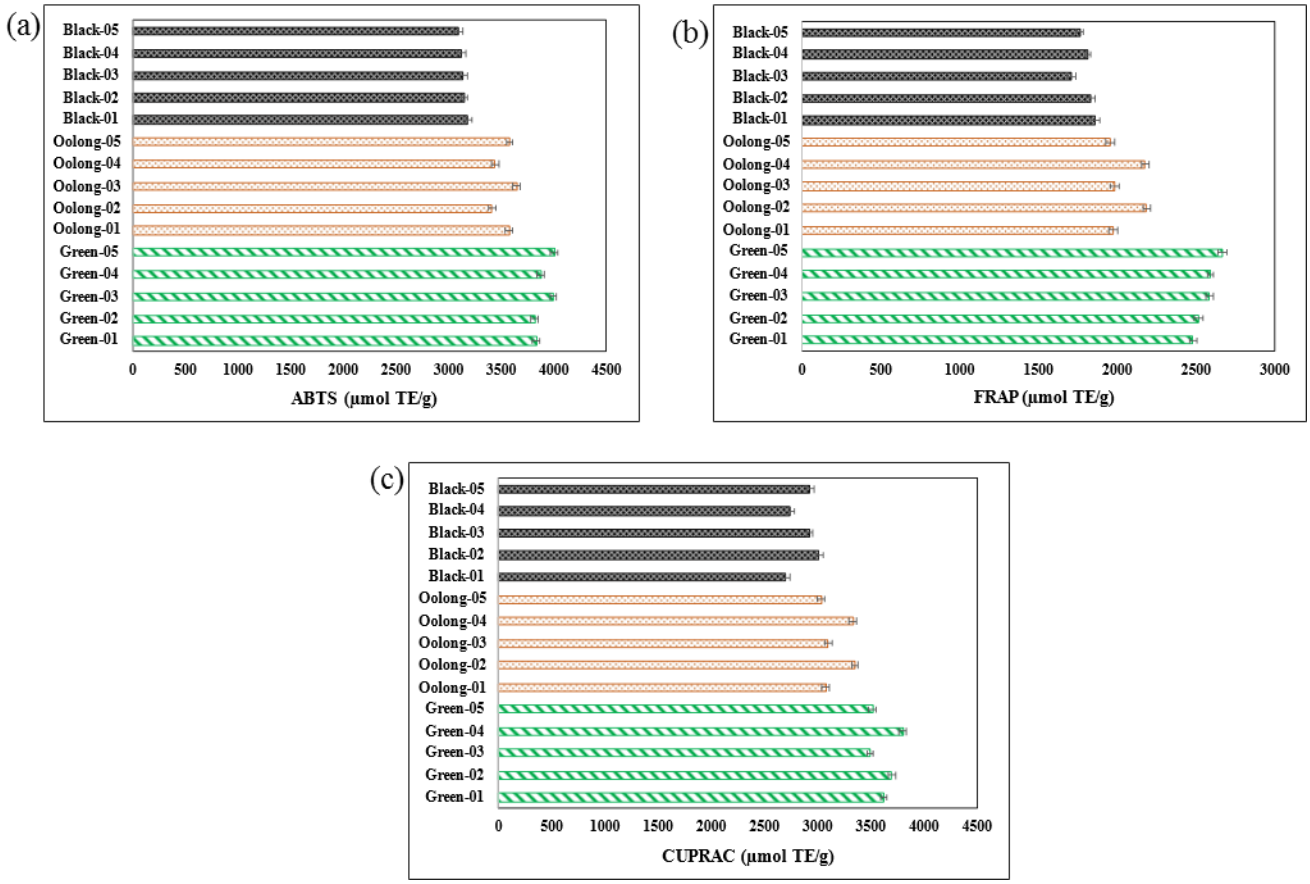

Figure 2. Trolox equivalent antioxidant capacities: (a) ATBS, (b) FRAP, and (c) CUPRAC

The TEACs of the dried tea products in CUPRAC analysis were higher than that of FRAP (2701 ± 35 to 3805 ± 35 μmol TE/g *vs.* 1708 ± 26 to 2668 ± 29 μmol TE/g). However, among the three types of tea, both FRAP and CUPRAC produced results that were similar to that of ABTS. This was supported by the strong correlation obtained (Figure 3) (R^2 = 0.8579, 0.8453, and 0.710 for pairs of FRAP-CUPRAC, ABTS-FRAP, and ABTS-CUPRAC, respectively). Similar results were observed in the publications of Zhao et al. [8] and Lee et al. [36]. As mentioned before, oxidation during fermentation could change the chemical compositions of tea, especially compounds with antioxidant properties, through decomposition, dimerization, and

polymerization, forming complex compounds with larger molecular weight [31-33]. The formation of these new compounds is likely to degrade the reactivity by the transition metal reduction mechanism. This was supported by the FRAP and CUPRAC values of the tea products in descending order green tea > oolong tea > black tea (FRAP: 2479 ± 24 to 2668 ± 29 µmol TE/g > 1956 ± 25 to 2187 ± 21 µmol TE/g > 1708 ± 26 to 1860 ± 27 µmol TE/g, respectively, and CUPRAC: 3494 ± 34 to 3805 ± 35 µmol TE/g > 3033 ± 40 to 3363 ± 31 µmol TE/g > 2701 ± 35 to 3017 ± 32 µmol TE/g, respectively), which also indicates the oxidation during the fermentation has certain effects on the TEACs by the transition metal reduction mechanisms [8, 22].

Generally, the variabilities in TEACs between samples of the same species or different species can also be contributed by the variations in raw materials, i.e., fresh tea leaves, due to the different plantation of origin, soil type, altitude, cultivation condition, quality of tea leaves, processing procedure, preservation method, and growing condition of tea plants [22, 37-39].

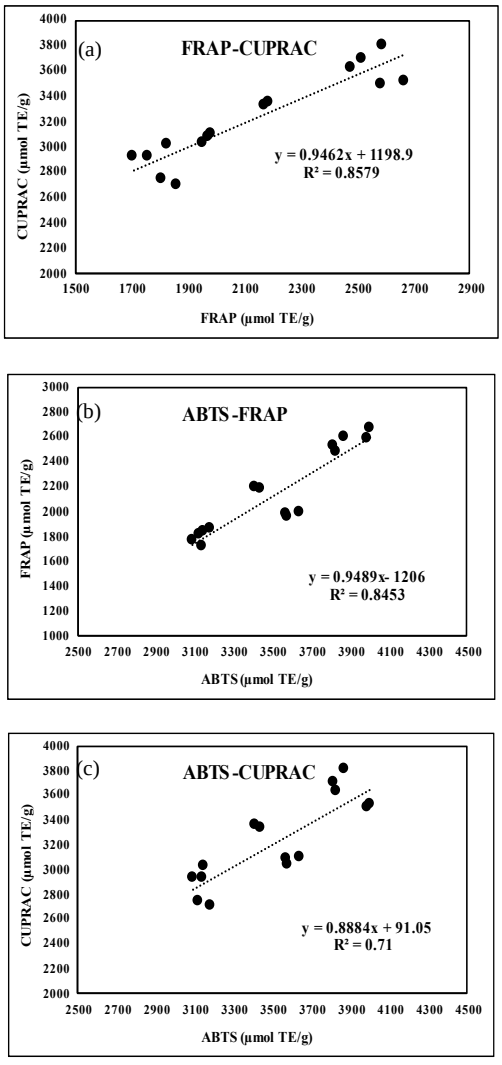

Figure 3. Correlation between (a) FRAP and CUPRAC, (b) ABTS and FRAP, and (c) ABTS and CUPRAC

Conclusion

This study evaluated the molecular absorption spectrophotometric methods for the determination of Trolox equivalent antioxidant capacities (TEACs) through different chemical reactions or in vitro assays. The reactions investigated for determination of TEACs were classified into two mechanisms: radical scavenging activity of ABTS and transition metal reduction via FRAP and CUPRAC. The performance analysis of the analytical method demonstrated low LODs and LOQs compared to the concentrations of antioxidants in dried tea products. The working ranges were wide (from 100 to 700 µmol TE/L), which is compatible with different types of tea matrices prepare through the same sample preparation procedure and dilution factor. The established calibration curves demonstrated the goodness of linearity ($R^2 > 0.995$). The repeatability, reproducibility, and recovery were favorable according to Appendix F of AOAC (2016). The Shewhart charts were constructed to control the analytical results achieved from the UV-Vis 1800 spectrophotometer (Shimadzu, Japan) on different working days. The analytical methods were then applied to several purchased dried tea products, i.e., green, oolong, and black teas, which demonstrated the variabilities in TEACs of the three tea types according to the differences in the processing period. The discrepancies in the result could be due to the increasing oxidation levels from green to oolong and black teas during the fermentation. This study contributes to food areas in terms of the determination and assessment of antioxidant capacities in tea and other tea-related products.

To broaden this study and better assess the tea products, more dried tea samples from various tea plantations should be collected. Additionally, the chemical profiles could be analyzed to adequately support the determined antioxidant capacity behaviors of different tea samples. The changes in TEACs due to the processing demonstrate the potential use of these TEACs as the contributing variables for grouping or discrimination of tea products, particularly in the case of samples in large quantity.

Acknowledgment

The authors would like to express the gratitude and appreciation to Nguyen Tat Thanh University for the assistance and support throughout this study.

ASSESSMENT ON THE CURRENT QUALITY AND IDENTITY CHARACTERISTICS OF MALAYSIAN PALM SUPEROLEIN

(Penilaian Kualiti dan Ciri Identiti Semasa Superolein Sawit Malaysia)

Abstract

An experimental investigation was conducted to assess the current quality and identity characteristics of palm superolein (PSO) produced in Malaysia. A total of 44 PSO samples were collected from several palm oil refineries and ports in Malaysia and were tested for several important indices for characterization of PSO, *i.e.,* iodine value, fatty acids composition, triacylglycerols composition, refractive index, apparent density, relative density, slip melting point, peroxide value, impurities content, moisture content, free fatty acids content, unsaponifiable matter and saponification value. Generally, the quality of PSO was within the specification listed in Codex CXS 210-1999, with slight variations compared to the previous assessment conducted two decades ago. Most prominent variations were observed for refractive index and apparent density of PSO in which the experimental temperature was changed to 40 °C, and a new set of range values were obtained. The findings from this current quality assessment have provided significant data for the revision of the international food standard, as well as the Malaysian national standard for PSO, to accurately reflect the present quality of PSO for consumer health protection, hence removing any barriers to the international trading of PSO.

Keywords: assessment, Malaysia, palm superolein, quality, standard

Abstrak

Satu kajian eksperimen telah dijalankan untuk menilai kualiti dan ciri identiti semasa superolein sawit (PSO) yang dihasilkan di Malaysia. Sebanyak 44 sampel PSO yang diperoleh dari beberapa kilang penapisan minyak sawit dan pelabuhan di Malaysia telah diuji untuk beberapa indeks penting bagi pencirian PSO seperti nilai iodin, komposisi asid lemak, komposisi triasilgliserol, indeks biasan, ketumpatan ketara, ketumpatan relatif, takat lebur gelincir, nilai peroksida, bendasing, kelembapan, asid lemak bebas, bahan tak tersaponinan dan nilai penyabunan. Secara amnya, kualiti PSO menepati spesifikasi yang disenaraikan dalam Codex CXS 210-1999, dengan sedikit perbezaan berbanding penilaian yang telah dijalankan dua dekad yang lalu. Perbezaan ketara dilihat pada indeks biasan dan ketumpatan ketara PSO di mana suhu eksperimen telah diubah kepada 40 °C, dan satu nilai julat baru diperoleh. Hasil penemuan daripada penilaian kualiti ini telah menyediakan data yang signifikan bagi semakan semula piawaian makanan antarabangsa, dan juga piawaian kebangsaan Malaysia bagi PSO, bagi memberikan gambaran yang tepat berkenaan kualiti semasa PSO untuk penjagaan kesihatan pengguna, seterusnya menghapuskan sebarang halangan dalam perdagangan antarabangsa PSO.

Kata kunci: penilaian, Malaysia, superolein sawit, kualiti, piawai

Introduction

Oil palm (*Elaeis guineensis*) is a special crop as two types of oils are produced from the palm fruits, *i.e.*, crude palm oil (CPO) from the fleshy mesocarp, and crude palm kernel oil from the kernel [1]. Palm oil is ranked as the most consumed edible oils with 75.45 million metric tonnes of world edible oil consumption [2]. In 2020, export revenue for palm oil products increased to RM 73.25 billion due to higher export prices of palm oil [3], whereby the export volume of PSO to various destinations in the world was 67,408 tonnes worth RM 226.02 million [4]. PSO is widely consumed as cooking oil due to its high stability during frying and less tendency for cloudiness at low temperature [5].

CPO is the first product obtained during the milling of fresh fruit bunches. Native peoples in African countries consume CPO, the unrefined form of palm oil which is high in carotenes and vitamin E contents [6], albeit most people would consume it in the refined form. A further refining process turns CPO into refined palm oil, which is then subjected to fractionation to yield a more edible form of palm oil. Palm oil fractionation is an industrial process to separate liquid and solid phases of palm oil, yielding palm olein (liquid phase) and palm stearin (solid phase), with distinctive physico-chemical characteristics. Fractionation mainly involves crystallization at low temperature, and filtration to separate the two phases [7].

It has become a new interest in the market for high value added or special cuts products, *i.e.*, high iodine value (IV) olein or PSO, which is manufactured through multiple stages of fractionation as shown in Figure 1 [8]. High IV olein of 64 to 66 can even be produced through a single step fractionation, although multiple stages are often required. This special cut product is tailored to cater palm olein with higher stability towards cloudiness at low temperature settings, through the removal of saturated triacylglycerols from the olein fraction.

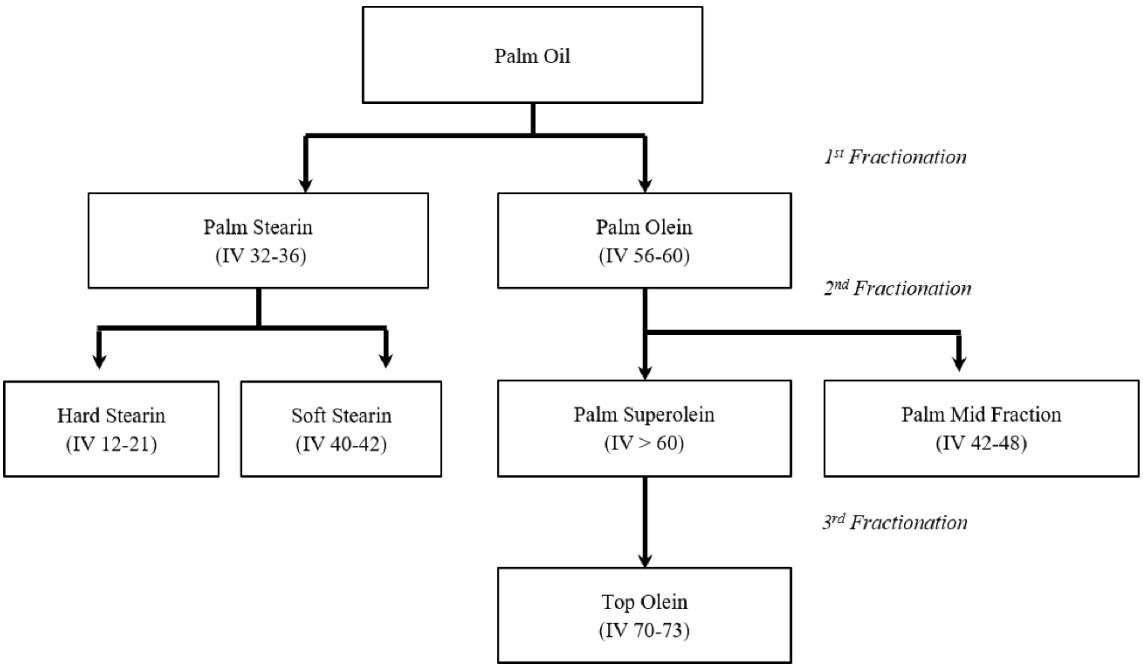

Figure 1. Multiple stages of fractionation in palm oil

PSO is the liquid fraction derived from palm oil produced through a specified controlled crystallization process to achieve a desirable IV of 60 and above [9]. It is produced by single or double fractionation. Although less demanded, it is one of the higher value fractions of palm oil. PSO has the ability to withstand colder temperatures, hence it has better resistance to clouding. It also has better clarity and stability. Generally, PSO appears transparent with light yellow in colour. Apart from being used as cooking and frying oils, it is also used for blending with polyunsaturated oils produced in temperate countries [10].

Parameters such as free fatty acids content, peroxide value and moisture content are among the important factors in determining the quality of the oil produced, and subsequently puts a price on the oil [11, 12]. Global trading of palm oil products is based on quality specifications set by international and national standards bodies. The standard specification documents commonly referred to includes Codex Alimentarius International Food Standards and Malaysian Standards. Trading specifications may also be practiced on a "willing buyer, willing seller" basis [13]. These standards are introduced to harmonise and establish uniformly accepted criteria for a certain product. The important quality parameters specified in Codex CXS 210-1999 are listed in Table 1 [9, 10].

Table 1. General characteristics of palm superolein

Parameter	**1995 Palm Superolein Assessment** [10] **(n = 32)**		**Codex CXS 210-1999** [9]
	Range	**Mean ± Standard Deviation**	
Refractive Index, RI (nD, 30 °C)	1.4631 – 1.4641	1.4634 ± 0.0003	1.459 – 1.460 (@ 40 °C)
Apparent Density, AD (g mL^{-1}, 30 °C)	0.9042 – 0.9054	0.9046 ± 0.0003	0.886 – 0.900 (@ 40 °C)
Iodine Value, IV (Wijs)	60.1 – 67.5	61.9 ± 2.15	≥ 60
Saponification Value (mg KOH g^{-1} oil)	181 -191	187 ± 3.18	180 – 205
Slip Melting Point, SMP (°C)	12.9 – 16.6	15.1 ± 0.91	-
Cloud Point (°C)	2.8 – 5.7	4.4 ± 0.71	-
Unsaponifiable Matter (%)	0.31 – 0.42	0.38 ± 0.03	≤ 13

Periodic assessments of the quality attributes of palm oil products assist in providing current information for revision of the standards, to reflect current production quality among palm oil producing companies. The previous and only published assessment on the characteristics of PSO was reported by Tang et al. [10] and presented limited information on the general characteristics and compositions of PSO (Table 1).

In view of the requirement for an up-to-date study on PSO quality, the objective of this article is to present the outcome of an assessment on the quality of Malaysian PSO for better understanding and evaluation of its current quality and identity characteristics for future improvement of the fractionation technology. The findings from this assessment were used for the revision of the Codex CXS 210-1999 Standard for Named Vegetable Oils and Malaysian Standard 1762:2004 – Palm Superolein Specifications. This round of assessment was believed to be timely as the last round of national assessment was conducted more than 25 years ago.

Materials and Methods

Sample collection

In the present study, a total of 44 refined, bleached and deodorized (RBD) PSO samples were collected from several palm oil refineries and ports in Peninsular Malaysia, Sabah and Sarawak in 2016, 2018 and 2019. One kilogram of sample was collected into a one litre opaque bottle, on a monthly basis, or whenever there was a PSO production at the refinery as PSO is usually manufactured upon request from the buyer. The samples were stored in a cool (~5 °C), dry place prior to analysis.

Chemicals and reagents

All chemical reagents and solvents used were analytical grade and high-performance liquid chromatography (HPLC) grade, and were purchased from Sigma-Aldrich, Michigan, USA.

Sample preparation

PSO samples collected were thoroughly shaken to ensure complete homogeneity according to the method described in MPOB Test Method p1.2 [14].

Physico-chemical parameters testing

The samples were subjected to physico-chemical characteristics evaluation which included iodine value, fatty acids composition, triacylglycerols composition, refractive index, apparent density, relative density, slip melting point, peroxide value, impurities content, moisture content, free fatty acids content, unsaponifiable matter and saponification value. The method of analyses was based on MPOB Test Methods, AOCS Official Methods and ISO Standard Methods. All measurements were done in triplicate, unless stated otherwise.

Free fatty acids (FFA) content

FFA content was determined according to the titration procedure based on AOCS Official Method Ca 5a-40 [15]. About 20 g of PSO sample was dissolved in neutralized *iso*-propanol and the free acids were titrated with 0.1 M sodium hydroxide solution (standardised with potassium hydrogen phthalate before usage). Phenolphthalein was added as an indicator to observe and to detect the endpoint. The endpoint is determined at the appearance of the first permanent pink colour which persists for 30 s. FFA analysis was carried out in duplicate and expressed as percentage of palmitic acid as it is the major fatty acid in palm oil.

Iodine value (IV)

The IV was analysed using the Wijs method based on the procedure described in ISO 3961 [16]. This method involved the dissolution of about 0.4 g PSO sample in a mixture of *iso*-octane and cyclohexane (1:1), and the subsequent addition of Wijs solution. The mixture was then incubated for 60 min, followed by the addition of potassium iodide (10 %) solution and 100 mL deionized water. The mixture was titrated with 0.1 M thiosulphate solution (standardised before usage) until the endpoint was reached. A blank solution was determined concurrently. Potentiometric measurement of the IV was carried out using an automated titration system T90 (Mettler Toledo, Switzerland), and the mean value of duplicate analysis was determined.

Refractive index (RI)

The RI was determined using refractometer Abbemat 300 (Anton Paar, Austria) at the temperature of 40 °C according to the method described in ISO 6320 [17]. The refractometer was calibrated daily against deionised water. A sufficient amount of PSO sample was dropped onto the measuring prism for the RI determination. The RI was determined in duplicate analysis.

Apparent density (AD)

The AD was determined at the temperature of 40 °C, using Densitometer DMA 4500M (Anton Paar, Austria), based on the method in ISO 18301 [18]. A heating element was attached to the densitometer to ensure that the samples remained melted and homogenised during the measurement. The densitometer was calibrated against air for every measurement. Duplicate analysis was carried out.

Relative density (RD)

The RD at 40 °C was determined by calculation using equation 1:

$$Relative\ density\ = \frac{Density\ of\ PSO}{0.9982} \quad (1)$$

where the density of PSO can be obtained during the measurement of apparent density and the value 0.9982 is the density of ultrapure water at 20 °C.

Moisture content

Moisture content was measured using the Karl Fischer volumetric moisture analyser (Mettler Toledo, Switzerland) according to the procedure described in ISO 8534 [19]. Samples were introduced into the flask containing Aqualine™ Complete 5 reagent (Fischer Scientific, USA). The fat content was titrated against an iodine solution and sulfur dioxide was oxidised by

iodine in the presence of water. The moisture content was measured in duplicate analysis.

Impurities content

Impurities content was determined using an oven method based on ISO 663 [20]. The sample was first filtered by using Whatman glass fibre filter paper, followed by washing with petroleum ether for several times. The filter paper with the filtrate was then heated in the oven at 103 °C for 2 h. The residue weight was measured and calculated as the impurities content in the percentage of mass fraction. The mean of duplicate analysis was reported as the impurities content.

Peroxide value (PV)

Analysis of PV was carried out using the titration technique and the potentiometric endpoint determination was based on the procedure described in ISO 27107 [21]. 5 g of PSO sample was dissolved in 50 mL acetic acid: iso-octane (3:2). Next, approximately 0.5 mL of saturated potassium iodide solution was added into the mixture and gently stirred for 1 min, followed by the addition of 30 mL deionized water. The mixture was then titrated with 0.01 M sodium thiosulphate ($Na_2S_2O_3$) solution until the endpoint was reached. The mean value of duplicate analysis was determined as the PV.

Slip melting point (SMP)

The measurement of SMP was carried out following procedures described in AOCS Official Method Cc 3-25 [22]. The sample was placed in a tube and solidified in the freezer, before heat was applied to the tube containing the sample. The sample was heated until the fat rose in the tube and the temperature at which the sample rose was recorded as the slip melting point. The measurement of SMP was carried out in triplicate.

Saponification value (SV)

The SV was analysed by titration of excess potassium hydroxide with hydrochloric acid solution, as described in ISO 3657 [23]. Approximately 2 g of sample was first mixed with 25 mL ethanolic potassium hydroxide solution and refluxed for 60 min. About 0.5 to 1.0 mL phenolphthalein indicator was added into the hot solution. The mixture was then titrated with hydrochloric acid until the pink colour of the indicator disappeared. A blank measurement was also carried out. The mean of two determinations was taken as the SV and expressed as a whole number.

Unsaponifiable matter

The unsaponifiable matter was determined following the method in ISO 3596 [24]. About 5 g of PSO was refluxed with 50 mL of potassium hydroxide solution for 1 h. The mixture was then cooled, and 100 mL of water was added and mixed well. The solution was then extracted several times with diethyl ether. Each time, the organic layer was collected and washed twice with 40 mL portions of water and once with 40 mL potassium hydroxide solution, and neutralised with 40 mL of water. The solution was evaporated at 103 °C for 15 min, allowed to cool and weighed until constant mass was obtained. The unsaponifiable matter was analysed in duplicate and the mean value was expressed as the result in percentage mass.

Fatty acids composition (FAC)

The FAC in the oil sample was measured as their corresponding methyl esters (FAME) based on the method described in ISO 12966 - Part 2 [25]. About 0.2 mL methanolic sodium methoxide was added to 0.05 g of dissolved oil sample for transmethylation to take place. After 5 min, approximately 1 mL of sodium chloride solution was added. The clear upper phase of methyl esters was carefully pipetted out and approximately 0.5 g of sodium hydrogen sulfate was added into the solution. The FAME was analysed using an Agilent GC 7890A series equipped with a flame ionization detector and a fused silica capillary column SP™ 2560 (100 m × 0.25 mm film thickness). The oven temperature was initiated at 120 °C and increased to 240 °C at 4 °C min^{-1}, then maintained for 7 min at 240 °C. Hydrogen gas was used as the carrier gas with a flow rate of 1 mL min^{-1}. The injection volume was 1 µL. The analysis was carried out in triplicate. FAC is expressed as percentage of respective fatty acids.

Triacylglycerols composition (TAG)

Quantification of TAG was carried out based on AOCS Official Method Ce 5b-89 [26] and Ce 5c-93 [27]. About 1 µL of samples dissolved in acetone was injected into

an Acquity UPLC® BEH C18 column (Waters Corp., Milford, Massachusetts, USA), with particle size of 1.7 µm, id 2.1 mm × 150 mm length, maintained at 30 °C. Isocratic elution using a mixture of acetone and acetonitrile (63.5:36.5) was carried out at a flow rate of 0.25 mL min^{-1} with a total runtime of 30 min. The detection of TAG was performed by refractive index and the TAG was quantified using the peak area normalisation method. The analysis was carried out in triplicate.

Statistical analysis

All statistical analyses were performed using Microsoft Excel 2013 (Microsoft Corporation, Redmond, WA). The linear correlation between selected quality parameters was assessed by Pearson's correlation coefficient using Minitab 19 (Minitab LLC, Pennsylvania, USA). All numerical data were expressed as the mean ± standard deviation (SD).

Results and Discussion

Physico-chemical characterisation of PSO

From the 44 samples of PSO analysed, the relevant quality control parameters such as RI, AD, IV, moisture and impurities (M&I), SMP, FFA, SV and unsaponifiable matter were found to be within the limits set by Codex CXS 210-1999 for PSO. Results are presented in Table 2 in terms of mean, standard deviation and range observed.

Table 2. Mean value with standard deviations and range of physicochemical characteristics of palm superolein

Parameter	2016/19 Palm Superolein Assessment (n = 44)			
	Mean	Standard Deviation	Min	Max
Refractive Index, RI (nD, 40 °C)	1.45933	0.00023	1.45898	1.45974
Apparent Density, AD (g mL^{-1}, 40 °C)	0.89785	0.00027	0.89720	0.89839
Iodine Value, IV (g I_2/100 g oil)	62.3	1.6	59.5	65.2
Moisture & Impurities, M&I (%)	0.05	0.01	0.02	0.08
Slip Melting Point, SMP (°C)	15.3	1.3	12.9	16.8
Free Fatty Acid, FFA (%)	0.08	0.04	0.02	0.14
Saponification Value (mg KOH g^{-1} oil)	201	10.6	181	217
Unsaponifiable Matter (%)	0.37	0.27	0.14	1.06
Peroxide Value (meq O_2 kg^{-1})	2.08	1.22	0.92	5.88

Determination of M&I contents in PSO is one of the quality requirements specified in the Malaysian Standard (MS) 1762 – Palm Superolein Specification [28]. The maximum M&I content allowed for PSO is 0.10%. The current assessment revealed that the PSO analysed had lower M&I (0.05%) than the maximum allowable limit, with a range of between 0.02% and 0.08%. Refined products should have lower amount of M&I than the crude palm oil as the crude palm oil was first subjected to drying process prior to the refining process. This step is important to avoid further hydrolysis reaction of the oil which will facilitate the increase in the FFA content of the oil [29].

FFA is commonly used as an early indicator of the quality and the acceptability of palm oil or any edible oil. It is one of the most important key quality parameters in the trading of oils and fats as it is a product of triacylglycerols hydrolytic degradation [13]. The Palm Oil Refiners Association of Malaysia (PORAM) standard specifications for RBD palm olein listed FFA as 0.1% maximum. The samples showed an average FFA content of 0.08% varying between 0.02% and 0.14%, of which were within the PORAM specifications. These ranges are acceptable as PSO is considered stable and less susceptible to hydrolytic reaction as high amount of moisture and FFA was significantly removed during the refining process [1].

PV is a parameter reflecting the degree of deterioration of palm oil products exposed to atmospheric oxygen [30]. From the PSO samples analysed, PV varied widely

from as low as 0.92 meq O_2 kg^{-1} to 5.88 meq O_2 kg^{-1}. This was probably due to the gap in time of production at the refinery as well as the time of analysis of the samples [31]. Although there was a wide variation of PV in the PSO samples, these values were acceptable by Codex which specifies PV up to 10 meq O_2 kg^{-1} for refined oils [9]. Moreover, PV is known to be unstable due to the fact that the hydroperoxides of the unsaturated fatty acids resulting from lipid oxidation are very unstable, and degrade into various volatile and non-volatile components [32]. This trend of PV instability may also be attributed to the rapid degradation of the hydroperoxides to secondary oxidation products, *i.e*., ketones, aldehydes.

RI is the measure of light ray bend angle when it goes through oil into air. It is highly dependent on the temperature it is measured, which usually is the temperature at which the oil is completely liquid [33]. It is typically used for the determination of purity together with other identity parameters. Tang et al. [10] reported that RI of PSO was in the range of 1.4631 and 1.4641, analysed at 30 °C. However, the values were not comparable to the values specified in the Codex CXS 210-1999 as the experimental temperature was not standardised to 40 °C. The recent Codex Committee of Fats and Oils in 2019 had endorsed a new range value at 40 °C. The PSO samples analysed at 40 °C had a mean value of 1.45933, with a narrow range from 1.45898 to 1.45974. This range is acceptable by Codex as it fell between the RI values of 1.459 to 1.460 as specified in Codex CXS 210-1999 [9]. RI is a physical characteristic associated to the structural property of the oil [34]. Hence, the more liquid the oil is, the higher the RI. It is important to note that the RI increases as the length of carbon chain and number of double bonds (unsaturation) of the fatty acid of the triacylglycerol increases [35], whereby the angle of refraction is reduced, and hence giving higher RI [36]. The values of RI may also be affected by oxidation and polymerisation processes [34, 37].

PSO is traded on a weight basis, but in fact measured in volume. The AD of PSO is an essential parameter for the weight determination in the cargo during shipment [10]. A similar case as in RI was observed for AD, whereby a new range value at experimental temperature of 40 °C was set at 0.886 to 0.900. In the present assessment, the AD measured at 40 °C was between 0.89720 and 0.89839 which fell within the values specified in Codex CXS 210-1999 [9]. It is important for the experimental temperature to be appropriate for testing of both RI and AD in which the oil samples are completely melted, as well as to harmonise with the reference methods recognised internationally such as ISO standard methods. The use of linear least square fit to correlate the function of RI and AD with IV, together with temperature was reported by Liew et al. [38]. Notably, both RI and AD were found to be linearly decreasing with temperature (30 to 80 °C), and linearly dependent on the IV of the oil. IV is a degree of the unsaturation of the fatty acids in the triacylglycerols. The high IV of PSO (>60) is contributed by the monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA) groups [39].

As PSO has higher IV compared to single-fractionated palm olein, it has better characteristics in terms of oil clarity, stability, and is less likely to turn cloudy [40]. Cloudiness of normal palm olein is often observed in low temperature settings during transportation and storage, as well as in cold weather [41]. This is a result of diacylglycerols (DAG) crystallisation. Although it does not affect the oil quality itself, it is always preferable by consumers to have a non-cloudy oil. Thus, the practice of blending palm olein with other soft oils, and double fractionating palm olein into PSO is applied to obtain a clearer oil. The control of the fractionation process is important to obtain a good quality product, more importantly palm olein of higher IV [42]. Optimising crystallisation temperature influences the yield and the quality of PSO. This advancement in fractionation technology has produced better quality PSO, as more solid fraction is refrained from passing through the membrane filter press, giving higher IV and improved chemical and physical properties of PSO.

PSO contains a high amount of unsaturated fatty acids (MUFA and PUFA) and the major fatty acids in PSO are mainly oleic acid (47%), palmitic acid (35%) and linoleic acid (14%) [40, 43]. Table 3 shows the FAC of PSO analysed in the current assessment. The FAC was

found to be within the range as reported in the previous articles and assessment [10, 40, 43], with oleic acid having the highest mean percentage (45.8%), followed by palmitic acid (35.7%) and linoleic acid (12.6%). The high content of unsaturated fatty acids in PSO makes it the most liquid form of palm oil products.

Table 3. Fatty acids composition of palm superolein

Fatty Acid (Weight Percent as Methyl Ester)	**2016/19 Palm Superolein Assessment (n = 44)**		**Codex CXS 210-1999** [9]
	Mean (%)	**Range (%)**	**Range (%)**
Lauric acid, C12:0	0.3	0.2 - 0.6	0.1 – 0.5

Oleic acid, C18:1	45.8	43.9 – 48.7	43.0 – 49.5
Linoleic acid, C18:2	12.6	11.1 – 13.7	10.5 – 15.0
Linolenic acid, C18:3	0.3	0.2 - 0.3	0.2 – 1.0
Arachidic acid, C20:0	0.3	0.1 - 0.4	ND – 0.4

*ND: not detected

The TAG composition of PSO is listed in Table 4. In general, PSO contains mostly TAG (91%) and DAG (9%) [43]. In this study, the PSO samples analysed showed slightly higher TAG (92.51%) and lower DAG (7.49%). PSO contains more triunsaturated and monosaturated TAG, and less trisaturated TAG, hence the greater IV. Additionally, the much lower trisaturated TAG content in PSO contributed to its resistance towards cloudiness. With regards to the correlation of TAG composition with IV, the function of TAG composition by HPLC analysis to predict the IV of the oil was reported by Haryati et al. [44]. The IV was estimated from the regression model mainly on the peak areas of the disaturated, trisaturated and triunsaturated TAGs.

The SMP is the temperature at which a fat change from solid to liquid phase. It is dependent on the FAC of the oil. The average SMP observed from the PSO analysed was 15.3 °C, with range values between 12.9 °C and 16.9 °C. These values were similar to those reported by Tang et al. [10], and they also reported that PSO with high IV had lower SMP as a result of complex composition of the PSO itself which is a mixture of various species of acylglycerols.

The SV is used to measure the types of acylglycerols in the oil by measuring alkali-reactive groups in the oil. A higher SV indicates low-molecular weight triacylglycerols of edible fats and oils. The range observed for SV was 181 to 217 mg KOH g^{-1}, a slightly wider range compared to the previous assessment in 1995. This range conformed to the lower limit of SV (180 mg KOH g^{-1}) in Codex CXS 210, and slightly exceeded the upper limit of 205 mg KOH g^{-1}. Low SV for PSO is attributable to the high amount of long chain fatty acids, *i.e.* oleic and linoleic acids in the composition of PSO.

The unsaponifiable matter is the fraction of substances in the PSO after saponification, which is not volatile at 103 °C that includes sterols, higher hydrocarbons and alcohols, aliphatic and terpenic alcohols, and foreign matter extracted by diethyl ether [45]. An average value of 0.37% of unsaponifiable matter was observed for PSO. Palm oil is classified as a vegetable oil having low unsaponifiable matter of less than 1.2% [46]. The previous study [46] also stated that sterols are the predominant unsaponifiable matter in most oils. In palm oil, Codex CXS 210-1999 listed β-sitosterol, campesterol and stigmasterol as the three main sterols found in PSO. Tocopherols and tocotrienols fractions are also abundant in palm oil products, in the range of 400 to 1400 mg kg^{-1} [9]. These minor components are highly useful in food applications as well as play a significant role in both human and animal nutrition.

Table 4. Acylglycerol composition of palm superolein

	2016/19 Palm Superolein Assessment (n = 44)	
Glycerol	**Mean (%)**	**Range (%)**
DAG	7.49	6.20 – 10.44
Triunsaturated TAG		
*OLL	0.63	0.52 – 0.88
OLO	2.38	2.04 – 2.67
OOO	5.36	4.55 – 6.37

MPP	0.10	0.03 – 0.93
PPP	0.13	0.06 – 0.51

*O – oleic; L – linoleic; P – palmitic; S – stearic; M – myristic

Correlation analysis of selected quality and identity parameters

The linear relationship for IV, RI, AD, FFA and moisture of the PSO samples was assessed using Pearson correlation. The correlation results shown in Table 5 demonstrates a positive relationship for RI-IV, AD-IV and FFA-moisture. A very strong positive correlation was observed for AD-IV with *p*-value of 0.000 (p <0.05), indicating the highly significant correlations. A similar observation was noted for FFA-moisture and this is expected as FFA is highly influenced by moisture content in the oil. Correlations between RI-AD and RI-IV were somewhat insignificant (p >0.05). More data are required to confirm and to derive conclusive correlations between each parameter.

Table 5. Correlation of selected parameters in PSO quality performance

Parameter	**Pearson Correlation Coefficient**	***p*-value**
RI-AD	-0.011	0.944
RI-IV	0.012	0.939
AD-IV	0.843	0.000
FFA-Moisture	0.538	0.012

Conclusion

The present study concludes that the physical characteristics and the chemical compositions of PSO have experienced slight variations over the last two decades, particularly in its RI and AD. This shift suggests that the current advancement in the

fractionation technology has produced better quality PSO for its various uses in the food industry. The overall quality performance of PSO was satisfactory and largely conformed to Codex CXS 210-1999. Periodic evaluation of PSO has helped in understanding the current situation of PSO produced in Malaysia in terms of its quality and the setting of realistic and achievable targets in the quality specification. These new sets of quality data will be used in the revision of guidelines for the identity characteristics of PSO in MS 1762:2004, Palm Superolein - Specification.

Abstract

Bismuth ferrite ($BiFeO_3$) has been demonstrated to be one of the most efficient perovskite-based photocatalysts for pollutant degradation under direct sunlight. The focus of this research was to study the photocatalytic activity of $BiFeO_3$ in relation to the degradation of the antibiotic ofloxacin. Different operational parameters for the optimized system were determined, such as photocatalyst dosage (0.05 g L^{-1} to 0.50 g L^{-1}), pollutant concentration (2.5 mg L^{-1} to 20 mg L^{-1}), reaction duration (2 hours), pH of solution (pH 2 to pH 12), and the effect of hydrogen peroxide, H_2O_2 as an oxidant (0.1 M to 0.7 M). X-ray Diffraction (XRD), Scanning Electron Microscope-Energy Dispersive X-ray (SEM-EDX), and Fourier Transform Infrared Spectroscopy (FTIR) analyses all corroborated that the rhombohedral $BiFeO_3$ has a high purity and large surface area. The most efficient condition for all selected parameters was 0.07 g L^{-1} $BiFeO_3$ at pH 8 in 10 mg L^{-1} of ofloxacin and the addition of 0.3 M H_2O_2 with 70.1% degradation and the total organic carbon left in the solution was 9.36%. The reaction obeyed pseudo-first order kinetics with R^2 value obtained is 0.9399, with decreasing *k* values as the initial concentration increased. This demonstrated that the system performed best at low concentrations. This discovery paves the way for future research into the operational parameters that contribute to the photocatalyst efficacy in removing antibiotics as a pollutant.

Abstrak

Ferit bismut, $BiFeO_3$ terbukti sebagai salah satu daripada fotopemangkin berasaskan perovskit terbaik untuk degradasi pelbagai pencemar di bawah cahaya matahari langsung. Kajian ini dijalankan untuk mempelajari prestasi fotoaktiviti $BiFeO_3$ terhadap degradasi antibiotik ofloxacin. Parameter operasi yang berbeza telah ditentukan untuk sistem yang dioptimumkan termasuk dos fotopemangkin (0.05 g L^{-1} hingga 0.50 g L^{-1}), kepekatan bahan cemar (2.5 mg L^{-1} hingga 20 mg L^{-1}), masa tindak balas (2 jam), pH (pH 2 hingga pH 12), dan kesan hidrogen peroksida (H_2O_2) sebagai agen pengoksidaan (0.1 M hingga 0.7 M). Keputusan analisis pembelauan sinar-x (XRD), spektroskopi inframerah-transformasi Fourier (FT-IR) dan mikroskop elektron imbasan-spektroskopi sinar-x penyebaran tenaga (SEM-EDX) mengesahkan ketulenan tinggi $BiFeO_3$ rombohedral yang telah dihasilkan dengan luas permukaan yang tinggi. Keadaan yang paling berkesan untuk semua parameter terpilih adalah dos $BiFeO_3$ 0.07 g L^{-1} pada pH 8 di dalam 10 mg L^{-1} ofloxacin dengan penambahan 0.3 M H_2O_2 yang menghasilkan degradasi ofloxacin sebanyak 70.1% dan jumlah kesuluruhan karbon yang tinggal didalam larutan adalah sebanyak 9.36 %. Tindak balas ini tergolong di dalam urutan kinetik pseudo-pertama dengan nilai R^2 tercapai sebanyak 0.9399, dengan nilai *k* menurun apabila kepekatan awal meningkat. Ini menunjukkan bahawa sistem ini adalah lebih efisyen pada kepekatan yang rendah. Penemuan ini telah membuka satu kajian berpotensi ke arah penerokaan faktor yang meningkatkan kecekapan fotopemangkin bagi penyingkiran pencemar antibiotik.

Introduction

Urbanization and industrialization have a detrimental effect on many countries water sources. Textile industries, hospitals, farms, and residences may discharge a variety of contaminants, including dyes [1], heavy metals [2], pesticides [3], and antibiotics [4]. Antibiotics can be classified as an emerging contaminant since their concentration in water bodies has increased over the years due to increases in utilization rates in the human and livestock sectors [5]. According to Ambrosetti et al. [6], antibiotics may exist in the environment as parent molecules, breakdown products, and they are partially metabolites in nature. Moreover, these antibiotic wastes are reported to be bioaccumulated, bio-transformed, and deposited in the solid and aqueous phases [7], thus increased the antibiotic persistence in the environment.

A fluoroquinolone antibiotic called ofloxacin (OFL) has been utilized for treating bacterial infections of the skin, lungs, and urinary tract [8]. Fluoroquinolones may be discovered in amounts ranging from 18.28 ng L^{-1} to 6,058 µg L^{-1} in hospital, wastewater, and slaughterhouse effluent. These range of values exceeded the values recommended by The World Health Organization (WHO) guideline that should be less than 100 µg L^{-1}. Although several reports claimed that the measured concentration of ofloxacin in water bodies is lower than the limit, its presence is still a severe problem that should be eliminated. Researchers have been working on developing methods to eradicate this contaminant using adsorption [9], biosorption [10], or photocatalysis [11] methods. Nonetheless, photocatalysis remains as one of the best strategies for antibiotic degradation as it is cost-effective and generates little waste. Conventional photocatalysts, such as TiO_2 and ZnO, have significant drawbacks, including a restricted response to visible light irradiation as a result of their large band gap energies of 3.2 eV and 3.3 eV, respectively [12,13]. As a result, research on alternatives has been conducted to overcome the restrictions.

Soltani et al. [14] discovered that bismuth ferrite ($BiFeO_3$) has a band gap of 2.17 eV, which is narrow and is theoretically suitable for the operation employing visible light irradiation. $BiFeO_3$ enhanced magnetic and optical characteristics, as well as its increased oxidizing capacity, has made it a viable photocatalyst [15]. This material exists in three common phases: perovskite ($BiFeO_3$), mullite ($Bi_2Fe_4O_9$), and sillenite ($Bi_{25}FeO_{40}$), each with slightly different photocatalytic performance [16]. Previously, Yang et al. [17] used a sillenite phase of $BiFeO_3$ in the degradation of levofloxacin, and the photocatalytic activity was exceptional. Zahra et al. [18] also employed $BiFeO_3$ for tetracycline breakdown and demonstrated substantial potential under visible light irradiation.

The initial concentration of pollutants, photocatalyst dosage, pH solution, and irradiation time are examples of the important operational parameters in the photocatalytic reaction. As Wang et al. [19] reported, the removal efficiency increases with increasing catalyst dosage until it reaches the optimum dosage and start to decline as the dosage further increase. The turbidity of the solution caused the reduction in the photon penetration through the solution. In their work, Hapeshi et al. [20] stated that the removal efficiency of ofloxacin started to decrease from 100 % to 88 % as the initial concentration increased from 10 mg L^{-1} to 20 mg L^{-1}. Besides, Hu et al. [16] also reported that the solution pH could affect the photocatalytic degradation of bisphenol A due to the alteration of the surface charge in different pH conditions.

The morphological, optical, and other features of the produced perovskite $BiFeO_3$ were studied in this work. Also, the influence of the operating settings on the ofloxacin photocatalytic degradation by $BiFeO_3$ was investigated under the illumination of sunlight.

Materials and Methods

Bismuth nitrate pentahydrate ($Bi(NO_3)_3.5H_2O$), iron nanohydrate ($Fe(NO_3)_3.9H_2O$), *kappa*-carrageenan, and ofloxacin were all purchased from Sigma-Aldrich with more than 99 % purity. Meanwhile, sodium hydroxide (NaOH) pellets, sodium nitrate ($NaNO_3$), ethanol (99.7%), and hydrochloric acid (HCl) (37%) were supplied from R&M Chemicals.

Synthesis of perovskite bismuth ferrite (BFO)

$BiFeO_3$ nanoparticles were synthesised utilising the sol-gel technique with bio-templating, as proposed by Satar et al. [21]. An amount 2.80 g bismuth nitrate pentahydrate ($Bi(NO_3)_3.5H_2O$) was first dissolved in 50 mL deionized water. The aforementioned solution was then mixed with 4.04 g of iron (III) nitrate nonahydrate ($Fe(NO_3)_3.9H_2O$). In 100 mL of deionized water, 1.00 g of *kappa*-carrageenan powder (1%) was dissolved completely. Following that, 40 mL of 1%-carrageenan solution and 10 mL of Bi and Fe salts solution were mixed and agitated with a magnetic stirrer. Using 1.0 M NaOH solution, the pH of the combination was adjusted to pH 10. The resultant sol was dried in an oven at 80 °C overnight after 2 hours of stirring. In the muffle furnace, the dried gel was calcined for 2 hours at 550 °C. Subsequently, the powder was rinsed multiple times with deionized water and ethanol prior drying at 80 °C for 2 hours.

Characterization of perovskite bismuth ferrite (BFO)

The X-Ray Diffraction (XRD) pattern of $BiFeO_3$ nanoparticles was obtained using a PANalytical X'Pert PRO with graphite monochromator and Cu K radiation ($\lambda = 1.5406$) in the range of 10 - 80°. The morphology and chemical composition of $BiFeO_3$ nanoparticles before and after photocatalytic activity were examined utilizing scanning electron microscopy (SEM, FEI-QUANTA FEG 650) and an Energy Dispersive X-Ray spectroscopy (EDX) microanalyzer (INCA X, Oxford Instruments). The band gap of $BiFeO_3$ was estimated using the reflectance percentage (%R) acquired from the UV-vis diffraction reflectance (UV-DRS) spectrophotometer (LAMBDA 25). The functional group present in $BiFeO_3$ was identified using Perkin Elmer's System 2000 IR in the wavenumber range 4000 – 400 cm^{-1}. Through nitrogen adsorption (BET analyser), the surface features and porosity of $BiFeO_3$ were investigated using the Micromeritics ASAP 2020 Surface Area and Porosity analyzer. Finally, the removal of total organic carbon (TOC) was assessed using a TOC analyzer (Shimadzu TOC-L).

Degradation of ofloxacin under direct sunlight

The photocatalytic activities of $BiFeO_3$ nanoparticles were investigated using the degradation of ofloxacin (OFL) solution in the presence of sunlight. This study was carried out between March and August 2021, from 11 a.m. to 3 p.m. Typically, 100 mL of 10 mg L^{-1} OFL solution (unadjusted pH) was placed into a beaker followed by adding catalyst (10 mg, that corresponds to 0.1 g L^{-1}). First, the solution was magnetically agitated for 30 minutes in the dark to produce adsorption-desorption equilibrium. The solution was then exposed to sunlight for 2 hours. Sampling was performed by withdrawing 5 mL of the solution at 20-minute intervals and filtering with 0.22-micron filters before been analyzed at 288 nm using UV-vis spectrophotometer (Shimadzu UV-2600). A control experiment was done

by using the same procedure but without the presence of photocatalyst. A calculation by using the following equation was made to obtain the percentage removal of OFL solution:

$$Removal\ (\%) = \left(1 - \frac{C_t}{C_o}\right) \times 100 \quad (1)$$

Based on the above equation, removal (%) represents the percentage removal of OFL in the experiments. C_t and C_o represent the concentration of OFL at the given time and the initial concentration of OFL, respectively. The effect of catalyst dosage in the experiment was carried out by varying the dosage at 0.05, 0.07, 0.09, 0.3, and 0.5 g L^{-1}. For the effect of pH, 0.1 M NaOH and 0.1 M HCl were used to alter the pH to obtain pH 2, 4, 6, 8, 10, and 12. In the initial concentration of the OFL solution, the concentration used are 2.5, 5, 10, 15, and 20 mg L^{-1} and finally, 0.1, 0.3, 0.5, and 0.7 M H_2O_2 were used to study the effect of hydrogen peroxide in the photocatalytic degradation OFL by $BiFeO_3$ photocatalyst. For each parameter, the test was repeated thrice to achieve an average value.

Results and discussion

Structural and morphological analysis of $BiFeO_3$

$BiFeO_3$ had been successfully synthesized by using the sol-gel method with kappa-carrageenan as a bio template as shown in Figure 1. The chains of κ-carrageenan performed cross-linking to give the protective layers and stabilize the Fe^{3+} and Bi^{3+} ions. As the pH of the mixture increases, κ-carrageenan self-capped the ions and this localized area became the nucleation and growth sites of the $BiFeO_3$ particles. The calcination process did the elimination of κ-carrageenan and the structure of $BiFeO_3$ remained. Figure 2 depicts SEM micrographs and EDX spectra of $BiFeO_3$ nanoparticles before and after photocatalytic degradation. Figure 2(a) shows the morphology of unused $BiFeO_3$ as distorted rhombohedral structure and homogeneously distributed. The average particle size calculated by J-image software, is 90 nm as in agreement with previous method. The SEM micrograph for the employed $BiFeO_3$ in Figure 2(b) confirmed that no substantial changes could be noticed, although average particle sizes increase to more or less than 170 nm. This could be due to $BiFeO_3$ agglomeration after being utilized in photocatalytic activity. The presence of elements such as Bi, Fe, and O in the sample was demonstrated by EDX and the absence of additional elements verified the samples purity. The XRD pattern of synthesized $BiFeO_3$ was demonstrated in Figure 3(a). The catalyst exhibited diffraction peaks at 2θ = 22.48°, 32.12°, 39.56°, 45.89°, 51.67°, 57.12°, and 67.18°, which corresponded to pure rhombohedral phase $BiFeO_3$ Miller's indices of (0 1 2), (1 1 0), (0 2 4), (1 1 6), (3 0 0), and (2 2 0). This pattern is in agreement to the standard perovskite $BiFeO_3$ data (JCPDS card No. 01-073-0548). The predominant peak that could be assigned was (1 0 1), and no corresponding impurity peak was observed, implying that the $BiFeO_3$ nanoparticles produced were pure and exhibited a highly crystalline distorted rhombohedral structure.

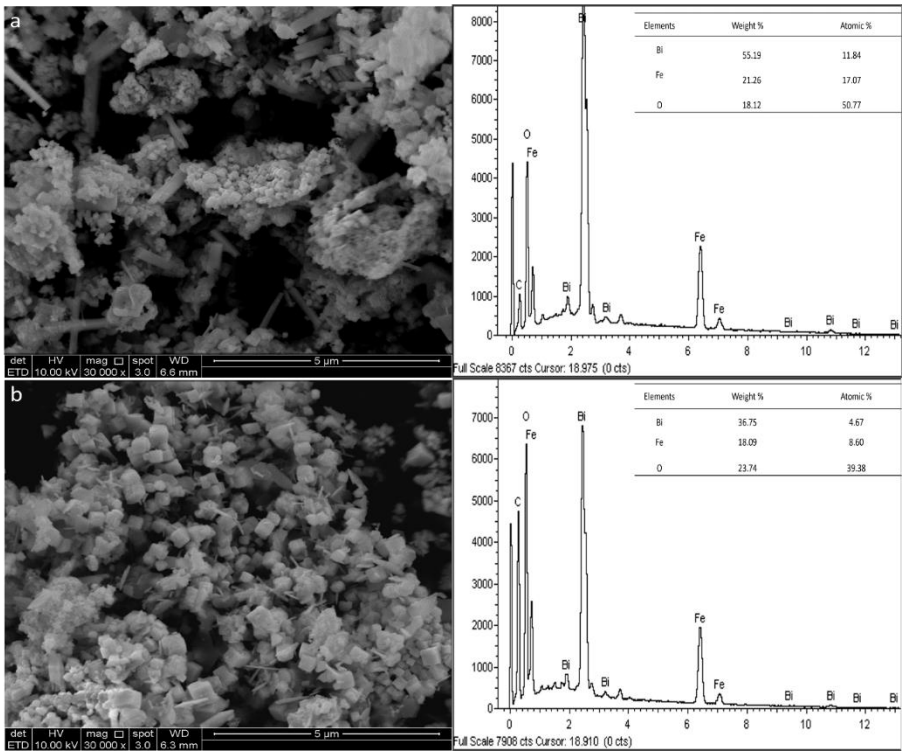

Figure 2. The SEM images of (a) $BiFeO_3$ photocatalyst, and (b) $BiFeO_3$ photocatalyst (used) and their elemental composition

Analysis of the N_2 sorption isotherm

Brunauer, Emmett, and Teller (BET) nitrogen adsorption analysis was used to determine the N_2 sorption isotherm, pore size, pore volume and surface area of $BiFeO_3$. Based on Figure 3(b), the isotherm obtained suggested that $BiFeO_3$ has Type IV and H3 hysteresis loop classification, implying that the sample was primarily composed of mesopores [22] typically range from 2 nm to 50 nm. The presence of plate-like particles in the sample, which aggregated to create slit-shaped pores, is indicated by the H3 hysteresis loop [23]. Figure 3(c) displays pore distribution model (PSD) based on Barrett-Joyner-Halenda (BJH) theory, with pore diameters ranging from 8 nm to 98 nm, confirming the material has mesoporous pores. The PSD plot demonstrated that the pore size and pore volume of $BiFeO_3$ were 31.94 nm and 0.041 $cm^3\ g^{-1}$, respectively, and the surface area obtained was 4.67 $m^2\ g^{-1}$. The porosity features are essential because they can be associated with the adsorption-desorption process of pollutant molecules to the photocatalyst prior to degradation by the photocatalysis process.

BFO optical analysis

The photocatalyst optical properties aid in determining their band gap energy, which is connected to the UV-absorption edge. The UV-vis diffraction reflectance spectra of the synthesized $BiFeO_3$ photocatalyst are depicted in Figure 3(d), and it exhibits substantial absorption of light in the visible light spectrum. Kubelka-Munk theory formula was used to determine the band gap energy of $BiFeO_3$. The corresponding band gap energy can be ascertained from the extrapolated tangent line in the plot of squared Kubelka-Munk functions, $F(R)^2$ vs photon energy of $E=h\nu$. The band gap energy obtained for the as-prepared $BiFeO_3$ is 2.04 eV, which is less than 2.10 eV found in previous investigations by Huo et al. [24]. The decrease in band gap energy could be caused by the lattice strain effect in $BiFeO_3$, which is correlated to particle size reduction. As a result, $BiFeO_3$ nanoparticles were demonstrated to

be responsive to visible light and can be employed for the photodegradation of contaminants under visible light.

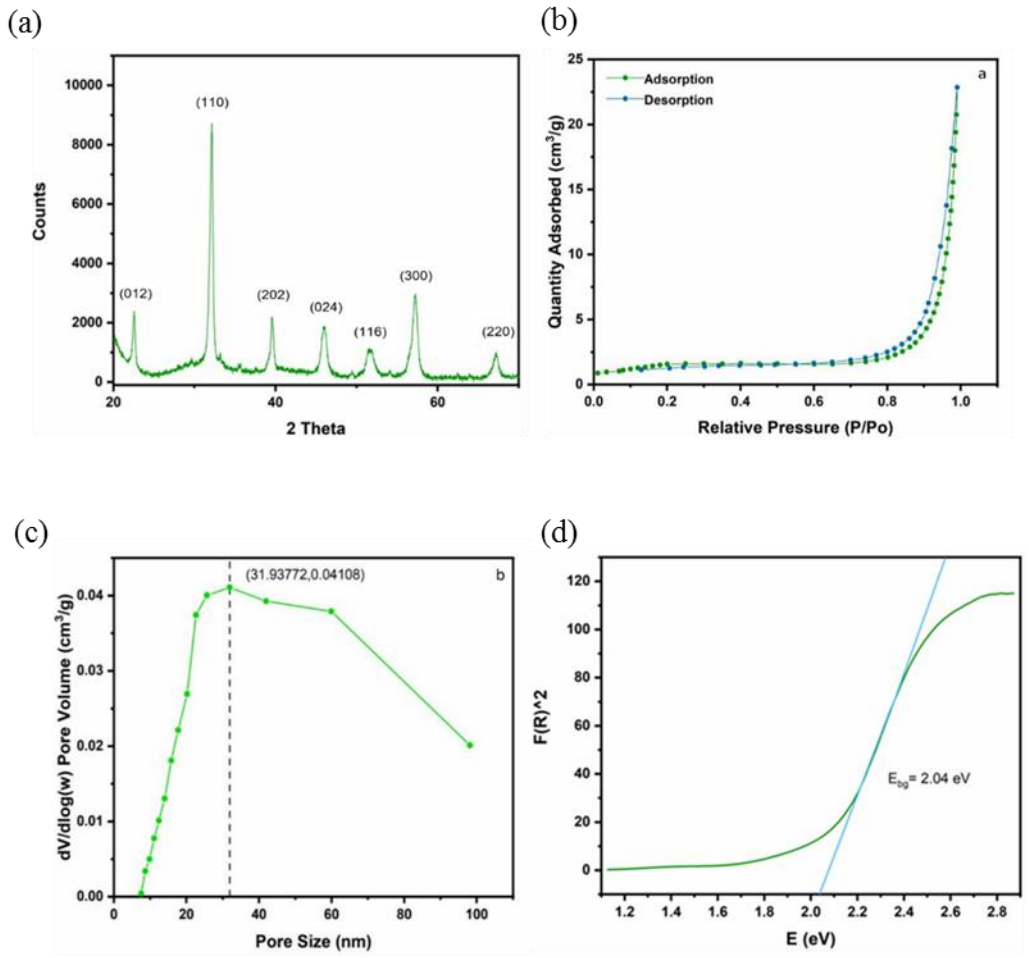

Figure 3. The (a) XRD pattern, (b) nitrogen linear adsorption, (c) pore size distribution and (d) bandgap energy of synthesized $BiFeO_3$ nanoparticles

BFO FTIR spectra

FT-IR spectroscopy analysis was utilized to validate the presence of functional groups in the synthesized perovskite $BiFeO_3$. Figure 4(a) reveals a broad and strong absorption band between 3000 cm^{-1} and 3500 cm^{-1} that can be referred to as stretching vibrations of the O-H group, while the bending vibrations mode of water can be detected at 1625 cm^{-1}. Bending vibrations of Fe-O and Bi-O may be observed at the sharp peak at 568 cm^{-1} and 457 cm^{-1}, respectively. These absorptions corresponded to the features of the octahedral FeO_6 group found in perovskite compounds like $BiFeO_3$.

Figure 4(b) depicts the FTIR spectrum of $BiFeO_3$ employed in the photocatalytic degradation of ofloxacin. There were slight changes observed, such as the shape of stretching vibrations of O-H group to a medium broad absorption band and the loss of nitrate groups at 875 cm^{-1}. However, some absorption bands, particularly the Fe-O and Bi-O bending vibrations of $BiFeO_3$ nanoparticles, were successfully preserved. As a result, this proves that $BiFeO_3$ is a stable catalyst that is not damaged by the contaminants.

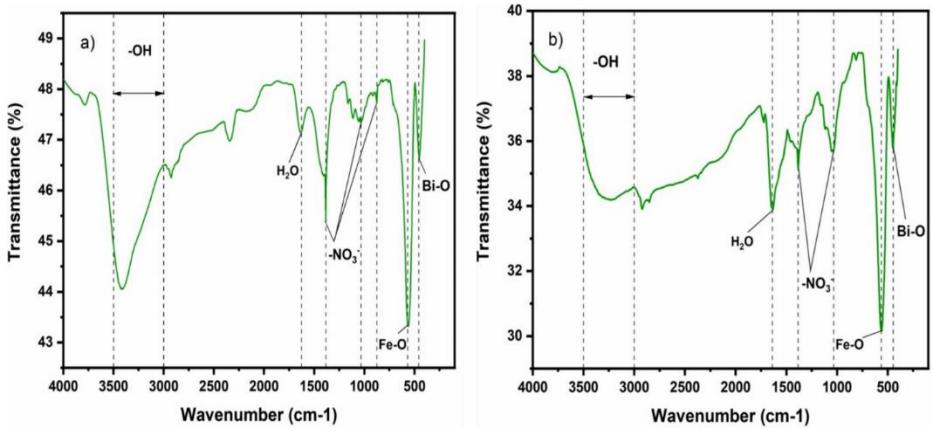

Figure 4. FTIR spectra of $BiFeO_3$ (a) before and (b) after photocatalytic reactions

Point of zero charge (PZC)

At a specific pH level, the point of zero charge (PZC) is a state in which there is no net charge on the surface of the molecules [25]. As illustrated in Figure 5(a), the point of zero charge (pH_{pzc}) pH value can be detected at the x-intercept of the plotted curve between the difference of final and initial pH and initial pH of the solution. $BiFeO_3$ pH_{pzc} value was 7.75, which is in the neutral region. When the pH value was less than pH_{pzc}, the presence of the positive charge on the surface of the $BiFeO_3$ can be observed. Whereas, at the pH value above pH_{pzc}, the presence of negative charge can be observed on the surface of the photocatalyst. The electrostatic interaction between the photocatalyst and pollutant molecules can be linked to the effect of pH on the photodegradation efficiency of $BiFeO_3$.

Degradation of ofloxacin by photocatalysis: Catalyst dosage

The degradation of ofloxacin in the control experiment gave a non-significance result, thus the research was continued with the operational parameter studies. The influence of catalyst dosage was studied by changing the $BiFeO_3$ dosage from 0.05 g L^{-1} to 0.50 g L^{-1} in a solution of 20 mg L^{-1} of ofloxacin without adjusting the pH level. This investigation is necessary to ascertain the best amount of catalyst to be utilized in order to maximize the photocatalyst's potential. Table 1 and Figure 5(b) illustrate the effect, which were tabulated and plotted respectively. As the dosage increased from 0.05 g L^{-1} to 0.07 g L^{-1}, the degradation efficiency of $BiFeO_3$ was raised from 29.32 % to 34.96 %. The behaviour can be elucidated by the fact that as the catalyst dosage increases, the number of active sites in the photocatalyst increases, which is closely proportional to the number of radicals produced during the degradation of ofloxacin [26]. However, as the catalyst dosage is continuously increased from 0.09 g L^{-1} to 0.50 g L^{-1}, the degrading performance began to decline from 32.93 % to 23.47 %. When the amount of catalyst used exceeded the optimum dose, the turbidity of the solution increased, and photocatalyst particle agglomeration occurred in the solution, affecting the light penetration and reducing the photocatalytic activity of $BiFeO_3$ [14]. Photooxidation kinetics of ofloxacin depended on $BiFeO_3$ loading and it was discovered that the rates increased as the $BiFeO_3$ loading increased until a certain limit and then the rates started to decrease back to a constant value. Therefore, an optimum $BiFeO_3$ dosage added is important to prevent the unnecessary excess catalyst and to ensure total absorption of light photons for efficient photo mineralization. According to the findings, the best catalyst dosage in the experiment was 0.07 g L^{-1}, with a removal rate of 35% in 120 minutes under sunshine exposure.

Table 1. The removal efficiency of OFL at different $BiFeO_3$ dosage with respect to time. (Condition: 20 mg L^{-1} OFL with unadjusted pH and 120 min irradiation under sunlight)

BFO Dosage (g L^{-1})	% Removal of OFL		
	Dark (30 mins)	1 hour	2 hours
0.05	0.32	14.21	29.32
0.07	0.26	14.87	34.96
0.09	0.65	17.82	32.93
0.30	3.20	18.08	31.70
0.50	2.56	11.16	23.47

The pH of the ofloxacin solution

The photocatalytic activity of the photocatalyst has been found to be directly connected to the pH of the pollutants, which has an important influence on the degradation performance. The pH change may modify the electrical double layer of the catalyst and pollutant interface, affecting the adsorption-desorption processes and the separation of the carrier charges in catalyst particles. Ofloxacin, according to Crespo-Alonso et al. [27], is an amphoteric molecule that exists as an anion at pKa 8.22 and a cation at pKa 6.05 while exists as a zwitterion between these pKa values. The pH value of the 20 mg L^{-1} ofloxacin solution with a catalyst dosage of 0.07 g L^{-1} was done by adjusting the pH of solution from pH 2 to pH 12. The removal efficiency of ofloxacin increases from 16.84 % to 36.70 % as the pH decreases from 12 to 8, as tabulated in Table 2 and plotted in Figure 5(c). Then, as the pH value dropped to 6, the performance declined to 21.01 %. As the $BiFeO_3$ is within the acidic region at pH 2, its photocatalytic performance decreases significantly, with a very low value of 0.84 %. This suggests that the breakdown of ofloxacin in the acidic medium is unfavourable. At pH 2 and pH 4, the surface charge of $BiFeO_3$ is positive, and ofloxacin exists as a cation at these pH levels. As a result, electrostatic repulsion between the photocatalyst and pollutant molecules arises, resulting in a decrease in degradation efficiency. Nevertheless, the photocatalytic performances also declined in the strong alkaline region as the surface charge of $BiFeO_3$ is negative and ofloxacin exists in its anionic state as its structure undergoes deprotonation, which caused the repulsion between ofloxacin and $BiFeO_3$ molecules. These suggest that the breakdown of ofloxacin in the strong acidic and alkaline medium are unfavourable [28]. Therefore, the optimum pH value was obtained at pH 8 as the removal effectiveness was the highest, with 36.70 % removal. The $BiFeO_3$ surface exhibited anionic behaviour at pH 8, and ofloxacin occurred in a zwitterionic state with both positive and negative charges. As a result, electrostatic interaction between the $BiFeO_3$ surface and ofloxacin molecules might occur, thereby improving the removal efficiency of the antibiotic. The study proved that pH value variation could affect the adsorption of ofloxacin on the surface of $BiFeO_3$ and its photodegradation efficiency.

Table 2. The removal efficiency of OFL at different pH with respect to time(Condition: 0.07 g L^{-1} $BiFeO_3$, 20 mg L^{-1} OFL and 120 min irradiation under sunlight)

Solution pH	% Removal of OFL		
	Dark (30 mins)	1 hour	2 hours
2	0.14	2.82	0.84
4	3.35	4.59	3.79
6	1.58	11.05	21.01
8	5.93	22.10	36.70
10	1.24	16.59	29.19
12	9.89	13.63	16.84

Initial concentration of ofloxacin solution

The initial concentration study was done by using different concentrations of ofloxacin from 2.5 mg L^{-1} to 20 mg L^{-1} with the 0.07 g L^{-1} catalyst dosage and in pH 8 medium. Generally, the initial concentration study was conducted to identify the optimum concentration for the photocatalyst to carry out the photocatalysis optimally. Table 3 and Figure 5(d) show that as the initial concentration of ofloxacin increases from 2.5 mg L^{-1} to 10 mg L^{-1}, the degradation efficiency of ofloxacin also increases steadily from 37.00 % to 46.13 %. The optimum initial concentration in the study was 10 mg L^{-1} due to the highest removal efficiency. The removal efficiency decreased to 37.52 % and 36.78 %, respectively, when the starting concentration rose to 15 mg L^{-1} and 20 mg L^{-1}. This can be explained as the higher the concentration of ofloxacin, the higher the number of ofloxacin molecules in the medium. Therefore, a greater amount of light being absorbed by the ofloxacin molecules and reduced the photo flux from hitting the photocatalyst surface. Besides, the competition between the ofloxacin molecules might increase because of higher amount of pollutant molecules compared to the amount of available active sites on the photocatalyst [29]. It may be deduced that a high initial concentration of ofloxacin will reduce its removal effectiveness.

Table 3. The removal efficiency of OFL at different initial concentration with respect to time. (Condition: 0.07 g L^{-1} $BiFeO_3$, OFL solutions with pH 8 and 120-min irradiation under sunlight)

Concentration OFL (mg L^{-1})	% Removal of OFL		
	Dark (30 mins)	1 hour	2 hours
2.5	1.72	30.77	37.00
5.0	6.40	27.34	41.79
10.0	6.10	30.14	46.13
15.0	5.03	22.54	37.52
20.0	5.42	22.44	36.78

Effect of hydrogen peroxide addition

The final parameter in this work is the influence of the addition of hydrogen peroxide (H_2O_2) to the extent of the photocatalysis reaction. The study on the effect of H_2O_2 addition was carried out by adding a different concentration of H_2O_2 from 0.1 M to 0.7 M in 10 mg L^{-1} of ofloxacin solution at a pH level of 8 with 0.07 g L^{-1} catalyst dosage. As shown in Table 4 and Figure 5(e), the removal efficiency drastically increases as the concentration of hydrogen peroxide introduced

increases from 0.1 M to 0.3 M with an efficiency of 56.68 % to 70.10%, respectively. However, as the concentration of H_2O_2 kept on increasing, only a small amount of increment can be observed in the removal efficiency being the highest of 72.42 % with 0.7 M of H_2O_2. The trend that can be seen from the study may cause by the increased number of radicals generated from the breakdown of hydrogen peroxide through the reduction of it at the conduction band and decomposition by the illumination of sunlight. As the concentration of H_2O_2 increases beyond 0.3 M, the generation of radicals may achieve saturation as the removal efficiency only slightly increases. The purpose of this study was to utilize the lowest possible concentration of H_2O_2 used with excellent removal efficiency as in low concentrations of H_2O_2, more efficient is the production of hydroxyl radicals and inhibition of charge carrier recombination. Besides, the solution may sometimes experience oxygen starvation because of slow oxygen mass transfer or oxygen consumption. The addition of H_2O_2 can help to achieve a sufficient oxygen supply and modify the $BiFeO_3$ surface, however high concentration of it could act as photoproduced holes scavenger. Therefore, the optimum concentration of H_2O_2 used in the study was 0.3 M. The results proved that the introduction of hydrogen peroxide with minimal concentration could successfully boost the photocatalytic degradation of ofloxacin by $BiFeO_3$.

Table 4. The removal efficiency of OFL at different concentration H_2O_2 used with respect to time. (Condition: 0.07 g L^{-1} $BiFeO_3$, 10 mg L^{-1} OFL with pH 8 and 120-min irradiation under sunlight).

Concentration H_2O_2 (M)	**% Removal of OFL**		
	Dark (30 mins)	**1 hour**	**2 hours**
0.1	13.42	44.75	56.68
0.3	7.46	31.32	70.10
0.5	13.04	59.39	70.97
0.7	10.14	59.39	72.42

Kinetic model and total organic carbon (TOC) removal

The Langmuir-Hinshelwood (LH) model was used to investigate the reaction kinetics for the photocatalytic degradation of ofloxacin. The model has usually been utilized for the heterogeneous photocatalytic degradation in various types of pollutants and simplified to pseudo-first order expression [16]. Figure 5(f) shows the plotted LH model and the data obtained are tabulated in Table 5. The LH equation had been simplified into a pseudo-first order kinetic model equation as follows:

$$ln\frac{C_t}{C_o} = kt \quad (2)$$

where, C_o and C_t are the initial concentration of ofloxacin and concentration of ofloxacin at the time, t, respectively. k is the degradation rate constant and t is the irradiation time. k value can be obtained directly from the slope of the plot between ln C_o/C_t versus irradiation time. Based on the plotted graph and its square of correlation coefficient (0.9399), r^2, it can be concluded that the reaction followed pseudo-first order kinetic and fitted the model perfectly and k value obtained from the graph was 0.0084 min^{-1}.

Next, total organic carbon (TOC) removal is an important study and can be used to identify the total carbon content of the organic pollution in the water bodies after being treated [30]. From the plot in Figure 6(a), after exposure to sunlight for 120 mins, 65.99% of ofloxacin has been degraded by $BiFeO_3$. On the contrary, as shown in Figure 6(b), the total organic content (TOC) in the solution has been significantly removed and left with only 9.36%. The great efficiency of mineralization shows that $BiFeO_3$ is an excellent photocatalyst to be applied in wastewater treatment.

Table 5. The rate constant and correlation factor of LH kinetic model for OFL antibiotic. (Condition: 0.07 g L^{-1} $BiFeO_3$, 0.3 M H_2O_2 added, 10 mg L^{-1} OFL with pH 8 and 120-min irradiation under sunlight)

Conclusion

In conclusion, a facile $BiFeO_3$ photocatalyst was synthesized effectively using the bio-templated sol-gel approach. The purity of the photocatalyst, as well as significant chemical and physical properties, were investigated using various experimental characterizations. $BiFeO_3$ has been shown to have important properties, such as a narrow band gap energy of 2.04 eV with a surface area of 4.67 m^2 g^{-1}. Photocatalysis in the presence of $BiFeO_3$ has been proven to have an excellent property to eliminate ofloxacin with 70.1 % removal efficiency under optimum conditions. The effect of the parameters was controversial in some cases; thus, it is required to further study the nature of the pollutant to be degraded, and on types of photocatalyst to be utilized in the photodegradation. The kinetic study was conducted and found that the reaction is in good agreement with Langmuir-Hinshelwood kinetic model. The TOC analysis showed a great mineralization of ofloxacin. The knowledge of photocatalytic activity and its operational parameters could provide a better understanding for the elimination of pollutants, especially antibiotics.

Abstract

Bakso is a meatball made from beef and is very popular among Indonesians. However, the increasing number of cases of counterfeits and mixing of this meatball with dog meat in the city of Yogyakarta has caused significant unrest in several communities, especially Muslims. This study aimed to detect the fat content of dog meat in meatballs circulating in the city of Yogyakarta with an analysis using a combination of the FTIR method and the chemometric PCA. This research was designed with the making of a variety of meatballs consisting of 25 grams of beef and dog meat in calibrated samples of 0%, 20%, 40%, 60%, 80%, 90%, and 100%, as well as other ingredients, such as flour, garlic, and spices, as much as 5% of the meat weight. Three of the calibrated samples were validated and extracted with a Soxhlet extractor using the n-hexane solvent. The extracted fat was further analyzed by FTIR and processed with the Minitab19 software. The results showed that the wavenumbers ranged from 1,750 to 800 cm^{-1}, producing various peak intensities as well as, with the PLS calibration equation $y = 0.998206x + 0.999929$, an R^2 value of 0.9982, an RMSEC of 1.37%, an RMSEP of 1.19%, and an RMSECV of 2.32%. Furthermore, the dog and beef fats were successfully classified using the multivariate PCA. In conclusion, the analysis results showed that the FTIR spectrophotometric method combined with chemometrics was effective at classifying dog fat from other animal fats. Meanwhile, the analysis results showed that 2 out of 3 samples contained other meat contaminants.

Keywords: dog meat, meatball, Fourier transform infrared, principle component analysis, partial least squares

Abstrak

Makanan bakso yang diperbuat menggunakan daging lembu sangat popular di kalangan masyarakat Indonesia. Bagaimanapun, kes pemalsuan dan pencampuran daging lembu dengan daging anjing dalam pembuatan bakso yang berleluasa di bandar Yogjakarta telah menimbulkan keresahan yang ketara dalam sesetengah masyarakat khususnya di kalangan umat Islam. Kajian ini bertujuan untuk mengesan kandungan lemak anjing dalam daging bakso yang beredar di bandar Yogjakarta dengan menggunakan analisis gabungan kaedah FTIR dan kemometri PCA. Kajian ini direka bentuk dengan membuat variasi daging bakso yang terdiri daripada 25 gram daging lembu dan kandungan daging anjing yang telah ditetapkan kepada 0, 20, 40, 60, 80, 90 dan 100%, serta bahan-bahan lain seperti tepung, bawang putih dan perasa sebanyak 5% daripada berat daging. Tiga sampel yang telah ditetapkan diekstrak dengan Soxhlet menggunakan n-heksana sebagai pelarut. Lemak yang diekstrak kemudiannya dianalisis oleh FTIR dan diproses dengan perisian Minitab19. Keputusan menunjukkan julat gelombang antara 1750 hingga 800 cm-1 menghasilkan keamatan puncak yang berbeza-beza dan persamaan PLS y = 0.998206x + 0.9999929, nilai R^2 = 0.9982, RMSEC 1.37%, RMSEP 1.37%, RMSEP 1.52%. Tambahan pula, lemak anjing dan daging lembu berjaya dikelaskan menggunakan analisis PCA multivariate. Kesimpulannya, hasil analisis menunjukkan kaedah spektrofotometri FTIR yang digabungkan dengan kimometrik berkesan dalam mengklasifikasikan lemak anjing daripada haiwan lain. Sementara itu, analisis menunjukkan 2 daripada 3 sampel mengandungi bahan cemar daripada daging yang lain.

Introduction

According to Sahih Hadith Muslim no. 1933 *"The eating of all fanged beasts of prey is unlawful."* Additionally, Sahih Hadith Bukhari no. 3314 and Sahih Hadith Muslim no. 1198 state, *"There are five (harmful) things upon whose killer there is no sin whether he is in a state of ihram or otherwise: rats, scorpions, crows, kites, and voracious dogs (Kalb aqur)"*. In this regard, halal is a food requirement and is a mandatory provision for Muslims [1]. Therefore, food is said to be halal if there is no evidence forbidding it; however, it can also become haram if it is not good for consumption [2].

The Muslim community forbids the consumption of dog meat. However, dog meat adulteration in food products including buns, sausages, shredded meat, and meatballs has recently gained notice. This become quite profitable due to the trade-in of wild dog meat in several countries, which is carried out at low prices [3]. Furthermore, considering that the price of beef is more expensive compared to other varieties of meat, some traders have tried to minimize the cost of meatball production by mixing beef with other kinds of meat during the manufacturing process. This act is now considered to be an effective solution to reduce the production price of meatballs [4]. According to news reported by IDN Times Jogja published on January 13, 2020, dozens of dogs are slaughtered daily at various slaughterhouses in Bantul, Yogyakarta, Indonesia, to be served as dishes. In this regard, it is feared that there are meatball traders who produce counterfeits by mixing beef with dog meat, and this has become very detrimental to the consumers, especially Muslim consumers who have been prohibited by the Islamic belief from the consumption of dog meat.

Several approaches are being used to detect and measure the fat content of dog meat and pork derivatives in food products. The first approach is to determine the ratio of several chemical constituents of the products and ensure that this ratio is constant. Secondly, it is to look for certain markers on food products, both in the form of chemical contents and morphological components that can prove the presence of pork derivatives in the food. Lastly, it is conducted in a physico-chemical analysis [5]. Subsequently, analytical methods have been developed for the analysis of non-halal products in raw materials and food products. These methods include Fourier-transform infrared (FTIR) spectrophotometry [6], chromatography [7], and differential scanning calorimetry (DSC) [8]. Furthermore, DNA-based methods such as polymerase chain reaction [9] and analysis methods based on odor identification (electronic nose) [10] are also used for the analysis.

FTIR was not able to distinguish dog fat from beef fat because they have peaks with the same wave number related to the functional groups of the compounds. The FTIR results differed in the peak intensity of each peak, but it is difficult to see the difference visually. The feasibility of FTIR spectroscopy in combination with

multivariate partial least squares (PLS) calibration was used for the quantitative analysis of dog meat in a binary mixture of beef in meatball formulations. The chemometric principal component analysis (PCA) was used for the classification of dog meat and beef meatballs [26-28].

Therefore, this research aimed to determine the presence of dog meat in meatball products with the partial least squares (PLS) model. The classification of dog fat and chicken fat was performed using a principal component analysis (PCA) with the FTIR method [11].

Materials and Methods

Materials

The main materials used in this research were reference meatballs made from a mixture of beef obtained from Gedong Kuning Market, Rejowinangun, Kotagede District, Yogyakarta City, Special Region of Yogyakarta, Indonesia. Likewise, the dog meat ingredients were obtained from Jombor Lor, Mlati District, Sleman Regency, Special Region of Yogyakarta. The flour, as well as seasonings, was made in varying degrees of concentrations. In addition, the market sample beef meatballs were obtained by random selection of 3, out of the several meatball traders in various parts of Yogyakarta City, namely Timoho, Balirejo, and Glagahsari Streets, Special Region of Yogyakarta, Indonesia, and these samples were taken in October 2020. The solvents used in this research were technical n-hexane (Merck®) and Na_2SO_4 (Merck®). Research method (workflow analysis) is as shown in Figure 1.

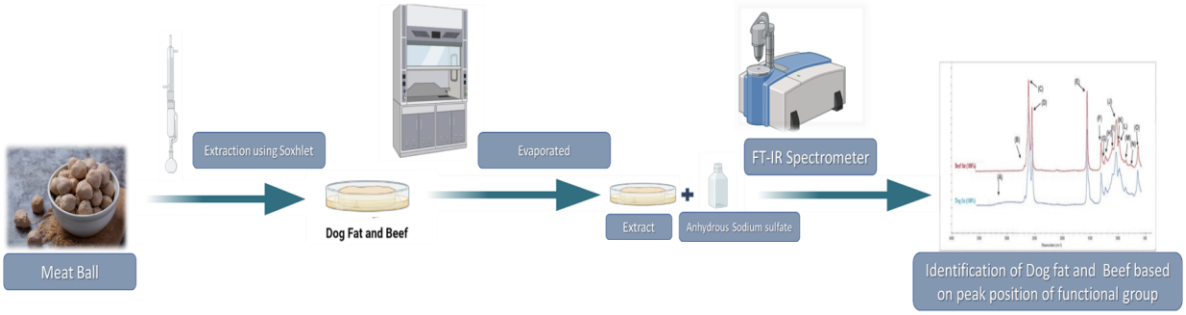

Figure 1. Workflow analysis of dog fat in beef meatballs using a Fourier-transform infrared spectrophotometer combined with chemometrics

Identification of dog species

Identification of dog species was carried out in the Laboratory of Animal Systematics, Faculty of Biology, Gadjah Mada University, Yogyakarta.

Table 1. Variations in concentration of beef and dog meatball samples

Concentration (%)	Beef (grams)	Dog Meat (grams)
Cow 100	25	-
Dog 20	20	5
Dog 40	15	10
Dog 60	10	15
Dog 80	5	20
Dog 90	2.50	22.50
Dog 100	-	25

Meatballs production with variations in concentration

The meat ingredients were mashed, and additional ingredients such as tapioca flour and spices, including shallots, garlic, ginger, and finely ground pepper, were added. The samples made in various concentrations can

be seen in Table 1. Meatballs were made by grinding beef and dog meat separately, consisting of 25 grams of meat. In addition, variations in concentration of dog meat in the beef meatballs made were: 0%, 20%, 40%, 60%, 80%, 90%, and 100% [12].

Fat extraction in meatballs

The meatballs were weighed according to the concentration made (Table 1), mashed, and extracted with a Soxhlet apparatus. Additionally, the solvent used was n-hexane, which was extracted for 4-7 hours at 70 °C. The extract was then added with anhydrous Na_2SO_4, which evaporated in a fume hood. The viscous extract was analyzed using an FTIR spectrophotometer [12].

Sample analysis with FTIR

The fat samples were analyzed using FTIR spectrophotometry. This analysis was carried out at a frequency of 4,000–650 cm^{-1}. Following this, the samples were dropped onto an ATR crystal at a controlled temperature (25 °C), and measurements were carried out on 32 scans at a resolution of 4 cm^{-1} [13].

Statistical data analysis

The qualitative and quantitative statistical analysis of FTIR spectrophotometric test results on meatball samples combined with PLS and PCA multivariate chemometric calibration with the Minitab 19 software on a computer device was carried out. The partial least squares (PLS) method was used to determine the linearity. A Microsoft Excel 2010 software worksheet was also used to relate the actual sample to the predicted sample concentrations. The accuracy of the PLS model was evaluated by the coefficient of determination (R^2), while that of the data analysis method was assessed using the root mean square error of cross-validation (RMSECV) and the root mean square error of prediction (RMSEP). The formula used to obtain the RMSECV (equation 1):

$$\text{RMSECV} = \sqrt{\frac{\sum_{i=1}^{n}(\hat{x}i - xi)^2}{n}},$$

where $\hat{x}i$ is the actual value of meatballs, xi is the value calculated from cross-validation of meatballs, and n is the number of calibrations or validation samples [14]. Meanwhile, the formula used to obtain the RMSEP (equation 2):

$$\text{RMSEP} = \sqrt{\frac{\sum_{i=1}^{n}(\hat{y}i - yi)^2}{n}},$$

where $\hat{y}i$ is the actual value of meatballs, xi is the predictive value of meatballs, and n is the number of calibrations or validation samples [4].

Results and Discussion

Identification of dog species used as sample

The identification of dog species was conducted using pictures of several parts of the animal's body, such as the face, tail, legs, and ears, and pictures of the combined parts as a whole body [15]. The identification results indicated that the type of dog used was the mutt otherwise known as a local dog with the Latin name *Canis lupus familiaris*. The mutt is a dog species characterized by a skull with a relatively elongated snout and teeth adapted for eating meat. This dog species is generally not intentionally bred by humans but survives in areas where humans live, such as streets, cities, and villages [16].

Meatball fat extraction

The fat content in the meatballs was extracted using the Soxhlet extraction method. Similarly, a non-polar solvent such as n-hexane can also be used to extract fat. The extraction process was carried out at a temperature of about 70 °C, which corresponds to the boiling point of n-hexane [17]. For optimal extraction, this process was conducted for approximately 5 hours. Subsequently, whether the extraction process had been optimized was demonstrated by the turn of the color of n-hexane into dripping clear like its original color. Lastly, the addition of sufficient anhydrous Na_2SO_4 was intended for binding to the water molecules that may still be contained in the n-hexane as the presence of water in fat may interfere with the response of the FTIR spectrum [18].

Based on Figure 2(a), the FTIR spectra obtained were in the wavenumber range 4,000-600 cm^{-1}. It can be seen that there is no significant difference between the beef and dog meatball fat spectra because the main components of both fats, which are triglycerides, are the same, and both are regarded as animal fats. Therefore, it was deemed necessary to carry out a further analysis with the chemometric PCA to distinguish the intensity of infrared absorption peaks, which are more varied, making it easier to classify the beef and dog meatball fat

spectra. The descriptions of the absorption peaks and the identified functional groups are summarized in Table 2. From Table 2, the beef and dog fat shared a similarity in functional fat groups. Carbonyl, CH, and CO groups appeared on the FTIR spectrogram. The difference in the variations of such functional groups can be seen with the chemometric PCA [29].

Wavenumber optimization as PLS calibration model

The results of the quantitative analysis which was carried out in the fingerprint area of the FTIR spectra to show a distinctive difference in the intensity of the absorption was significant and became the target for selecting the optimization wavenumbers [19]. The selection of these wavenumbers was intended for a calibration model that produces an R^2 value that is close to 1 and the smallest RMSEC [11]. The wavenumbers selected ranged from 1,750 to 800 cm^{-1}.

Additionally, the results of the optimization of the calibration model showed an optimal range of wavenumbers from 800 to 1,750 cm^{-1} with the equation y = 0.99820x + 0.99992. Moreover, the resulting coefficient of determination (R^2) was 0.99820 (Figure 3), with an RMSEC value of 1.464435%. The optimization results obtained indicated the accuracy between the predicted value and the actual value, which was 99.82%. The random error value also indicated an error in the sample prediction from the calibration model equation with an RMSEP value of 1.52% and an RMSECV of 2.329%.

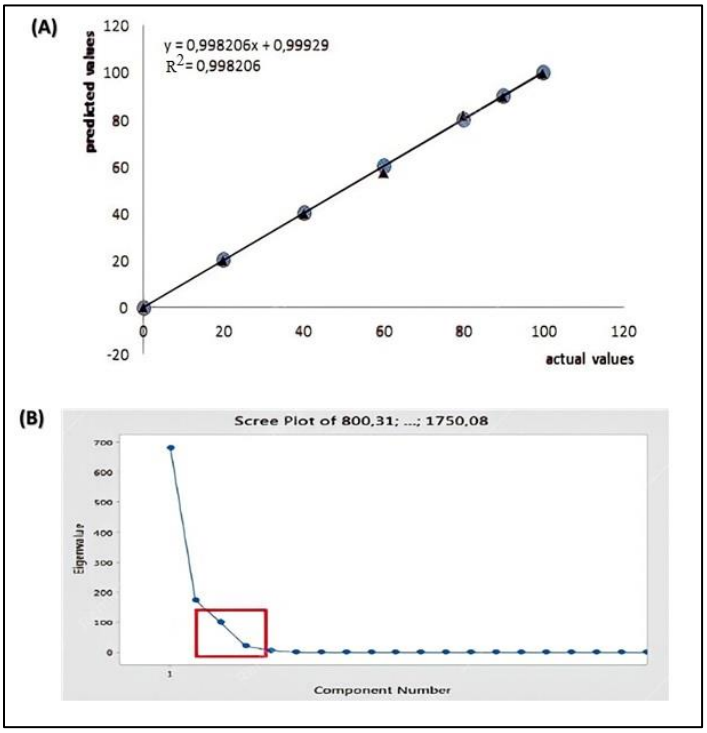

Figure 3. (a) The concentration variation of dog and beef fat resulted using the PLS data calibration model (0–100%) and (b) screen plot of the relationship between eigenvalues and PC results from the PCA

Pattern recognition analysis with the principal component analysis (PCA)

The PCA was performed using an absorbance data set of dog and beef fats, in addition to market samples, in the 1,750–800 cm^{-1} area, which was the fingerprint area. From this frequency range, information on which frequency contributes more to the PCA model will be obtained, and with the market samples, a clear separation between dog and beef fats will be provided. The PCA was performed with the help of Minitab19 and was integrated with Microsoft Excel 2010 [25]. The chemometric PCA was selected for grouping the variables of each sample used. With the variable of fatty acids of each group of samples, the proximity of chemical properties will be known.

Scree plot

The selection of the number of main components (PC) was one of the aspects that contributed to the success of the PCA results. In addition, the choice of the number of PCs in the PCA could be determined from the eigenvalues generated by each of the main components.

Therefore, the number of PCs gained was relevant for explaining the initial information from PC data with eigenvalues > 1 [20].

Furthermore, the eigenvalue is used to describe a large number of variations and is said to be part of the total variation that can be explained by each PC. Based on Figure 3 (b), PC1 with an eigenvalue of 683.35 was able to explain 69.3% of the variance in the initial variable. Meanwhile, PC2 with an eigenvalue of 174.06 was able to explain 87.0% of the variance, PC3 with an eigenvalue of 99.76 was able to explain 97.1% of the variance, and PC4 with an eigenvalue of 21.17 was able to explain 99.2% of the variance, which was part of the elbow, where there was a significant decrease in eigenvalues. Of the first 4 PCs, 99.2% of data variance was included and was relevant to explain the characteristics of the alert variable and the information contained [21].

Score plot

The PCA analysis was performed by the comparison of components after entering spectral data of 100% dog and beef fats. The analysis was then carried out by replication to ensure that the principal components were separated from other components using an optimized wavenumber [22]. The separation and grouping of the two score plots are presented in Figure 4 (a).

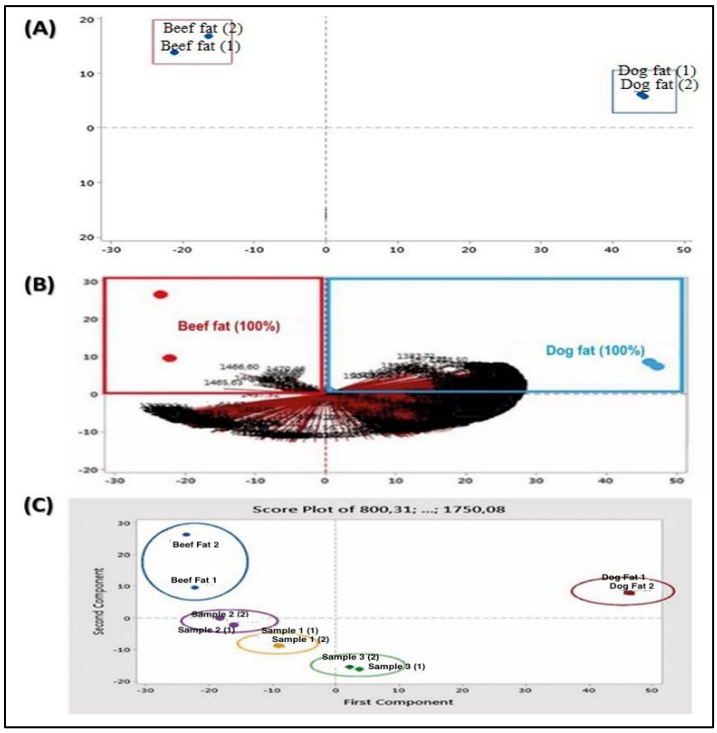

Figure 4. (a) Score plot PCA results in 100% dog fat and 100% beef fat. Note: red (beef fat) and blue (dog fat), (b) biplot of 100% dog fat and 100% beef fat, and (c) the score plot result of the PCA market sample, 100% dog, and 100% beef

Figure 4 (a) shows the results of the PCA analysis of two samples occupying different quadrants. Sample A (red) consisted of 2 beef tallows which were separated by 100% and had similar properties as a result of the close distance between the two fat plots which were also within the same quadrant, while sample B (blue) consisted of two 100% dog fat data which were found in different quadrants and at a great distance from sample A. Additionally, the two samples in the biplot were shown to be sticking together. Hence, the closer the distance between the two plots, the more the fat similarities. Meanwhile, the farther apart the plots, the lesser the similarities between the fats. From this, it can be seen that sample A and sample B were well separated because they are in different quadrants [23].

Figure 4 (b) shows that 100% beef fat (red) and 100% dog fat (blue) both had special variables. The beef fat was in the same quadrant with several variables, including 1,348.96–1,360.53 cm^{-1}; 1,453.10 cm^{-1}; 1,456.96 cm^{-1}; 1,457.92 cm^{-1}; 1,465.63 cm^{-1}; 1,466.60 cm^{-1}; and 1,470.46 cm^{-1}. Based on this, it can be said that the wave numbers 1,348.96–1,360.53 cm^{-1}; 1,453.10 cm^{-1}; 1,456.96 cm^{-1}; 1,457.92 cm^{-1}; 1,465.63 cm^{-1}; 1,466.60 cm^{-1}; and 1,470.46 cm^{-1} are therefore characteristic of the beef fat.

Comparatively, the results of the dog fat were in the same quadrant with many variables, including 800.31–1,430.92 cm^{-1}; 1,475.28–1,487.81 cm^{-1}; and 1,520.60–1,727.91 cm^{-1}. Hence, it indicates that these wavenumber variables are characteristic of dog fat because they were all in the same quadrant.

Analysis of beef meatball samples circulating in Yogyakarta City

The grouping contained in the score plot of dog and beef fats has explained that the two samples were perfectly separated and were in different quadrants; hence, they can be applied to the market samples. The samples of market beef meatballs analyzed were 3 meatballs obtained from 3 different places in Yogyakarta city. The results of the spectra were then analyzed by the PCA together with a reference sample of 100% beef and dog fats at the wavenumber of the optimization results to determine the presence of dog meat adulteration in the market sample. The results of the FTIR spectra of the three samples are presented in Figure 2 (b).

At first glance, the spectra of the market samples looked the same, but the three fat spectra had different intensities for each wavenumber, especially in the fingerprint area. To further confirm the difference in the intensity of the three spectra, the score plot was used as shown in Figure 4 (c). The results of the PCA on the FTIR spectra of 100% dog and beef fats, with the three market samples, are shown in the score plot, with the five fats being in separate quadrants. None of the three market samples had proximity to both dog and beef fat standards.

Furthermore, all market sample plots were in different quadrants from the standard % dog fat plot, indicating that both plots did not share a similarity. The result of this research therefore showed that the three meatball samples were not adulterated with dog meat. However, of the three market sample plots, only number 2 was in the same quadrant as the 100% beef fat plot. This shows that sample 2 had similar characteristics with beef fat. The further the plots of sample 1 and sample 3 from the 100% beef fat plot, the greater the difference in characteristics. In Figure 4 (C), the two samples (1 and 3) were most likely not pure beef and were likely to contain other types of meat contamination, which can be proven by further research.

Conclusion

The quantitative analysis of dog fat using PLS chemometrics resulted in optimization of wavenumbers in the range 1,750-800 cm^{-1} with the calibration model equation $y = 0.998206x + 0.99992$, which was quite accurate with a predicted value of 99.82% of the actual value. Furthermore, a coefficient of determination (R^2) of 0.998, an RMSEC of 1.46%, an RMSEP of 1.52%, and an RMSECV of 2.32% were obtained. In this regard, it can be concluded that the meatball samples in the market did not contain dog fat, but they were suspected to contain other types of fat.

Abstract

Thiourea is a carbon, hydrogen, sulphur, and nitrogen-based organic molecule. The thiourea group has been improved by replacing various substituents for its hydrogen atoms at the nitrogen terminal, resulting in a wide range of biological activities, especially on anticancer properties. Despite the fact that thiourea derivatives have remarkable anticancer potential, finding a novel anticancer agent that is both safe and selective remains a challenge. This paper summarizes recent research on thiourea compounds that can be used to treat malignant cell lines. Several synthesis methods and the effects of substituents as well as their anticancer therapeutic potential in a variety of healthy and malignant cell lines are discussed. As a result, it is envisaged that this review will guide the design and synthesis of new thiourea derivatives in the future for the development of highly effective and selective anticancer

drugs.

Keywords: thiourea derivatives, synthesis method, anticancer activity, substituents

Abstrak

Tiourea merupakan sebatian organik yang mempunyai atom karbon, hidrogen, sulfur dan nitrogen. Modifikasi sebatian organik tiourea ini dengan menggantikan atom hidrogen pada terminal nitrogen dengan pelbagai kumpulan penukargantian yang terpilih telah menghasilkan sebatian yang mempunyai pelbagai aktiviti biologi. Salah satu daripada aktiviti biologinya adalah sebagai agen antikanser. Meskipun sebatian terbitan tiourea ini dilaporkan mempunyai aktiviti antikanser yang signifikan, namun masih terdapat cabaran untuk mencari sebatian terbitan tiourea baru yang selamat dan bersifat selektif. Kertas ini meringkaskan kajian terkini mengenai sebatian terbitan tiourea yang boleh diaplikasi untuk kajian merawat sel kanser. Pelbagai kaedah sintesis, kesan kumpulan penukargantian serta potensi sebatian ke atas pelbagai jenis sel termasuk sel sihat dan malignan telah dibincangkan. Ulasan ringkas ini dapat memberi panduan untuk meningkatkan kemajuan dalam mencipta dan mensintesis sebatian antikanser baru yang berkesan dan selektif berasaskan tiourea.

Kata kunci: terbitan tiourea, kaedah sintesis, aktiviti antikanser, kesan kumpulan penukargantian

Introduction

The incidence and mortality of cancer-related diseases are quickly growing year after year, with 19.3 million new cases and 10 million deaths reported in 2020. Despite the availability of advanced treatments including immunotherapy, radiotherapy and chemotherapy, the number of cancer cases has not decreased in the last 30 years [1]. This pattern was linked to acquired resistance, rapid mutability as well as bad effects that occurred for a year after taking current anticancer drugs [2, 3]. Therefore, finding a new anticancer drug that is efficient and safe is crucial to solving the alarming issue. The anticancer properties of thiourea derivatives are undeniable. Besides that, they also play an important role in a wide range of biological activities such as anti-thyroid [4], anti-bacterial [5], anti-inflammatory [6], anti-malaria [7], antioxidant [5], antihypertensive [8], anti-viral [9] and anticancer [10].

The discovery of 5-fluorouracil (5-FU), sorafenib, and tenovin medicines spurred substantial research into thiourea derivatives as potential anticancer therapies (Figure 1). A compound of 5-FU, cyclic fluorinated urea has been used to treat colorectal cancer [11] and other solid tumours (gastrointestinal tract, pancreas, ovary, liver, brain, and breast) for over 50 years, whereas Sorafenib is a diaryl urea-containing compound that has been clinically tested for lung, breast, colon, ovarian, pancreatic, and gastric cancer. Meanwhile, tenovin with thiourea-based compounds exerted inhibitation towards the colon, prostate, gastric and lung cancer [12, 13].

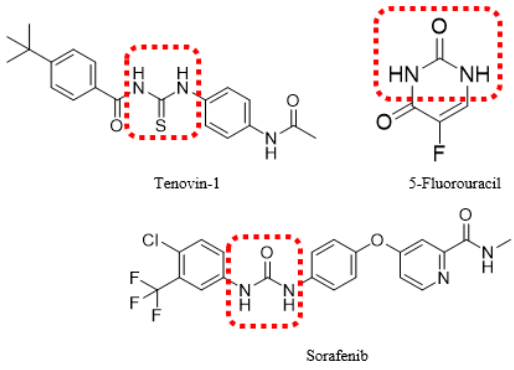

Figure 1. Thio(urea) scaffold-containing anticancer chemotherapeutics [12, 13]

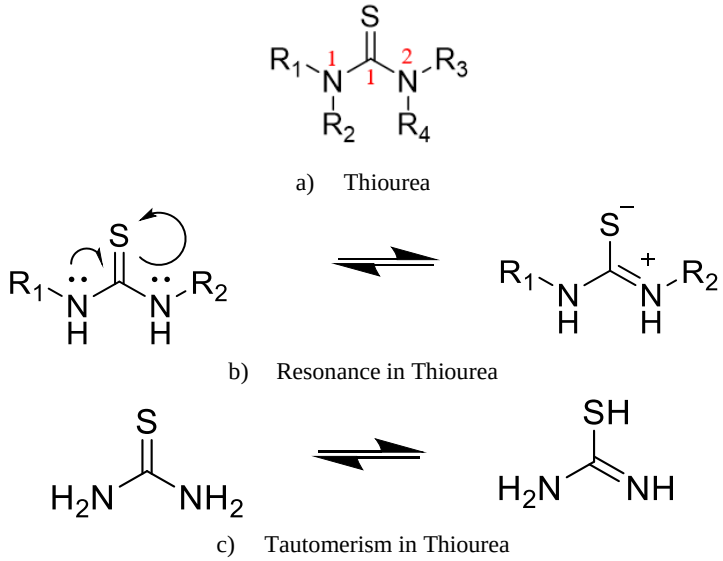
Over the years, many reports have been published on the synthesis of thiourea derivatives and their evaluation as anticancer agents along with the structure-activity relationships (SAR). The nature and different types of substitutions on nitrogen atoms of thiourea moiety considerably boosted the anticancer activity and determined whether the thiourea was mono-substituted, di-substituted or multi-substituted [14]. However, the substitution of one hydrogen atom at each thiourea nitrogen atom with desirable moieties dominates the structural pattern of thiourea derivatives as an active chemical [14, 15]. It is concluded that coupling the thiourea scaffold with other substituents results in

pharmacophore molecules which are extremely good anticancer agents [15, 5, 6]. The derivatives were reported to demonstrate potent cytotoxic activities against a series of cancer cells including breast [16], lung [17], renal [18], colon [5], prostate [19], liver [20] and ovarian [18] cancers. These have sparked an interest in expanding the research by synthesising novel thiourea compounds as possible anticancer drugs. Thus, the present review aims to summarize the recent development in thiourea derivatives in terms of the synthesis pathway, anticancer activities as well as the effect of substituents on the anticancer activities.

Chemistry of thiourea

Thiourea or thiocarbamide moiety is the first urea analogue which was synthesized for the first time by Marceli Nencki, a Polish scientist [21]. It is defined by the substitution of a sulfur atom for the oxygen atom. A lot of research articles are focused on thiourea scaffold as anticancer chemotherapeutics than urea moiety because of their remarkable polarity, reactivity, and efficient process of preparation [22]. A sulfur atom has a large size and is less electronegative resulting in the electrons being more polarizable as well as a stronger nucleophile for better reactivity than an oxygen atom [23]. Thiourea is considered an important group in drug design due to its extensive biological properties [22]. The thiourea scaffold serves as an excellent building block in constructing anticancer molecules with the presence of C=S regarded as an excellent acceptor, while thiourea N-H moiety is a favourable hydrogen bond donor. This dual nature of thiourea functionality is crucial in the drug's aqueous solubility and permeability [24]. The unique feature of thiourea moiety with desirable electron-rich characteristics is beneficial for thiourea derivatives which allows them to easily bind with a variety of enzymes and receptors in biological systems. Moreover, these interactions play a key role in the stability of ligand-receptor interactions subsequently, inhibiting the progression of cancer [25].

Thiourea (Figure 2a) compound is a needle-like glossy crystal with a colourless to pale yellow, bitter-tasting and ammonia-like odour. Thiourea is slightly soluble in cold water and soluble in hot water with a boiling point of 150-160 ºC [17]. Figure 2b shows the resonance forms of thiourea in which the amphoteric character of thiourea is demonstrated by its resonance, which indicates electrophilic attack at the C-1 position; nucleophilic attack at either N-1 or N-2. Meanwhile, the tautomerization at H-atom that is attached to either N-1 or N-2 position would form two pairs of isomers namely thione and thiol (Figure 2c).



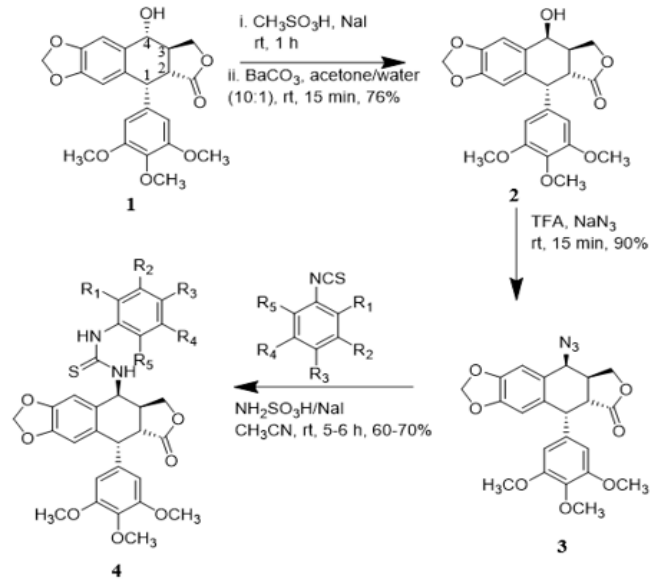


Figure 2. Thiourea scaffold showing numbering (a), resonance (b) and tautomerism (c)

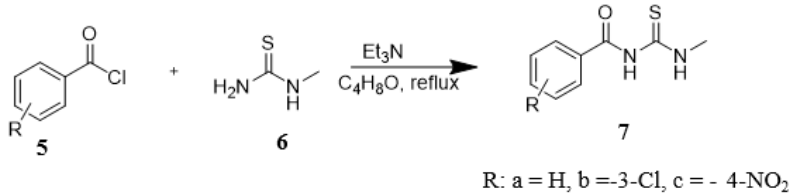
Thiourea is a chemically interesting compound over the years due to its planar and flexible structure which exhibits greater π-electron delocalisation which also would enhance the binding ability to a variety of proteins in the biological system. The thiourea moiety is easily protonated under acidic conditions and interact with important amino acid residues on cancer cells such as carboxyl and phosphate groups, thus enhancing the anticancer activities [26].

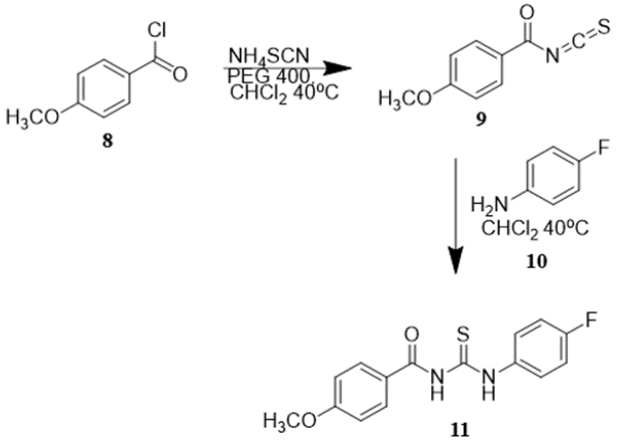
Synthesis pathway of thiourea derivatives and their anticancer activities



A lot of research on the thiourea moiety is currently ongoing to identify novel lead compounds to combat various cancers. The thiourea pharmacophore (-HN-C(=S)-NH-) is important in designing novel anticancer chemotherapeutics which leads to further development through structural modification. This pharmacophore acquires specific binding sites such as the hydrogen binding area thus increasing the binding affinity of the ligand-protein complex. The presence of C=S and N-H functional groups on thiourea which represents weak hydrogen bond acceptor as well as hydrogen bond donor respectively would significantly enhance the blocking of the enzymatic activity and simultaneously be a potent anticancer agent.

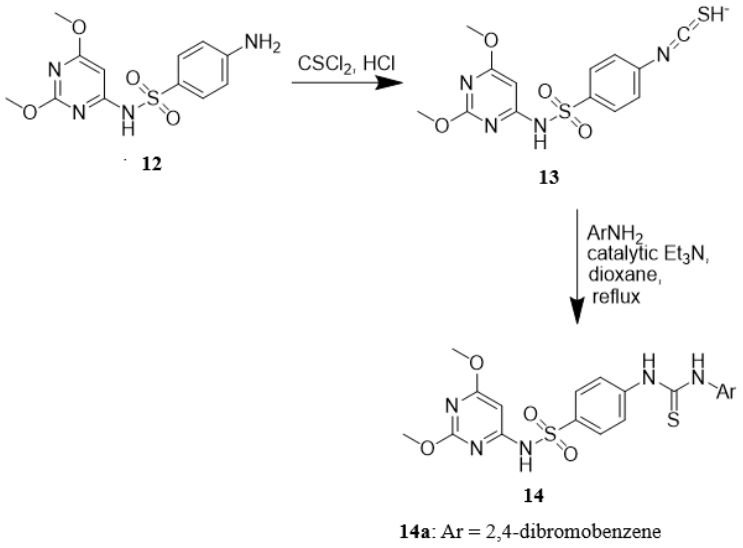
A novel of podophyllotoxin–thiourea derivatives (Scheme 1) were synthesized and evaluated for their in vitro cytotoxicity against A549 (human lung cancer), MDA MB-231 (human breast carcinoma), DU-145 (human prostate cancer), LNCaP (androgen-sensitive human prostate adenocarcinoma) and HGC- 27 (human gastric carcinoma) cell lines by MTT assays [27]. The synthesis strategy of podophyllotoxin–thiourea congeners **4a–u** was successfully performed by reaction with various isothiocyanates in the presence of NH_2SO_3H and NaI from 4ß-azido intermediate **(3)** and 4ß-deoxy-epipodophyllotoxin **(2)**. Among the compounds synthesized, compound **4a** was found to be effective in the DU-145 cell line compared to etoposide (standard drug) with half-maximal inhibitory concentration (IC_{50}) values less than 10 µM which is the range of 0.50-7.89µM. These compounds were further assayed for cytotoxicity on normal human prostate cell line (RWPE-1) and were shown as safe to be used. The introduction of bulky groups at the C-4 position at the podophyllotoxin thiourea derivative (**4**) significantly aids the antitumor activity [28]. The *N*-substituted benzene thiourea derivatives at the C-4 position showed that R_3 substituent (**4**) was significant for anticancer activity. For example, the presence of a small group such as methoxy **(4a)** increases the electron density and activates the ring. However, a bulky substituent at the R_3 position of the phenyl ring resulted in no cytotoxic activity.

Scheme 1. Synthesis of novel podophyllotoxin-thiourea congeners



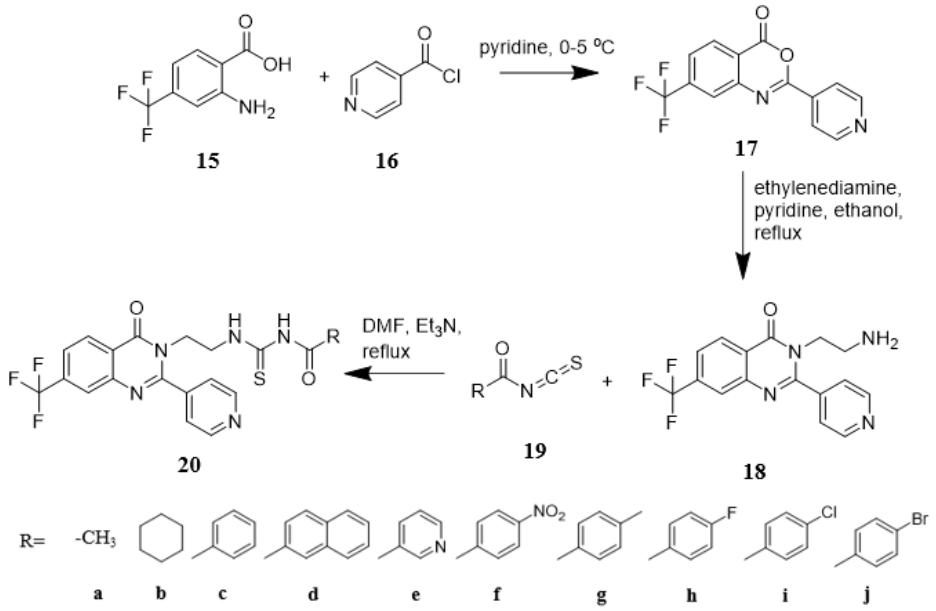
The 1-benzoyl-3-methyl thiourea derivatives were designed with different substitutions at *meta* and *para* positions on the phenyl ring of 1-benzoyl-3-methyl thiourea [29]. The compounds **7a-c** were synthesized from the reaction of starting material *N*-methylthiourea **(6)** with several ring-substituted benzoyl chlorides **(5)** (Scheme 2). The standard MTT assay was used to assess in vitro cytotoxicity against cervical cancer cell lines (HeLa). All of the compounds had higher cytotoxicity, with IC_{50} values ranging from 160 to 383µg/mL, than hydroxyurea (HU) as a reference drug, which had an IC_{50} of 428 µg/mL. It is revealed that the presence of benzoyl and methyl group on thiourea would increase the resonance within the compounds thus improving the compound stability and enhancing cytotoxic activity. The nitro substituents on the *para*-position **(7c)** had the highest activity, making it more active than HU. The electron-withdrawing group (EWG) substitutions such as chloro at the *meta*-position and nitro at the *para*-position of the aromatic ring improve the lipophilicity of molecules and are responsible for increased cytotoxicity [29]. The strong EWG would withdraw electrons through a π-bond due to the overlap of a *p* orbital on the substituent with a *p* orbital on the aromatic ring and stabilized by the electron-donating group (EDG) from methyl by resonance. Meanwhile, the absence of a sidechain on benzoyl showed the lowest activity among the synthesized compounds **(7a)**. These findings suggest that 1-benzoyl-3-methylthiourea derivatives could be used as anticancer agents in HeLa cells.

Scheme 2. Synthesis reaction of the 1-benzoyl-3-methylthioureas



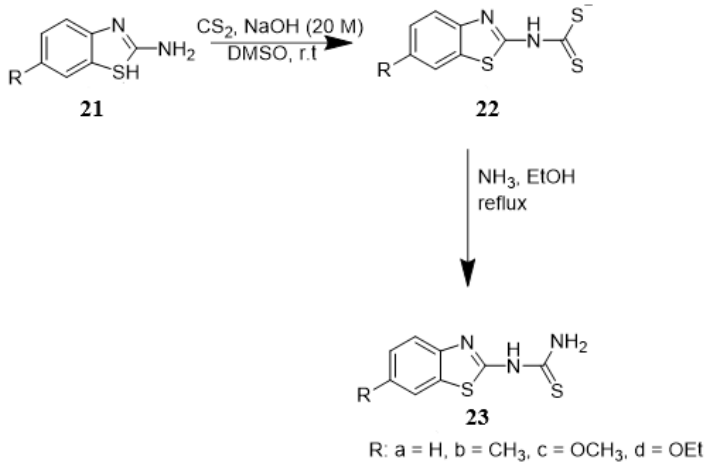
Encouraged by the outstanding anticancer activity from the presence of EWG as substituents at phenyl rings, the effect of EDG on the phenyl ring was also studied. The EDG group has been introduced to the

phenyl ring of benzoyl moiety linked thiourea in a compound of *N*-4-methoxybenzoyl-*N'*-(4-fluorophenyl)thiourea **(11)** and tested against HeLa cell line and compared with HU as a standard drug [30]. Scheme 3 shows that the compound was synthesized by the reaction of 4-methoxybenzoyl chloride **(8)** with ammonium thiocyanate to give an intermediate compound namely 4-methoxybenzoylisothiocyanate (**9**). Further reaction of **(9)** with 4-fluoroaniline **(10)** yielded the desired compound. The MTT results displayed that the compound has a lower inhibitory concentration IC_{50} value (0.720 ± 0.07 mM) which is more potent than HU (16.535 ± 2.092 mM). The presence of *p*-methoxy on benzoyl moiety and *p*-fluoro on phenyl ring enhanced the cytotoxic activity due to the lipophilic, electronic and steric properties. The methoxy (EDG) is a strongly activating group with the electron donor which imparts the resonance effect whereas fluorine (EWG) deactivates the ring by withdrawing the electron of the ring and stabilizing the compound. Thus, the combination of EWG and EDG in a thiourea compound potentially enhanced anticancer properties.



Scheme 3. Synthesis of *N*-methoxybenzoyl-*N'*-(4-fluorophenyl)thiourea derivatives

Subsequently, several novel thiourea derivatives bearing sulfonamide were synthesized and screened against HepG2, MCF-7, Caco-2, HCT-116, PC-3 cancer cell lines and Vero-B normal cell line [6]. The compounds were synthesized from the starting compound *N*-(2,6-dimethoxypyrimidin-4-yl)-4-isothiocyanatobenzenesulfonamide **(13)** as represented in Scheme 4. Among the compounds synthesized, compound **14a** which contains 2,4-dibromobenzene as a substituent exhibited broad selective cytotoxicity against cancer cells HepG2, MCF-7, Caco-2, and PC-3 with IC_{50} values 19.3, 20.5, 15.08 15.6 µg/ml respectively. This compound is a potent anticancer agent which might be due to the substitution of EWG (bromine atom) at *ortho* and *para* positions which activates the benzene ring through inductive effect, thus enhancing the anticancer properties.

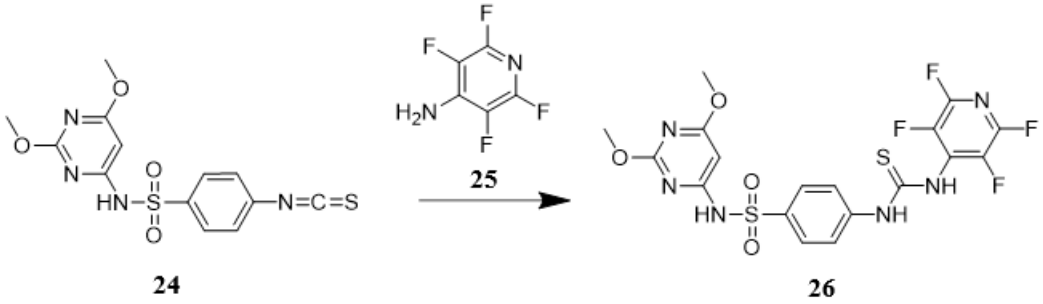


Scheme 4. Synthesis thioureas derivatives bearing a sulfonamide moiety

Another series is the novel 7-trifluoromethyl-2-pyridylquinazolin-4(3H)-one-based acyl thiourea derivatives **(20a-j)** as potential antiproliferative agents. The compounds were synthesized and tested for cytotoxicity in both cancerous human ovarian cancer (SK-OV-3), cervical cancer (HeLa), renal cancer (Caki-2) as well as noncancerous human umbilical vein endothelial cell (HUVEC) cell lines [18]. From the MTT bioassay results, the fluorine substitution on the benzoyl group was the most advantageous compared to other EWG due to the high electronegativity, highest carbon-fluorine bond strength, and smallest atomic radius (50 pm) as well as increased hydrophobic properties [31]. Compounds containing halogen atoms have higher potency overall. The presence of nicotinoyl and acetyl as the substituents contributed more to electron delocalization in the compound resulting in outstanding efficacy, whereas the absence of any functional or donor group on the benzoyl ring resulted in inert compounds. In addition, the conjugation bonds contributed by the quinazoline group in substituted thiourea derivatives correlated to the increase of lipophilic properties which is a salient feature for inhibition of DNA replication thus leading to the increased antiproliferative activity. However, all compounds showed desirable cytotoxicity towards the noncancerous cell line. It was discovered that modifying the substituent at the thiourea linkage gave different cytotoxic potentials to specific cell lines as summarized in Scheme 5. Specifically, thiourea-bearing quinazoline compounds with 4-fluorophenyl functionality **(20h)** and pyridyl moieties **(20e)** showed encouraging anticancer effects and could be used as a platform to design further chemotherapeutic agents.

Scheme 5. Synthesis of acyl thiourea derivatives of 7-trifluoromethyl-2-pyridylquinazolin-4(3H)-one

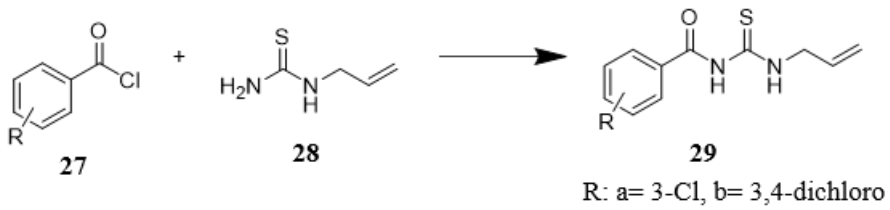
A new series of benzothiazole thiourea derivatives (**23a-d**) were tested for anticancer activity on human breast cancer cells (MCF-7), human cervix epithelial carcinoma (HeLa), human colon cancer cell line (HT-29), human leukaemia cell line (K-562), and mouse neuroblastoma cell line (Neuro-2a) [5]. The derivatives were prepared by the treatment of substituted 2-amino benzothiazole **(21)** with carbon disulfide and the ammonolysis of intermediate **(22)** in ethanol under reflux conditions as shown in Scheme 6. The compounds showed weakly to moderately cytotoxic activity with IC_{50} values ranging from 0.39 µM and up to 200 µM. Compound **23d** exhibited the most potent cytotoxic activity which was roughly four times more effective than cisplatin against the two cancer cell lines MCF-7 and HT-29, as depicted in Table 1. The synthesized compounds showed no cytotoxic effects on normal cells (L-929). The highest cytotoxicity of compound **23d** reflects the higher EDG nature of the ethoxy group and its steric effect. Therefore, combining benzothiazole and thiourea moieties might contribute to the improvement of the antiproliferation action.



Scheme 6. General synthesis of the benzothiazole thiourea derivatives

Table 1. Cytotoxic activities of compounds (**23a–d**) against MCF-7, HeLa, HT-29, K-562, and Neuro-2a cancer cell lines

	Cell Lines (μM)					
Compound	**MCF-7**	**HeLa**	**HT-29**	**K-562**	**Neuro-2a**	**L-929**
23a	8.55	21.7	8.1	69.7	57.4	134.1
23b	11.9	47.3	14.8	85.3	235.3	135.0
23c	12.8	45.2	15.0	98.1	200.5	230.7
23d	6.72	4.97	3.90	40.5	22.7	107.6
Cisplatin	6.25	0.39	16.2	25.8	211.0	0.7



* The agent with IC_{50} > 100 μM is considered to be inactive

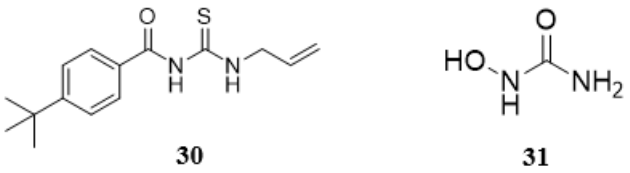
Inspired by the activity profile of a previous report [6] on thiourea-based sulfonamide derivatives, a new compound was developed namely *N*-(2,6-dimethoxypyrimidin-4-yl)-4-(3-(arylthioureido)benzenesulfonamides derivatives [20]. The desired compound was synthesized and tested for antiproliferative activity. The reaction scheme is depicted in Scheme 7. The antiproliferative assay showed that compound **(26)** with more EWG (fluorine atom) substituted to phenyl ring showed broad selective cytotoxicity against HepG2, MCF-7, Caco-2, and PC-3 cancer cells with IC_{50} values ranging from 15.08 μg/mL to 20.5 μg/mL. This compound also exhibited no cytotoxicity toward healthy cells (Vero-B). This work is in line with the previous study [6,20,29,18,15] which stated that EWG attached to phenyl ring bearing thiourea moiety would enhance the anticancer activity.

Scheme 7. Synthesis of thiourea derivatives bearing sulfonamides 26

Besides, two novel compounds namely *N*-(allylcarbamothioyl)-3-chlorobenzamide (**29a**) and *N*-(allylcarbamothioyl)-3,4-dichlorobenzamide **(29b)** were synthesized by reacting ally thiourea **(28)** and *N*-benzoyl chloride **(27)** as presented in Scheme 8 [15]. The compounds that have a different number of chlorine atoms on the phenyl ring were screened for cytotoxicity study on human breast cancer cell lines (T47D) using the MTT assay. This study concluded that an extra chlorine atom in compound **29b** contributed to higher cytotoxicity activity than compound **29a** and standard drug 5-FU with IC_{50} values of 86 μg/mL, 128 μg/mL and 213 μg/mL, respectively. The increased number of chlorine (EWG) would reduce the electron density and deactivate the ring but was stabilized by the presence of ally thiourea. Thus, the effect of the allyl group, as well as more EWG on thiourea structure, showed a substantial increase in antiproliferative activity as the conjugation makes the compounds more stable.

Scheme 8. Synthesis thiourea derivatives **29a-b**

Next, potent anticancer drugs were synthesized featuring the novel 4-*tert*-butylbenzoyl-3-allylthiourea framework and screened against MCF-7 cells overexpressed by HER-2 (MCF-7/HER-2) [32]. From the results of the MTT assay, compound **30** showed the best antiproliferative activity in comparison with positive control HU **(31)** with IC_{50} values of 0.15±6.48 mM and 2.01±1.05 mM, respectively (Figure 3). The *tert*-butyl functional group is EDG which will activate the *para* position of the phenyl ring due to more electron donation from C-H subsequently increasing compound conjugation. Thus, this study confirmed that a compound with allyl group and EDG is significantly cytotoxic and has the potential to be developed as a breast anticancer agent with HER-2 overexpression.



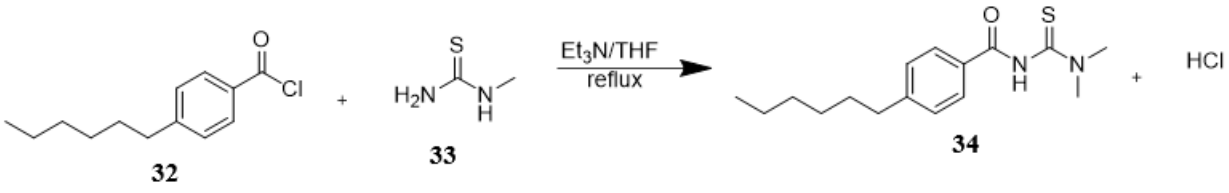


Figure 3. Structure of 4-t-butylbenzoyl-3-allylthiourea (30) and hydroxyurea (31)

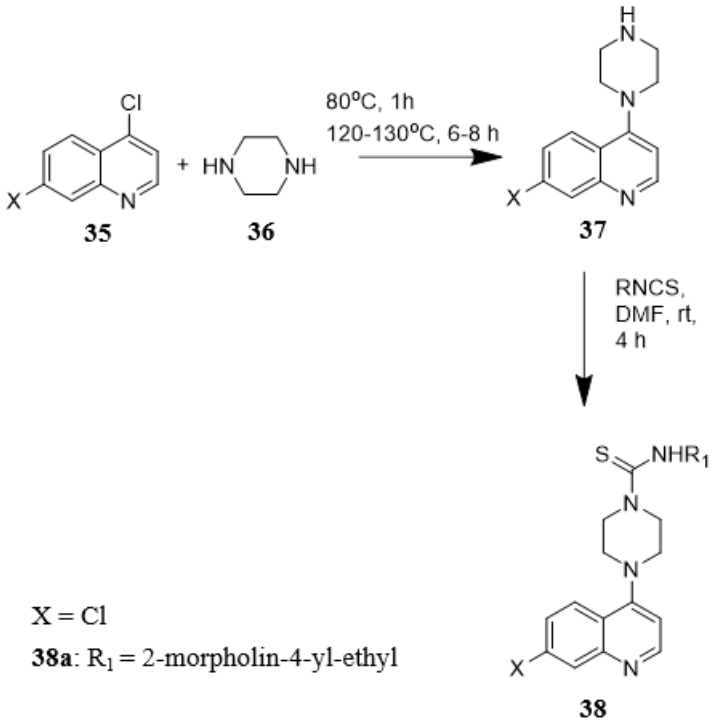
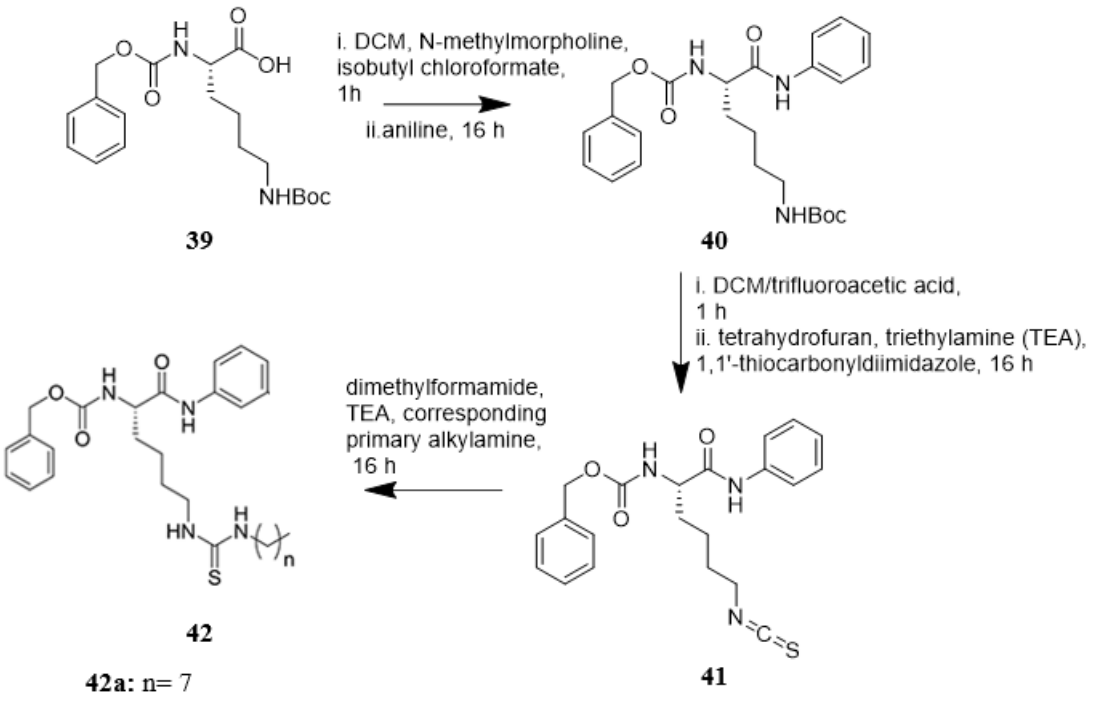


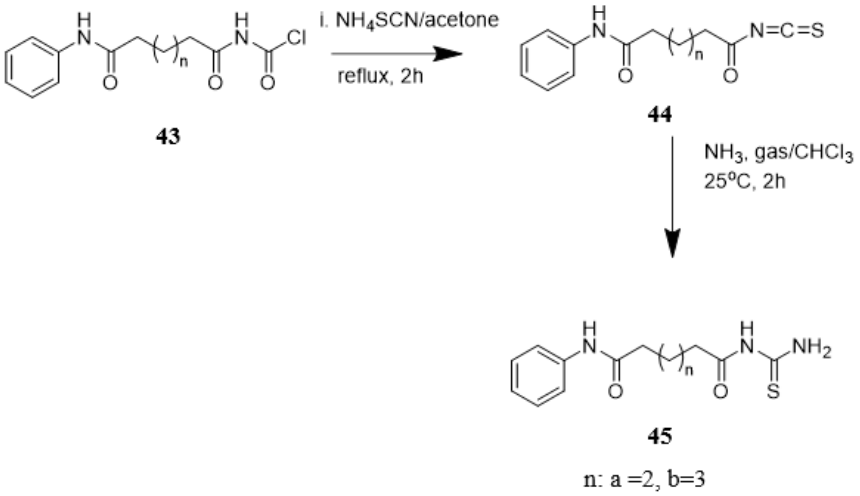
A new potent compound was discovered by reacting 4-hexylbenzoyl chloride **(32)** and *N*-methylthiourea **(33)** as shown in Scheme 9 [33]. The compound 1-(4-hexylbenzoyl)-3-methylthiourea **(34)** displayed significant anticancer activity against four cancer cell lines as compared to the control (hydroxyurea). This compound revealed low IC_{50} values; HeLa = 412 µM (5632 µM), MCF-7 = 390 µM (2829 µM), WiDr = 433 µM (1803 µM), and T47D = 179 µM (1803 µM). The incorporation of *n*-heptane aliphatic substituent would enhance the activity due to the increased lipophilic as well as pharmacokinetic properties. However, replacing the aliphatic chain with a tricyclic aliphatic reduces anticancer activity.

Scheme 9. The reaction between 4-hexyl benzoyl chloride with *N*-methylthiourea



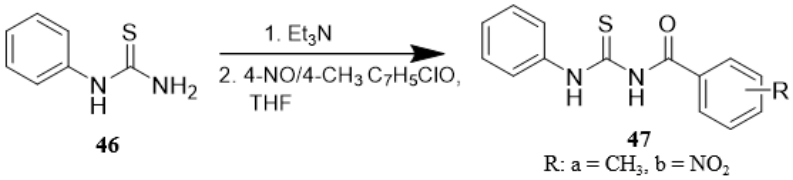
A new compound 4-piperazinylquinoline derived thioureas (Scheme 10) was developed and examined for their antiproliferative activity on three human breast tumour cell lines (MDA-MB231, MDA-MB468, and MCF7) as well as two non-cancer breast epithelial cell lines (184B5 and MCF10A) [16]. Among the novel compounds synthesized, compound **38a** namely (4-(7-chloro-quinoline-4-yl)-piperazine-1-carbothioic acid

(2-morpholine-4-yl-ethyl)-amide) showed significantly improved antigrowth/antiproliferative activity against breast cancer cells; MDA-MB231, MDA-MB468 and MCF7 with IC_{50} values ranging from 3.0 to 4.6 µM which is 7 to 11-fold selective to cancer cells and non-toxic to non-cancer cells. Attachment of quinoline, piperazine and morpholine on thiourea significantly enhanced antiproliferative activity with the cytotoxicity value 7 to11-fold higher in cancer than in noncancerous cells. This might be due to the heterocyclic compounds possessing hydrogen bond donor-acceptor capability which subsequently would enhance the lipophilic properties [34,35,36].



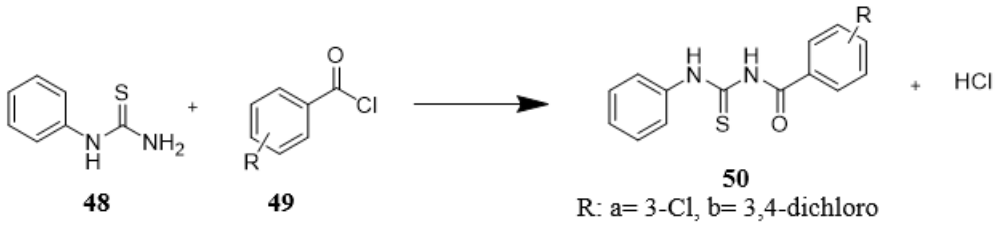
Scheme 10. Synthesis of 4-piperazinyl quinoline derived thiourea

Sirtuin 2 (SIRT 2) is an enzyme that is responsible for tumour suppressors in general, although knocking it down or inhibiting it has a broad anticancer effect in human breast cancer cell lines through boosting c-Myc degradation [37]. A novel lysine-derived thioureas as SIRT2 inhibitors were synthesized against MCF7 (breast cancer), MDA-MB-468 (breast cancer), MDA-MB-231(breast cancer), BxPC-3 (pancreatic cancer), NCI-H23 (lung cancer), A549 (lung cancer), SW948 (colorectal cancer), HCT116 (colorectal cancer), and CCD841 CoN (colon cell) [38]. The chemical reaction to synthesize the compounds is shown in Scheme 11. In comparison to thioamide-type inhibitor (reference drug), compound **42a** was highly selective and demonstrated broad cytotoxicity amongst cancer cell lines, specifically, human colorectal cancer cell line HCT116 with half-maximal growth inhibitory (GI_{50}) values of ~7 µM. None of the inhibitors was toxic to noncancerous HME1 epithelial cells.



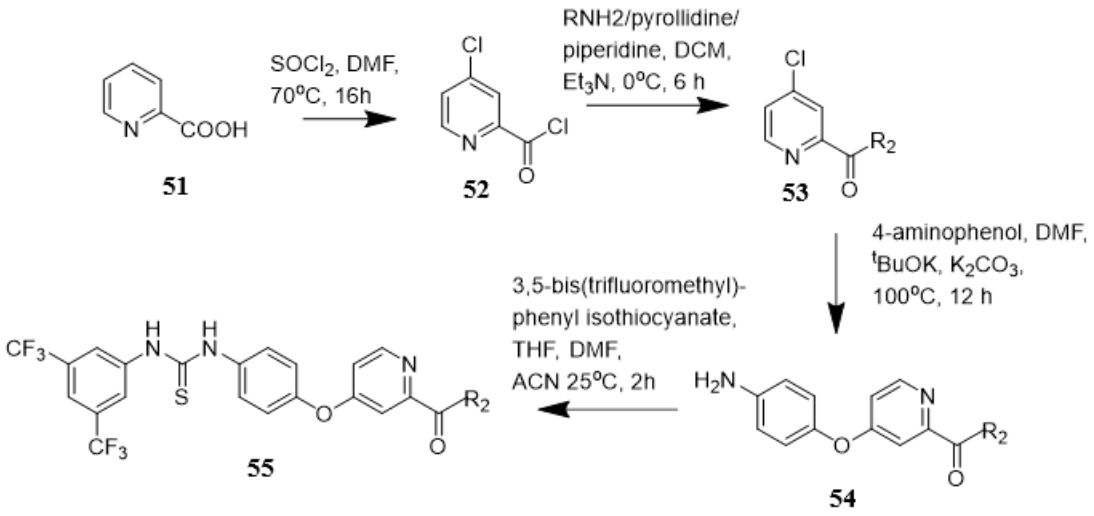
Scheme 11. Synthesis of Thiourea derivatives with varying chain lengths

Other novel compounds that were discovered are namely *N*-adipoyl monoanilide thiourea **(45a)** and *N*-pimeloyl monoanilide thiourea **(45b)** as histone deacetylase (HDAC) inhibitors [39]. Generally, HDAC is important to regulate epigenetic or non-epigenetic, as well as in cancer cell death, apoptosis, and cell cycle arrest [40]. The compounds were synthesized as shown in Scheme 12. Both compounds showed better inhibition against human colon adenocarcinoma (HRT-18) and mouse hepatoblastoma (HC-04) cells with a low cytotoxic effect on normal human breast cells (HBL-100) through MTT assay. It was also found that compound **45b** had higher antiproliferative activity than compound **45a** against the tested cancer cells with IC_{50} values of 21.44 µM and 24.12 µM and 27.37 µM and 30.42 µM, respectively against HC-04 and HRT-18 cell lines. The increased chain of carbon would increase the lipophilicity of the compound and subsequently enhance the cytotoxicity [41].



Scheme 12. Synthesis of the target compounds (45a-b)

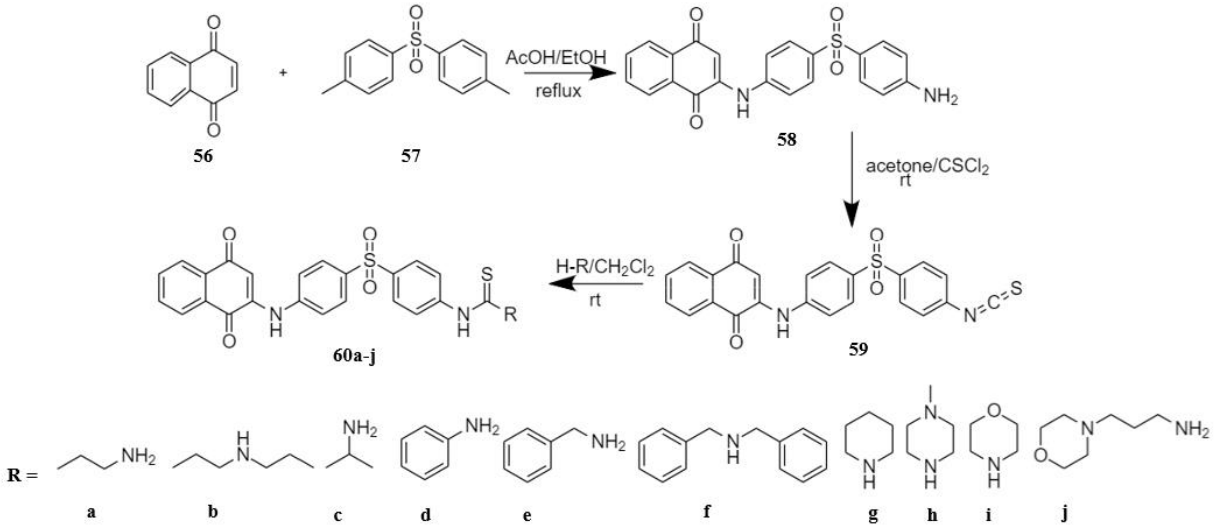
Two compounds of *N*-(phenylcarbamothyoil) benzamide derivatives **(47)** were synthesized by reacting *N*-phenylthiourea, triethylamine **(46)**, and 4-nitro/4-methylbenzoyl chloride as presented in Scheme 13 [42]. This study investigated the effect of electronic and lipophilic substitution on anticancer activity. Compound **47b** with a strong electronic effect of 4-NO_2 (σ = 0.78) is more potent with lower IC_{50} values compared to compound **47a** with a strong lipophilic effect of 4-CH_3 (π =0.56) with IC_{50} values of 0.12±0.014 and 1.08±0.013 mM, respectively. The effect of the EWG is stronger than the EDG. Overall, the tested compounds have better activity than HU (4.58 ±0.019 mM) and are non-toxic to healthy Vero cells. The study suggested that *N*-(phenylcarbamothyoil) benzamide derivatives compound has a stronger electronic effect than lipophilic effect.



Scheme 13. Synthesis of *N*-(phenylcarbamothyoil) benzamide derivatives

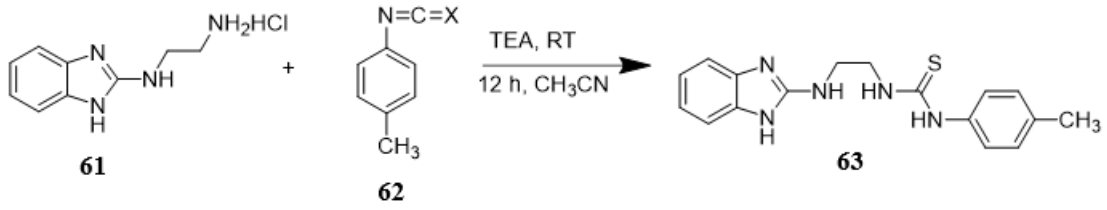
In response to the strong EWG effect in cytotoxicity, another two compounds of *N*-benzoyl-*N'*-phenylthiourea derivatives were designed, namely *N*-(3-chloro)benzoyl-*N'*-phenylthiourea **(50a)** and N-(3,4-dichloro) benzoyl-*N'*-phenylthiourea **(50b)** [43]. The test compounds were synthesized from *N*-phenylthiourea (**48**) with benzoyl chloride derivatives (**49)** via acyl nucleophilic substitution reactions as represented in Scheme 14. A cytotoxicity study obtained from the MTT assay showed that **50a** has a higher cytotoxic effect than **50b** with IC_{50} values of 0.43 mM and 0.85 mM respectively. Overall, all compounds showed better anticancer activity compared with HU (IC_{50} = 4.58 mM). The activities of these two novel compounds were projected to be cell-targeted because they were harmful to cancer cells but not to Vero normal cells.

Scheme 14. Synthesis of *N*-benzoyl-*N'*-phenylthiourea or *N*-(phenylcarbamothioyl)-benzamide derivatives



The synthesis of a series of novel thiourea derivatives containing 3,5-bis(trifluoromethyl)phenyl moiety (R_1) at terminal thiourea and phenylamino (R_2) at the terminal acyl position is shown in Scheme 15 [44]. Compound (**55a)** showed the best cytotoxicity against seven cancer cell lines: NCI-H460, Colo-205, HCT116, MDA-MB-231, MCF-7, HEpG2 and PLC/PRF/5 with IC_{50} values of 1.86, 9.92, 6.42, 8.21, 9.19, 6.21 and 7.82µM, respectively. Compound **55a** was found to be most potent with higher antiproliferative activities than Sorafenib and has excellent activity against normal cell HUVEC (IC_{50}: 2.81µM). When 3,5-bis(trifluorophenyl) was replaced with a nitro group (**55b**), good antiproliferative activity was observed. Meanwhile, none and weak activities were reported for unsubstituted (**55c**) and EDG substituent ring **(55d**) on phenyl ring respectively.

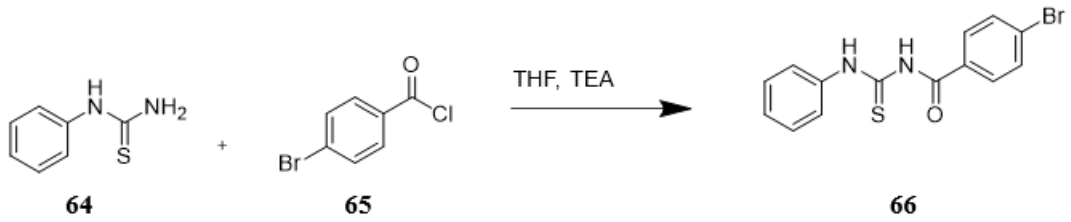
Scheme 15. Synthesis novel thiourea derivatives **55a-d**



Another novel thiourea compounds that are potent anticancer chemotherapeutic are thiourea bearing dapsone-naphthoquinone derivatives [45]. The synthesis pathways of the desired compounds **(60a-j)** are illustrated in Scheme 16. The reaction between 1,4-naphthoquinone **(56)** and dapsone **(57)** produces 2-[4-(4-aminobenzenesulfonyl)-phenylamino]-[1,4]naphthoquinone **(58)**. The 2-[4-(4-isothiocyanato-benzenesulfonyl)-phenylamino]-[1,4]naphthoquinone **(59)** was obtained by adding thiophosgene to the **(58)** suspension in acetone. Finally, the synthesis of thiourea derivatives **(60a-j)** was completed by adding primary or secondary amines to the isothiocyanato intermediate **(59)**. The most effective compound was found to be a thiourea derivative containing *N*-methyl piperazine (**60h**) with an IC_{50} of 5.8±0.55 µM against chronic

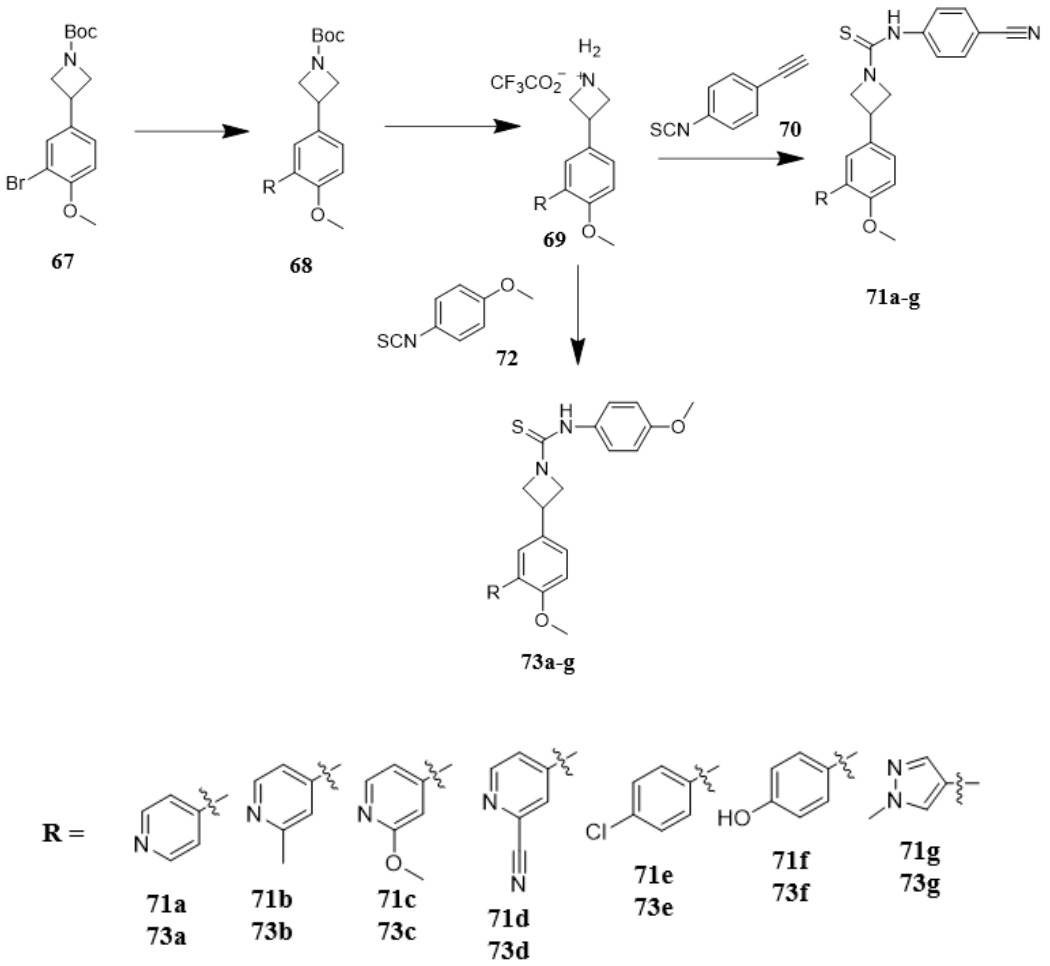
myelogenous leukaemia (CML) (K562 cell lines). The anticancer action of thiourea derivatives was diminished by increasing the inhibitory effect of nucleophile steric hindrance. The anticancer activity of compounds **(60d–f)** containing phenyl, benzyl, and dibenzyl amines, respectively is significantly reduced. The anticancer activity of compounds **(60g-j)** revealed that adding N-CH_3 group to the thiourea skeleton considerably increased the anticancer activity of **60h**, with an IC_{50} of 5.8±0.55 µM. Furthermore, the anticancer activity of **60h** was 5.2 times more active than the carbon-substituted compound 60g (IC_{50}=30.37±2.21 µM) and 5 times more active than the oxygen-substituted compound **60i** (IC_{50}=29.06±2 µM).

Scheme 16. Preparation of the aimed compound (**60a–j**)



A new thiourea benzimidazole derivatives were synthesized, as outlined in Scheme 17 [47]. The cytotoxic activity of the compounds was assessed in human breast cancer cell lines viz MDA-MB-231 and MCF-7. The compound 1-(2-(1*H*-benzo[d]imidazol-2-yl-amino)ethyl)-3-*p*-tolylthiourea **(63)** was found with higher activity in MCF-7 with IC_{50} values of 25.8 µM, as compared with MDA- MB-231 cells (54.3µM). It was revealed that benzimidazole is connected to thiourea moiety through ethylenediamine linker contributed to the anticancer activity due to its resonance structure. These findings could lead to the development of novel thiourea benzimidazole compounds with significant anticancer properties.

Scheme 17. Synthesis thiourea benzimidazole derivatives **63**



Next, a potent compound was revealed namely *N*-(4-bromo)-benzoyl-*N'*-phenylthiourea **(66)** [47]. The compound was synthesized by reaction of N-phenylthiourea **(64)** and 4-bromobenzoyl chloride **(65)** through acyl nucleophilic substitution as depicted in Scheme 18. In vitro cytotoxicity assay was carried out on HER2-positive primary breast cancer cells and produced IC_{50} values of 0.54 mM, lower than standard

drug hydroxyurea with an IC_{50} value of 11.61mM. This finding is correlated to the previous study [42] which confirmed that the inductive effect of EWG showed greater cytotoxicity than the lipophilic effect of EDG. Thus, the substituent of EWG for benzoyl ring of thiourea is important and could be further developed as an anticancer candidate for HER2-positive breast cancer.

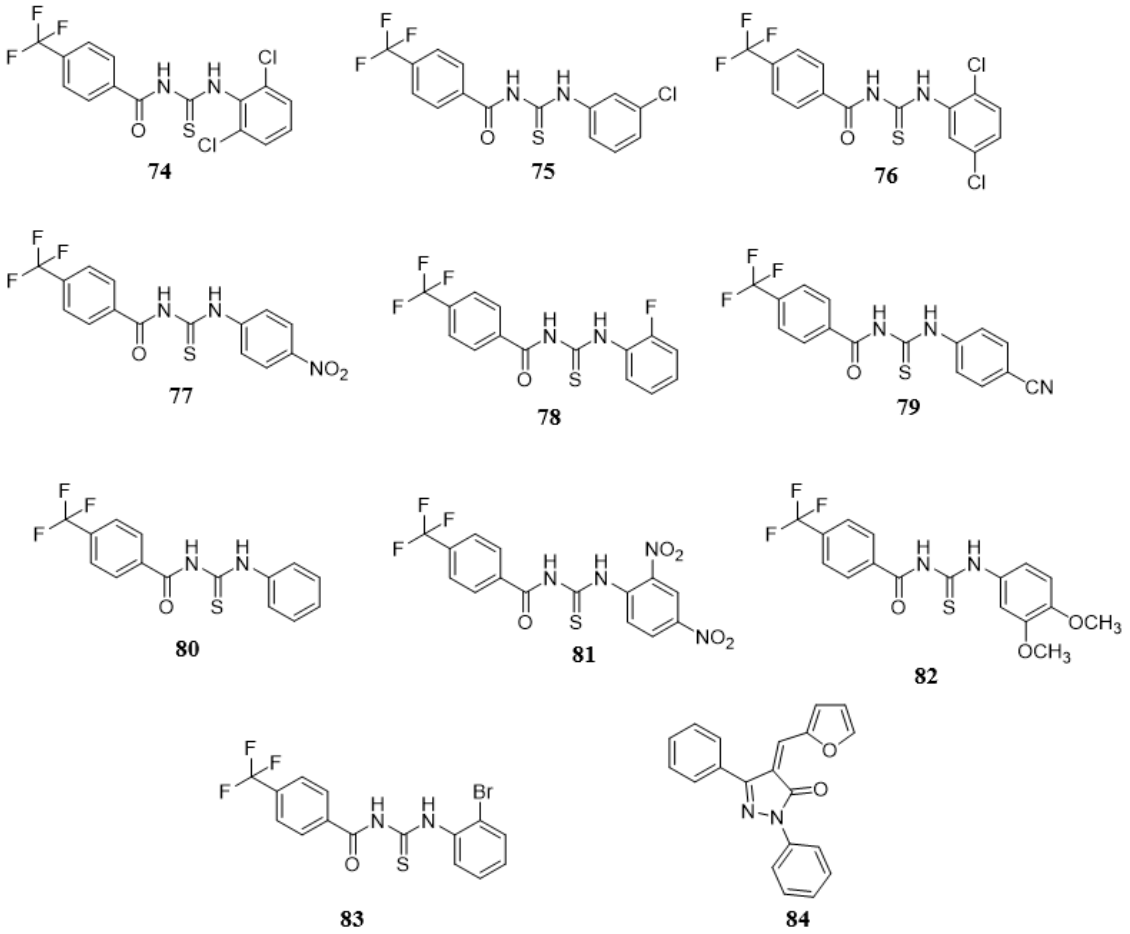
Scheme 18. Synthesis of *N*-(4- bromo)-benzoyl-*N*'-phenylthiourea **66**

Other than that, a novel series of compounds were developed with thiourea-azetidine hybrid **(71a-g)** and **(73a-g)** [48]. The synthesis pathway of these compounds is illustrated in Scheme 19. All compounds were evaluated for their in vitro anticancer activity against various human cancer cell lines viz; lung (A549), prostate (PC3), breast (MCF7), liver (HepG2), colon (HCT116), ovarian (SKOV3), skin (A431), brain (U251), and kidney (786-O). With medium effective dose (EC_{50}) values of 0.25, 0.6, 0.03, and 0.03 µM, the compound of 3-(4-methoxy-3-(2-methoxypyridin-4-yl)phenyl)-*N*-(4-methoxyphenyl)azetidine-1-carbothioamide **(73c)** was shown to be the most potent member against PC3, U251, A431, and 786-O cancer cell lines, respectively, and demonstrated more potency than doxorubicin. In the A431 cell line, the median effective concentration (EC_{50}) values for compounds **73a-g** ranged from 0.03 to 12.55 µM. For A431 and 786-O cell lines, compound 3-(4-methoxy-3-(pyridin4-yl)phenyl)-N-(4-methoxyphenyl)azetidine-1-carbothioamide **(73a)** was shown to be highly effective, with EC_{50} values of 0.77 and 0.73 µM, respectively. All of the substances have a good to moderate level of toxicity. The study revealed that thiourea derivatives containing EDG (–OCH_3) on the phenyl ring and pyridine **(73a)**, substituted pyridine derivatives **(73b-d)** and substituted pyrazole derivative **(73g)**, respectively were found to be the most potent than compounds with substituted pyridine **(71a-d)** and pyrazole heterocycle derivatives **(71g)**, which contained EWG (–CN, in place of –OCH_3). In their series, the compound with *p*–chloro substitution and EWG (–CN) on the phenyl ring **(71e)** was found to have significantly higher activity against HepG2 and HCT-116 cell lines than phenyl derivatives with EDG (*p*-OH) **(71f)**. Out of nine cancer cell lines studied, the derivatives with EDG on both sides (–OH and –OCH_3) **(73f)** showed good to moderate activity on cell lines of A431, A549, HepG2, and HCT-116. Thus, this study confirmed that EDG substituent would enhance the cytotoxic activity.

Scheme 19. The synthesis of thiourea-azetidine derivatives (71a-g and 73a-g)

Another study is the synthesis and evaluation of several thioureas and benzylidine moieties as carbonic anhydrase-II (CA-II) inhibitors [49]. The CA-II enzyme is important to catalyse the reversible hydration of carbon dioxide, which results in the creation of bicarbonate and proton. The inhibition of this enzyme is used as a biomarker and therapeutic target in the treatment of leukaemia, cystic fibrosis, glaucoma, and epilepsy [50]. Within this study, several thiourea derivatives and compound **84** of the benzylidene series showed outstanding inhibitory activity against CA. The cytotoxic evaluation against 3T3 cell lines (Mouse Fibro-blast) using MTT assay exhibited prominent inhibition activity with IC_{50} values ranging from 1.90 ± 1.30 to 25.90 ± 2.05 µM compared to standard inhibitor acetazolamide (IC50 = 0.13 ± 0.05). Meanwhile, benzylidene derivatives showed weak inhibition potential with IC_{50} values in the range of 52.68 ± 0.47 to 348.57 ± 3.32 µM. Also, the study reported that *N*-(trifluoromethyl) benzoyl moiety in thiourea is important for CA II inhibition. The structures of thiourea derivatives are shown in Figure 4. It was revealed that compound **(82)**, with ethoxy substituents (EDG) on the N-phenyl ring, significantly enhance the potency of the compound with an IC_{50} value of 1.90 µM. The presence of EDG increased the electron density and activate the ring. Unsubstituted *N*-phenyl ring **(80)** showed a slight decrease in anticancer activity. However, the presence of EWG such as F, CN, NO_2 and Br group on the *N*-

phenyl ring for compounds (**74-83)** suppresses the activity with IC_{50} values ranging from 4.40 ± 1.80 µM to 25.90 ± 2.05 µM. On the other hand, the presence of furylmethylene ring increased the potency of compound **84**. Overall, it is indicated that EDG on the benzene ring of thiourea derivatives and benzylidene have significantly enhanced the anticancer activity.



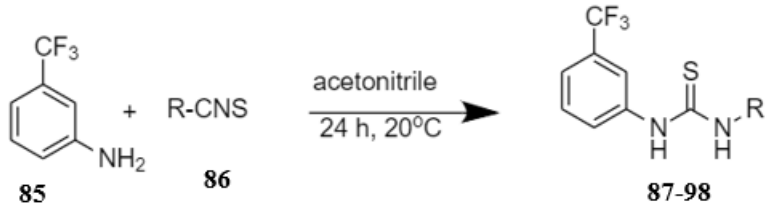


Figure 4. Structure of thiourea derivatives **74-84**

The potent *N*-(trifluoromethyl) benzoyl moiety linked to thiourea potential for anticancer activity led to the synthesis of 1,3-disubstituted thioureas **(87-98)** [12]. The synthesis pathway of these compounds involves a single-step reaction of 3-(trifluoromethyl)aniline **(85)** with various isothiocyanates **(86)**, belonging to a group of dihalogenophenyl **(87-90)**, halogenomethylphenyl **(91-92)**, alkylphenyl **(96)**, or monophenyl-substituted **(91–95)** derivatives (Scheme 20). Then, the cytotoxicity of the compounds was investigated against four human carcinoma cell lines, such as SW480 (primary colon cancer), SW620 (metastatic colon cancer), PC3 (metastatic prostate cancer), and K-562 (chronic myelogenous leukaemia), as well as against the normal cell line HaCaT (immortalized human keratinocytes), the IC_{50} values are summarized in Table 2. This study summarized the increasing impact of cytotoxicity according to the terminal benzene moiety functionalities as follows: 4-bromo- **(97)** < 2-(trifluoromethyl)- **(93)** < 2-methyl-5-chloro- **(92)** < 4-cyano- **(96)** < 2-methyl-3-chloro- **(91)** < 2,3-dichloro- **(90)** << 2,4-dichloro- **(89)** < 4-chloro- **(95)** < 3-chloro-4- fluoro- **(87)** < 4-(trifluoromethyl)- **(94)** < 3,4-dichloro- **(88)**. Dihalogenophenyl

derivatives **(87-90)**, compounds **94- 95** were the most active among the series towards all tumour cell lines with $IC_{50} \leq 10$ µM. The most promising drug candidates **(87-90, 94, 95)** were weakly cytotoxic towards normal HaCaT cell lines. Meanwhile, the introduction of the unsubstituted alkylphenyl group **(98)** to the thiourea branch dramatically decreased the compound's bioactivity. The structural modifications of the thiourea terminal moieties indicated the dihalogenophenyl derivative **(88)**, followed by its isomer **(89)** and para-substituted analogue **(94)**, as the most effective in cancer treatment. Therefore, this study highlighted the significance of EWG substituent in enhancing anticancer activity.

Conclusion

This review summarizes the recently synthesized thiourea compounds and their anticancer activities. It shows that thiourea moiety is important in discovering potent, effective and safer drugs to treat cancer. As described above, there were numerous synthesis pathways to prepare the thiourea derivatives. Based on the evaluation of thiourea derivatives as an anticancer agent, modification of thiourea moiety with suitable substituents at N1 and N2 improved the cytotoxicity properties of the compounds. The study also indicates that the substituent containing electron donating and electron withdrawing groups play an excellent role in improving anticancer activities. Even though most of these reported compounds are in clinical trials, the urgent need for further derivation and cytotoxicity studies will provide an opportunity for managing therapeutic values more efficiently and with greater efficacy. In short, the thiourea derivatives scaffold is a valuable candidate in the design and development of novel compounds that warrants further investigation with a clinical trial.

Abstract

Eleusine indica belongs to the Pocaceae family and is abundantly found in many tropical countries. Because of its anti-malarial, antioxidant, anti-viral, and antidiabetic properties, among many others, studies are being aimed on developing time and cost-effective methods that could efficiently extract its active components. This study focused on the optimization of the microwave-assisted extraction (MAE) of phenolic contents from *E. indica*. A response surface methodology (RSM) using a Box-Behnken design (BBD) of experiment was employed to determine the optimized condition for the extraction method. The extraction was performed with three varying factors (ethanol concentration, microwave power, and irradiation time) and one response (total phenolic content or TPC). A maximum TPC of 74.81 ± 5.22 GAE mg/g was obtained through MAE, using 57.23% (v/v) ethanol with microwave irradiation of 217.77 W for 4.53 minutes. The optimized condition had an extraction yield of 11.62 ± 1.97%. The ethanolic *E. indica* extract obtained using the optimum condition contained mostly of triterpenes, saponins and glycosides; and moderately of flavonoids and tannins.

Keywords: *Eleusine indica*, microwave-assisted extraction, phenolic compound extraction, response surface methodology

Abstrak

Eleusine indica dari keluarga Pocaceae dan ia sering dijumpai di negara tropika. Oleh kerana sifatnya anti-malaria, antioksida, anti-viral dan antidiabetik, banyak kajian dijalankan bangi membangunkan kaedah yang berkesan dari aspek masa dan kos bagi tujuan pengkestrakan komponen aktif. Kajian ini memberi tumpuan kepada pengoptimuman pengekstrakan berbantu gelombang mikro (MAE) bagi kandungan fenolik dari *E. indica*. Kaedah gerak balas permukaan (RSM) mengunakan reka bentuk eksperimen Box-Behnken telah dibangunkan bagi penentuan keadaan optimum kaedah pengekstrakan. Pengekstrakan telah dijalankan Bersama tiga faktor (kepekatan etanol, kuasa gelombang mikro, dan masa penyinaran) dan satu respons (jumlah kandungan fenolik atau TPC). Nilai maksimum TPC ialah 74.81 ± 5.22 GAE mg/g diperolehi melalui MAE, mengunakan 57.23% (v/v) etanol bersama

217.77 W penyinaran gelombang mikro selama 4.53 minit. Keadaan optimum telah menghasilkan ekstrak 11.62 ± 1.97%. Ekstrak etanolik *E. indica* mengunakan keadaan optimum mengandungi triterpen, saponin dan glikosida, dan flavonoid dan tannin.

Kata kunci: *Eleusine indica*, pengekstrakan berbantu gelombang mikro, pengekstrakan sebatian fenolik, kaedaj gerak balas permukaan

Introduction

For many years, plants with medicinal properties have been widely used as sources of traditional medicines to treat various disease and illnesses. Since then, immense efforts have been put into the study and optimization of extracting active components from plants in the aim of increasing their medicinal potencies and applications. Plants are rich in many natural products, such as secondary metabolites, which possess valuable pharmacological activities. These secondary metabolites include phenols, phenolic glycosides, flavonoids, cyanogenic glycosides, saponins, unsaturated lactones, and glucosinolates [1]. Phenolic compounds have been found to have anti-inflammatory [2], anti-mutagenic [3] and antimicrobial activities [4]; exhibit chemoprotective [5]; and inhibit nitric oxide production [6]. Recent reports have found high phenolic compounds in *Eleusine indica* [4, 7, 8].

E. indica (also known as goose grass) is an invasive annual weed which is native in tropical and subtropical regions. It has been used as a traditional medicine for treating diarrhea and malaria [9]. It has also shown anthelmintic [10], antioxidant [4], anti-viral [11] and antidiabetic [12] properties. The crude chloroform and methanolic extracts of *E. indica* were reported to contain tannins, flavonoids, and alkaloids which exhibited anti-fungal and antibacterial activities against *Enterobacter aerogenes*, *Escherichia coli, Klebsiella agerogenes, Proteins vulgaris, Pseudomonas aerogenes, Staphylococcus aureus*, and unspecified *Streptococcus* and *Bacillus* species [13].

The phenolic compound extraction from *E. indica* is commonly performed using a conventional maceration method, which may involve different solvent systems (water, methanol, ethanol, ethyl acetate, or hexane) [14]. However, this extraction technique consumes high amounts of solvent, requires long extraction times, and impose a high risk of degrading the heat-labile constituents in the sample. To resolve these drawbacks, increasing studies are being done aiming to develop more efficient extraction techniques. Of these methods, the microwave-assisted extraction (MAE) shows one with the highest potentials. The application of MAE does not only reduce the amount of solvent and extraction time needed; it also improves the extraction yield with minimal degradation of bioactive compounds in the sample [15]. The amounts of phenolic compounds extracted from pineapple peelings using conventional (Soxhlet) and microwave-assisted methods have been compared and it was found that at a similar sample-to-solvent (ethanol) ratio, MAE required 6-fold less time to extract around 7-fold more phenolic content compared to Soxhlet method [16]. Further, the overall operational cost of microwave-assisted processes is estimated to be lower than those using conventional heating in terms of energy consumption and the overall process turnover time [17]. Hence, the use MAE could be a good alternative for extracting phenolic compounds in medicinal plants.

Few reports are available on the extraction of total phenolic compounds (TPC) from *E. indica*. These studies either used cold maceration [4], decoction [8], or ultrasonication [7] in their extraction procedures. The main factors affecting MAE efficiency include sample particle size, pre-leaching time, microwave power, extraction temperature, solvent to solid ratio, solvent composition, and extraction time/cycles [18].

For studying a process with multiple variables, an experimental design that can generate optimum conditions from a minimum number of experiments is highly desired. Response surface methodology (RSM) is a useful technique for studying the effects of important factors, unaccompanied or in combination with the involved processes [19]. It is also capable of generating a mathematical model of the possible interrelationship among the tested variables. Compared to other designs of experiments for RSM, such as Central Composite Design (CCD), the Box-Behnken Design (BBD)

requires fewer design points to study processes with a minimum of three levels and allows for studying processes with extreme ranges.

Achieving higher yields using safer and better extraction method (considering economic, environmental and practical dimensions) for the phenolic content extraction in *E. indica* using MAE presents many economic and medicinal potentials. Therefore, this study aimed to determine the optimum condition for the microwave-assisted extraction of phenolic compounds from *E. indica*, at varying ethanol concentrations, microwave power and microwave irradiation time using RSM with a BBD experimental design.

Materials and Methods

Chemicals and reagents

The Folin-Ciocalteu reagent, sodium carbonate (Na_2CO_3), hydrochloric acid (HCl), sulfuric acid (H_2SO_4), and acetic acid were purchased from Sigma-Aldrich (St. Louis, Mo). Gallic acid and ethanol were purchased from ATR Trading System (Metro Manila, PH). All other chemicals and reagents used in this study were analytical grade.

Sample collection

The *Eleusine indica* plants were collected from Barangay Dalig, Batangas City, Philippines. The samples were authenticated at the Bureau of Plant Industry, Department of Agriculture, Manila, Philippines with the certificate number of PLT-ID-CRPSD-0833-18.

Sample preparation

The collected plant samples were rinsed with tap water followed by distilled water to remove dirt from the surface. They were air-dried in a well-ventilated area at room temperature until a constant weight difference of ± 0.001 kg was obtained. The dried samples were crushed using an Astron BL153 food processor, and then sieved using a size 30 mesh screen. The sieved samples were transferred into air-tight glass containers and stored in room temperature for further analyses.

Microwave-assisted extraction of phenolic contents

Preliminary experiments were carried out to determine the working ranges of individual parameters, prior the RSM experiments. Ethanol was chosen as the solvent for the microwave-assisted extraction (MAE) process since it has been reported to extract higher concentrations of phenolic compounds compared to water, methanol, and acetone [16, 20, 21]. The determined parameter ranges for the MAE of the TPC from *E. indica* were investigated and optimized using a response surface methodology (RSM), following a BBD of experiment.

In here, the three selected variables (ethanol concentration, microwave power, and irradiation time) were varied at either a low, medium, or high level (coded as -1, 0, and +1, respectively). The measured TPC from each extraction experiment served as the responses. These responses were then used to generate a mathematical model for the process. The design matrix used in this study is summarized in Table 1.

Table 1. Independent variables and their coded levels for the Box-Behnken Design (BBD) of experiment

Factors	Code	Unit	Coded Variable Levels		
			-1	0	1
Ethanol concentration	A	% v/v	20	40	60
Microwave power	B	Watt (W)	210	350	490
Microwave irradiation time	C	minute (min)	4	7	10

The extraction process was performed based on the study of Pan *et al*. with some modifications on the pre-setting procedure [22]. Preliminary experiments were carried out to test and determine the working ranges of individual parameters (i.e., sample-to-solvent ratio, pre-leaching time, solvent concentration, microwave power, and irradiation time) for the phenolics extraction process. The three parameters with the highest individual effects on the phenolic extraction yield were then selected and their individual and combined interactions were studied further using RSM.

Prior to microwave treatment, the air-dried *E. indica* samples were subjected to a pre-leaching step by soaking them in varied concentrations (20, 40, or 60% v/v) of ethanol (20 mL/g dried sample) for 90 minutes. Using a MWX203 BL Whirlpool microwave oven (with eleven discreet MW power level settings ranging from 0 to 700 W), the mixtures were then exposed to varying microwave power levels (210, 350, or 490 W) for either 4, 7, or 10 minutes. After microwave treatment, the sample mixtures were cooled to room temperature, then filtered through a Whatman No. 1 filter paper (Whatman, Maidstone, Kent, UK). The filtrates were transferred into volumetric flasks and were diluted to a final volume of 100 mL.

***E. indica* extract sample preparation**

The TPC of the ethanolic *E. indica* extracts were determined using the Folin-Ciocalteu method [23]. In brief, 1 mL of each extract was transferred into a volumetric flask, followed by the addition of 5 mL of the Folin-Ciocalteu reagent and 4 mL of Na_2CO_3 solution, respectively. The solutions were mixed and then incubated (away from light) for 1 hour at room temperature, prior to absorbance read-out.

Gallic acid standard preparation

A 1 mL volume of each standard solution was transferred into a volumetric flask, followed by the addition of 5 mL of the Folin-Ciocalteu's phenol reagent and 4 mL of Na_2CO_3 solution, respectively. The solutions were mixed and then incubated (away from light) for 1 hour at room temperature, prior to absorbance read-out.

Spectroscopic analysis of standard and sample solutions

The absorbance of each of the prepared standard and sample solutions was measured at 760 nm using a UV-2700 UV-Vis spectrophotometer (Shimadzu Corporation, Kyoto, Japan). The TPC in each of the original sample solutions were computed using the generated standard calibration curve equation and were expressed as the milligram of gallic acid equivalent (GAE) per gram of dried *E. indica* sample, as shown in the equation 1:

$$TPC = C1\ (V/w) \quad (1)$$

TPC is total phenolic content expressed as GAE (mg/g); C1 is the GAE concentration in the sample (mg/mL); V is the volume of extract in mL; and w is the weight of the initial dried plant sample used (g).

Extraction process optimization and validation

The optimization of the microwave-assisted extraction of phenolic compounds from *E. indica* was carried out using the Design- Expert® v10.0.8 (Stat-Ease Inc., Minneapolis, MN, USA) software. An analysis of variance (ANOVA) was applied to test the validity of the generated model. The adequacy of the fitted model was determined by evaluating the lack of fit and the coefficient of determination (R^2). The model's Fisher variation ratio (F-value), probability value (Prob > F), and adequate precision (AP) were also evaluated to test for its significance and adequacy.

Extraction yield of the optimized MAE

To obtain the dried *E. indica* extract, the ethanolic extract was concentrated using a rotary vacuum evaporator (Buchi rotavapor R-205) set at 280 rpm for 15 min. at 40°C. The extraction yield was calculated using equation 2 [24]:

$$\text{Extraction yield (\%)} = (\text{mass of dried extract / mass of } \textit{E. indica}) \times 100 \quad (2)$$

Phytochemical screening

Standard procedures for the phytochemical screening of the *E. indica* extract obtained from the optimized MAE condition were performed to identify and estimate the presence of its chemical constituents such as alkaloid, flavonoid, saponin, triterpenoid, steroid, tannins, and glycosides [25].

Test for Sterols (Liebermann-Burchard Test). About 1 g of the sample was dissolved in 2 mL of acetic acid. The soluble portion was collected and was kept on ice. One to two drops of H_2SO_4 was then added to the solution. The development of color from violet to blue or bluish-green indicates the presences of steroidal rings.

Test for Triterpenoids (Salkowski Test). A 0.5 g of sample was mixed in 2 mL of chloroform. Then, 3 mL of concentrated H_2SO_4 as dropwise added to the mixture. The development of a reddish-brown color indicates the presence of triterpenoids.

Test for Flavonoids (Shinoda Test). Magnesium ribbon fragments were mixed with 2 g of the sample. Then, a few drops of concentrated HCl were added. The development of a pink to red color indicates the presence of flavanoids.

Test for Saponins (Froth Test). Hot distilled water was used to dissolve 5 g of sample and the mixture was then filtered. The filtrate was vigorously shaken. The formation of a persistent froth that lasts at least 15 minutes indicates the presence of saponins.

Test for Glycosides (Fehling's Test). Hot distilled water (5 mL) was used to dissolve 1 g of sample and the mixture was then filtered. Into each of two test tubes, 2 mL of the filtrate was added. In the first test tube, 1 mL of HCl was added; nothing was added to the second test tube (control). Both of the tubes were placed in a water bath at 100ºC for 5 minutes, then cooled to room temperature. Anhydrous sodium carbonate was added to neutralize the sample until there was no more effervescence. To each test tube, 1 mL of freshly mixed Fehling's A and B (1:1) was added. The test tubes were then placed in a water bath at 100ºC for 2 mins. The formation of the brick red precipitate indicates the presence of glycosides.

Test for Tannins (Ferric Chloride Test). The dried extract was dissolved in hot water then filtered. Few drops of 5% ferric chloride solution were added. A dark green or bluish-black color indicates the presence of tannins.

Results and Discussion

Microwave-assisted extraction parameters and responses

A total of fifteen experiments were performed to generate a response surface model (RSM) for the extraction of phenolic contents in *E. indica* at varying ethanol concentration, microwave power, and microwave irradiation time. The experimental factors used in this study and their responses are listed in Table 2. Each value is the mean of triplicate analysis. The results from the experiment revealed TPC varying from 16.82±1.3 to 74.81±3.9 GAE mg/g.

Table 2. Experimental factors and their responses for the MAE of TPC from *E. indica*

Standard Number	Run Number	A: Ethanol Concentration (% v/v)	B: Microwave Power (W)	C: Irradiation Time (min)	TPC [a] (GAE mg/g)
1	2	20	210	7	25.67 ± 1.5
2	4	60	210	7	60.05 ± 3.6
3	12	20	490	7	35.20 ± 3.7
4	13	60	490	7	25.41 ± 1.8
5	11	20	350	4	34.53 ± 4.1
6	10	60	350	4	62.67 ± 1.4
7	3	20	350	10	25.55 ± 1.5
8	15	60	350	10	16.82 ± 1.3
9	7	40	210	4	74.81 ± 3.9
10	9	40	490	4	58.80 ± 4.5
11	8	40	210	10	30.93 ± 2.1
12	6	40	490	10	29.23 ± 1.8
13	5	40	350	7	44.46 ± 3.3
14	14	40	350	7	44.11 ± 2.1
15	1	40	350	7	41.80 ± 2.5

[a] TPC values are expressed as mean ± standard deviation (SD), calculated from three independent experiments.

Optimization of the MAE of phenolic compounds in *E. indica* using RSM

The responses obtained from the batch microwave-assisted extraction experiments, with respect to the variables used, were fitted with the second-order polynomial equation 3:

$$Y = b_o + \sum_{i=1}^{k} b_i X_i + \sum_{i=1}^{k} b_{ii} X_i^2 + \sum_{i=1}^{k-1} \sum_{j=i+1}^{k} b_{ij} X_i X_j + e_i \quad (3)$$

where Y is the predicted response, b_o is the constant coefficient, bi is the linear coefficient, b_{ij} is the interaction coefficient, b_{ii} is the quadratic coefficient, Xi and X_j are the coded values of the AC activation factors, and e_i is the error.

As shown in Table 3, an analysis of variance (ANOVA) was performed to determine which model-order best fit the responses for the process in study. The acceptability of the model was evaluated based on correlation coefficient (R^2) and standard deviation. The model fitting revealed that the microwave-assisted extraction of phenolic compounds in *E. indica* best followed a second-order response surface model.

Table 3. ANOVA of the quadratic model of MAE of TPC from *E. indica*

Source	Sum of Squares	df	Mean Square	*F*-value	*p*-value	Remark[a]
Model	3872.59	9	430.29	37.29	0.0005	sig.
A - Ethanol Conc.	242.11	1	242.11	20.98	0.0059	sig.
B - MW Power	229.26	1	229.26	19.87	0.0067	sig.
C - Irradiation Time	2056.96	1	2056.96	178.24	< 0.0001	sig.
AB	487.67	1	487.67	42.26	0.0013	sig.
AC	340.11	1	340.11	29.47	0.0029	sig.
BC	51.16	1	51.16	4.43	0.0891	not.sig.
A^2	385.08	1	385.08	33.37	0.0022	sig.
B^2	41.14	1	41.14	3.57	0.1176	not sig.
C^2	10.04	1	10.04	0.87	0.3937	not sig.
Residual	57.70	5	11.54			
Lack of Fit	53.50	3	17.83	8.49	0.1071	not sig.
Pure Error	4.20	2	2.10			
Standard deviation = 4.43				R^2 = 0.9600		
Coefficient of variance = 10.90				Adjusted R^2 = 0.9300		
Adequate precision = 17.077				Predicted R^2 = 0.8631		

[a] sig. = significant; not sig. = not significant

A high correlation coefficient value of 0.9600 was obtained in the present study, indicating that only 4.00% of the total variation is unexplained by the generated model.

The ANOVA results for the quadratic response surface model for TPC extraction gave an F-value of 37.29 and a corresponding probability > F that is less than 0.05, validating that the model is significant. For the model terms, probability factor (prob > F) values less than 0.05 are considered significant. In this work, model terms *A*, *B*, *C*, *AB*, *AC*, and A^2 were significant while *BC*, B^2 and C^2 were insignificant terms. To improve the model's efficiency, insignificant model terms were excluded from the study.

Adequate precision (AP) describes the ratio between signal and noise and is used to decide whether the

predicted model can be utilized to move along the design space [26]. The obtained AP ratio of 17.077 that is higher than the desired value of 4 suggested that the model presented in this work is efficient to predict TPC of the extract, within the established set of parameters.

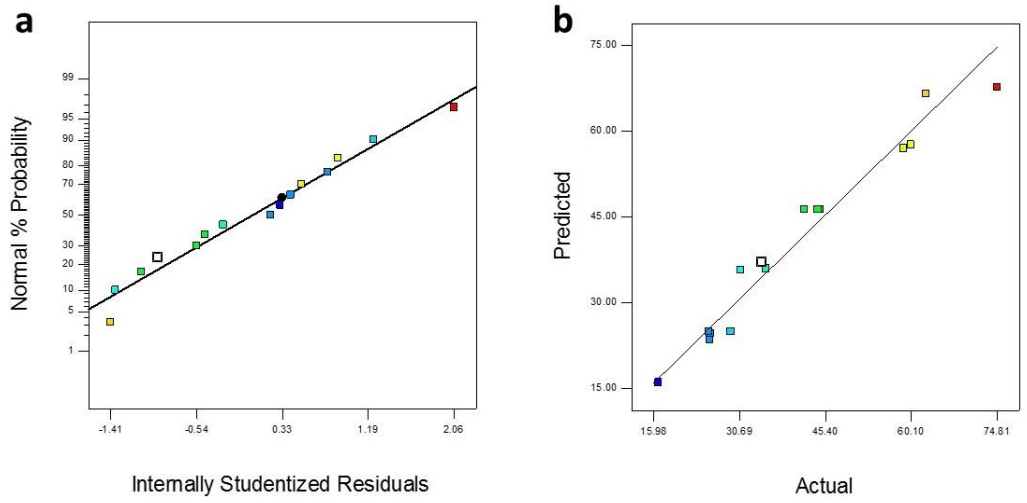

Figure 1. Plots of the (a) normal probability versus studentized residuals and the (b) predicted versus actual values for the MAE of TPC from *E. indica*

The normal probability plot of the studentized residuals for TPC extraction is illustrated in Fig. 1a. The linear plot illustrated adequate standard distribution, with minor scattering, between the residuals and the experimental points. Fig. 1b revealed good agreement between the experimentally-obtained and the model-generated responses. This indicated that the data generated by the model were valid and may represent that of the real system.

The final regression model, in terms of the coded factors for total phenolic content (TPC), is expressed in equation 4:

$$\text{TPC (GAE mg/g)} = 46.31 + 5.50A - 5.35B - 16.03C - 11.04AB - 9.22AC - 10.57A^2 \quad (4)$$

where TPC is total phenolic content expressed as GAE (mg/g), *A* is the ethanol concentration (% v/v), *B* is the MW irradiation power (210 to 490 W), and *C* is the MW irradiation time (4 to 10 min).

On the other hand, the final regression model, in terms of the actual factors for the total phenolic content (TPC), is expressed equation 5:

$$\text{TPC (GAE mg/g)} = -54.41274 + 4.84476(\text{ethanol conc.}) + 0.11950(\text{MW Power}) + 0.80238(\text{MW irradiation time}) - 3.94342\text{x}10^{-3}\,(\text{ethanol conc.})\,(\text{MW Power}) - 0.15368(\text{ethanol conc.})\,(\text{MW irradiation time}) - 0.02642(\text{ethanol conc.})^2 \quad (5)$$

Both equations 4 and 5 can be used for predicting the TPC yields along the design space. However, only the coded coefficients are proportional to the observed effect since the intercept in coded values is in the center of the design. In the actual values, the intercept usually lies far from the design space. The coefficients in terms

of actual factors account for differences in the factor ranges which may not be directly interpreted. Eq. 4 presents the relative effects of the model terms toward the TPC yield. Specifically, it could be observed that irradiation time exhibits the largest effect toward the TPC yield of the MAE process, while microwave power presented a comparable magnitude but contrasting effect as that of ethanol concentration.

The optimum extraction condition was established using Design-Expert® v10.0.8 (Stat-Ease Inc., Minneapolis, MN, USA) software. In the software optimization step, the goal for each operational condition (ethanol concentration, microwave power, and irradiation time) was set to be 'within' range while the response (TPC) was set as 'maximum' to achieve the highest possible yield. The highest predicted TPC was obtained at 52.23% v/v of ethanol, with microwave irradiation of 217.77 W for 4.53 min. with a predicted TPC of 75.22 GAE mg/g.

To further illustrate the relationships among parameters, ethanol concentration, microwave power input and irradiation time, toward the responses predicted by the model, three-dimensional (3D) surface response plots were generated, as shown in Figure 1.

In the plots shown in Figure 2, one variable was kept constant at the optimum value, while the two remaining parameters were varied within their experimental ranges. Figure 2a shows the 3D response surface plots of the combined effects of the ethanol concentration and microwave power, while the irradiation time was kept at the optimum value of 4.53 minutes. The predicted TPC in the *E. indica* extract showed an increasing trend with increasing ethanol concentration of up to 57.23%. Beyond this point, the TPC levels started to plateau which indicated that higher concentrations of the solvent had minimal effect on the TPC extraction. On the other hand, a decreasing trend in TPC yield was observed beyond the established optimum MW power around 218 W.

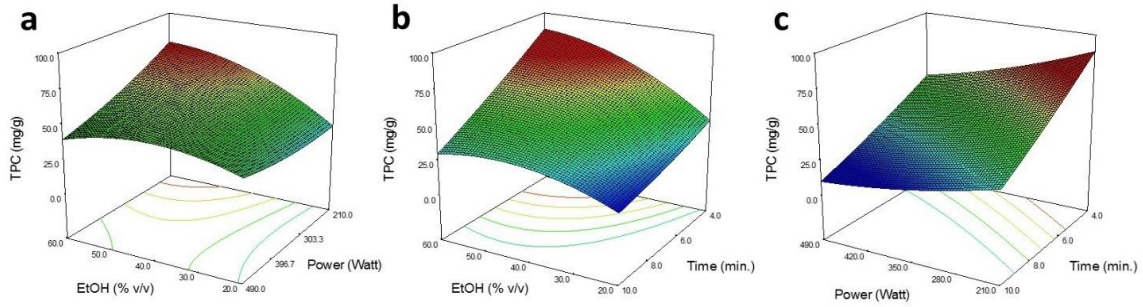

Figure 2. 3D response surface plots showing the predicted total phenolic content in the *E indica* extract as a function of (a) microwave power and ethanol concentration; (b) microwave irradiation time and ethanol concentration; and (c) irradiation time and microwave power.

Figure 2b shows the effect of the contact between ethanol concentration and microwave irradiation time on the TPC of *E. indica* when microwave power is fixed at 217.77 W. Increasing the ethanol concentration up to its optimum level showed positive correlation with the TPC in the extract, while a decreasing trend in TPC was observed as the irradiation time was increased above the optimum level of around 4.5 mins.

Figure 2c demonstrates the contact between microwave power and irradiation time on the TPC value at a fixed ethanol concentration of 57.23%. The 3D plot showed that the TPC level was at its highest when both parameters were set near their lowest levels.

Experimental validation of the predicted TPC from the optimized MAE condition

The predicted TPC in the *E. indica* extract obtained using the optimized MAE condition was validated by comparing experimentally obtained TPC values with the predicted TPC value. Table 4 shows the comparison of the experimental and the predicted TPC in the *E. indica* extracts obtained from the optimized MAE condition.

Table 4. Experimental validation of the predicted TPC obtained from optimized MAE condition

Optimized MAE Condition			Experimental TPC (GAE mg/g)	Mean Exp. TPC ± s.d. (GAE mg/g)	Predicted TPC (GAE mg/g)	% Error
Ethanol Conc. (% v/v)	MW Power (W)	Irradiation Time (min.)				
57.23	217.77	4.53	71.00 72.72 80.75	74.81 ± 5.23	75.22	0.541

As shown in Table 4, the obtained experimental TPC value of 74.81 ± 5.23 GAE mg/g was in close agreement with the predicted TPC of 75.22 GAE mg/g. A computed relative percent error of 0.541% between the predicted and obtained experimental value was observed. This validated the reliability of the generated predictive model and the goodness-of-fit with the experimental results.

Extraction yield of the *E. indica* extract obtained using the optimized MAE condition

Table 5 shows the extraction yield of the ethanolic *E. indica* extracts obtained using the determined optimum MAE condition. The mean extraction yield was determined to be 11.62 ± 1.96%.

Table 5. Extraction yield of the ethanolic *E. indica* extract obtained using the optimized MAE condition

Sample	Extraction Yield (%)
Trial 1	10.85
Trial 2	10.16
Trial 3	13.86
Mean ± s.d.	11.62 ± 1.96

Qualitative determination of phytochemicals in the *E. indica* extract

Based on Table 6, the ethanolic *E. indica* extract obtained using the optimized microwave-assisted extraction condition showed was abundant in triterpenes, saponins and glycosides. On the other hand, moderate amounts of flavonoids and tannins were observed. Sterols were not detected in the extract.

Table 6. Phytochemicals present in the *E. indica* extract obtained using the optimized MAE condition

Secondary Metabolite	Presence [a]
Sterols	(-)
Triterpenes	(+++)
Flavonoids	(++)
Saponins	(+++)
Glycosides	(+++)
Tannins	(++)

[a] presence is reported as either (-) absent, (+) traces, (++) moderate, or (+++) abundant

In this paper, the microwave-assisted procedure for the extraction of phenolic contents in *E. indica* was optimized, aiming to maximize TPC extraction yield while minimizing both the processing time and solvent consumption. The established optimized condition yields high amounts of extracted TPC, at a quicker processing time compared to conventional maceration methods.

In the predictive model equation, irradiation time showed to have the largest effect toward the TPC yield of the MAE process, while microwave power presented a contrasting effect as that of ethanol concentration. In the MAE of TPC from pomegranates, it was observed that more phenolics could be extracted using 50% ethanol than 70% [27]. It was associated with the fact that both the dielectric constant and dielectric loss factor of water are higher than those of ethanol. Under the same microwave power, the solvent with a fair ratio of ethanol and water may absorb more thermal energy enough to increase diffusion of phenolics. Based on the 3D response models (Figures 2a-c), the amount of TPC extracted from the sample start to decrease when the sample was exposed to higher microwave power for longer periods of time.

Introduction to microwave energy could strengthen the molecular interaction between the electromagnetic field and sample and improve the efficiency of the extraction process [28]. However, the observed decrease in TPC yield when the sample is exposed to MW levels that are beyond the established optimum could be caused by degradation of the desired phenolic compounds at higher levels of microwave power. Similar observations were seen in the findings of Peng et al. and Zheng et al. [29, 30].

While the nature of solvents used for MAE greatly contributes toward extraction efficiency, polar solvents such ethanol and water can get rapidly heated as they become exposed to too high levels of microwaves, resulting to the degradation of thermo labile phenolics and/or coextraction of other unwanted compounds in the sample [31]. More so, exposure to too much MW energy input for an excessive period could cause the sample mixture's temperature to extremely and abruptly elevate, initiating the rapid break down of the plant matrix. Hence, the MW power input and irradiation time must be maintained at the optimum level to achieve a selective MAE process and avoid solute degradation due to abrupt cell bursting from pressure buildup [32].

The optimum MW power level and irradiation time established for the MAE of TPC in *E. indica* both lie near the lower ends of the studied ranges. While this could indicate a possibility that the method may still be further optimized by exploring lower levels of MW power and shorter irradiation times, it was not done in this present study because of a limitation in the MW irradiation mechanism of the commercial microwave oven used.

The ethanolic *E. indica* extract obtained in this work contained different phenolic compounds such as triterpenes, saponins, glycosides, flavonoids, and tannins which are comparable to the finding in the study of *E. indica* by Morah and Otuk [13]. Phenolic compounds have been identified to exhibit many medicinal properties. The current optimized procedure was able to extract high amounts of secondary metabolites from *E. indica*, which can be further processed and used for medicinal applications.

Conclusion

The optimization of microwave-assisted extraction (MAE) of phenolic contents from *E. indica* was investigated in this present work. A second-order regression model for predicting the total phenolic contents (TPC) at varying ethanol concentration, MW irradiation power, and MW irradiation time was developed, with a high R^2 value of 0.9600. The diagnostic plots for the generated model demonstrated good agreement between the predicted and experimentally–obtained TPC extraction, proving the validity of the predictive model. Analysis of the 3D response plots derived from the model revealed interactions among the three parameters. Optimization was carried out using RSM following BBD with three variables. The optimized conditions for the MAE of TPC was successfully established through initial contact of dried *E. indica* samples to 57.23% v/v ethanol, followed by MW irradiation at 217.77 W for 4.53 min.

This resulted to the TPC yield of 74.81 ± 5.23 GAE mg/g. By optimizing the ethanol concentration, microwave power, and irradiation time for MAE, we were able to extract high amounts of phenolic compounds from *E. indica* in a short processing time. The obtained extract in this work contained abundant amounts of important secondary metabolites that could be further processed and used for medicinal applications.

Acknowledgments

The authors would like to extend their gratitude to Mr. Russel Jimenez for his technical assistance during the conduct of this study.

Abstract

Studies on physical and chemical compositions of stingless bee honey from northern region in Malaysia are still limited. Therefore, this study evaluates the physicochemical profile [pH, free acidity, ash content, total dissolved solids (TDS) and 5-hydroxymethylfurfural (5-HMF)], multi-elemental composition and antioxidant property of fresh stingless bee honey of *Heterotrigona itama*. Twenty honey samples were collected from the Northern regions (Kedah and Penang) of Malaysia. The results revealed that the values for pH, free acidity, ash content, and TDS were pH 3.01-3.43, 65.42-184.66 meq/kg, 0.07-0.61 g/100g, and 258.83-365.67 ppm, respectively. The concentration of 5-HMF in the honey samples elevated from not detected (fresh) to a maximum of 214.38 mg/kg (after 6- and 15-months storage). For multi-elemental composition, potassium was the highest concentration (16.13-1623.75 mg/kg) followed by calcium (36.23-272.5 mg/kg), sodium (31.25-148.25 mg/kg), aluminum (25.35-62.25 mg/L) and magnesium (11.14-179.75 mg/kg). Iron (< 0.02-41.55 mg/kg), copper (< 0.05-23.15 mg/kg), manganese (< 0.02-13.85 m/kg) and zinc (< 0.01-4.63 mg/kg) were found in low concentrations. Arsenic, lead, nickel, barium, cadmium and chromium were found in lower concentrations than the limit of detection, which indicates no contamination or environmental pollution on the studied areas. The total phenolic content (TPC) of the samples was 95.0-364.9 mg GAE/100g, showed relevant amounts of antioxidant properties, suggesting a source of natural antioxidants. In conclusion, the ash content, pH, and 5-HMF of fresh honey samples were compliant with the limit set by the Malaysian Standards. The 5-HMF concentration of all the honey samples after prolonged storage for six months exceeded the permitted range, which indicates that the honey samples deteriorated. Therefore, it is advised to consume the honey in less than six months.

Abstrak

Kajian tentang komposisi fizikal dan kimia madu lebah tanpa sengat dari wilayah utara di Malaysia masih terhad. Oleh itu, kajian ini menilai profil fizikokimia (pH, keasidan bebas, kandungan abu, jumlah pepejal terlarut (TDS) dan 5-hidroksimetilfurfural (5-HMF)), komposisi pelbagai unsur dan sifat antioksidan madu lebah tanpa sengat segar iaitu *Heterotrigona itama*. Dua puluh sampel madu telah dikumpul dari wilayah Utara (Kedah dan Pulau Pinang) Malaysia. Keputusan menunjukkan bahawa nilai pH, keasidan bebas, kandungan abu, dan TDS masing-masing adalah pH 3.01-3.43, 65.42-184.66 meq/kg, 0.07-0.61 g/100g dan 258.83-365.67 ppm. Kepekatan 5-HMF dalam sampel madu adalah daripada tidak dikesan (segar) kepada maksimum 214.38 mg/kg (selepas penyimpanan 6 dan 15 bulan). Bagi komposisi berbilang unsur, kalium adalah berkepekatan tertinggi (16.13-1623.75 mg/kg) diikuti kalsium (36.23-272.5 mg/kg), natrium (31.25-148.25 mg/kg), aluminium (25.35-62.25 mg/L) dan magnesium (11.14-179.75 mg/kg). Besi (< 0.02-41.55 mg/kg), kuprum (< 0.05-23.15 mg/kg), mangan (< 0.02-13.85 m/ kg) dan zink (< 0.01-4.63 mg/kg) didapati dalam kepekatan rendah. Arsenik, plumbum, nikel, barium, kadmium dan kromium didapati mempunyai kepekatan lebih rendah daripada had pengesanan yang menunjukkan tiada pencemaran atau pencemaran alam sekitar di kawasan yang dikaji. TPC sampel ialah 95.0-364.9 mg GAE/100g, menunjukkan jumlah sifat antioksidan yang relevan, mencadangkan sumber antioksidan semulajadi. Kesimpulannya, kandungan abu, pH, dan 5-HMF sampel madu segar adalah mematuhi had yang ditetapkan oleh Piawaian Malaysia. Kepekatan 5-HMF bagi semua sampel madu selepas penyimpanan berpanjangan selama 6 bulan telah melebihi julat yang dibenarkan, menunjukkan sampel madu semakin merosot. Oleh itu, adalah dinasihatkan untuk mengambil madu kurang daripada 6 bulan.

Introduction

Honeybees are categorized into two main groups: sting bees and stingless bees [1]. The name of the respective groups indicates the presence of sting on the bees. Stingless bees live in forests that have warm and humid conditions [2]. Hence, they can be found in Australia, Africa, Southeast Asia, and South America [3]. The honey produced by stingless bees is known as stingless bee honey. Other than honey, stingless bees are able to produce propolis, royal jelly, pollen, and beeswax. There are about 600 species with 56 genera of stingless bee honey identified worldwide [4]. In Malaysia, there are 33 species of stingless bee from the genus of *Trigona* and *Melipona* such as *Heterotrigona itama*, *Tetrigona apicallis*, *Geniotrigona thoracica*, *Lepidotrigona terminata*, and *Trigona binghami* [5, 6]. On the other hand, as the species of stingless bee vary, the chemical and physical compositions of stingless bee honey also change. Besides the bees' species, there are other factors that influence the compositions of honey such as botanical origin, extraction season, number of nectar source(s), and geographical origin [7].

Stingless bee honey mainly contains sugars (fructose and glucose), water and minor constituents of vitamins, enzymes, amino acids, minerals, and phenolic compounds (flavonoids and phenolic acids) [8]. In conjunction with the constituents of honey, there has been growing interest in the potential use of local and overseas stingless bee honeys for the food, pharmaceutical, and cosmetic industries in recent years [9, 10]. Therefore, the nutritional, therapeutic, and medical benefits as well as biological properties of stingless bee honey have been studied all over the world. Even though there are studies about the Malaysian stingless bee honey, they are limited to stingless bee honey from the northeast and southern end of Peninsular Malaysia [11, 12]. Therefore, this study is vital as it covers the investigation of various physical and chemical compositions of the Malaysian stingless bee honey belonging to *Heterotrigona itama* species from the northern region of Peninsular Malaysia. The physical and chemical compositions were physicochemical properties, total phenolic content, multi-elemental composition, and 5-hydroxymethylfurfural (5-HMF) content. These parameters have been chosen for this study because they have their respective significance as briefly discussed below. The investigated parameters were compared to the Malaysian Standard for stingless bee honey (Table 1) established by the Department of Standards Malaysia, in line with the international standards established by the Codex Alimentarius Commission and European Council Directive with the advice of the International Honey Commission [13, 14].

Table 1. Malaysian Standard for stingless bee honey

Parameter	Malaysian Standard
Moisture (g/100g)	Max 35
Sum of fructose and glucose (g/100g)	Max 35
Sucrose (g/100g)	Max 7.5
Maltose (g/100g)	Max 9.5
Free acidity (meq/100g)	Not applicable
Ash content (g/100g)	Max 1.0
5-HMF (mg/kg)	Max 30
Diastase activity	Not applicable
pH	2.5-3.8
Presence of plant phenolics	Present

In this study, there are four physicochemical properties that were investigated (pH, free acidity, total dissolved solids, ash). Stingless bee honey is naturally acidic; its acidity helps to minimize the growth of bacteria which can improve honey shelf life [15]. The acidity of stingless bee honey is caused by the presence of organic acids, for example, formic acid, oxalic acid, acetic acid, tartaric acid, etc. [5]. On the other hand, when the storage period of honey increases, the acidity of honey also increases due to the fermentation process which converts alcohol into organic acid [16]. Thus, the degree of deterioration of stingless bee honey can be investigated by measuring their pH and free acidity [17]. By measuring the total dissolved solids of stingless bee honey, the total content of inorganic and organic elements can be associated [18]. The ash content analysis of stingless bee honey indicates the total inorganic elements, including sodium, potassium, magnesium, calcium, iron, zinc, manganese, chromium, copper, and aluminum in the samples [19]. In short, all these four properties are well-known criteria for the determination and evaluation of stingless bee honey quality [20].

Polyphenols are one of the most abundant and extensively dispersed chemical groups in plants since the nectar is obtained from blossoms of plants and hence it contains polyphenols too [21]. The common polyphenol compounds in stingless bee honey are flavonoids and simple phenolic derivatives [22]. According to the Malaysian Standards, the presence of phenolic compounds shows the good quality of stingless bee honey [13]. The higher the total phenolic content, the higher the quality of the honey [23]. By determining the total phenolic content of honey, the antioxidant properties of honey can be identified [24]. This is because the total phenolic content has a strong correlation with redox and antioxidant capacities [25]. Other than TPC assay, there are a few other tests normally used to determine the antioxidant properties of the honey which are the DPPH, β-carotene linoleic acid emulsion method, and iron reduction power [26, 27, 28].

Minerals in the honey are particularly important since the mineral contents are dependent on the plant uptake from the soil that the source of the nectar-bearing plant is located and the environment where the bees will collect the nectar for the production of the honey [29]. Furthermore, the content of heavy metals in honey is an indicator of surrounding environmental pollution [30]. As honeybees interact with water, soil, air, and plants located within a particular radius from beehives, pollutants will consequently be brought by honeybees into beehives [31].

During the manufacturing and storage process of foods that are rich in sugar, the chemical alteration of carbohydrates can occur [32]. The chemical alteration of carbohydrates will be triggered if the food is in acidic condition; thus, the formation of furfural compounds via the dehydration process of carbohydrates in honey is unavoidable [32]. Furfurals are organic compounds; and

the common furfural compounds found in foodstuffs are 5-hydroxymethylfurfural (5-HMF), 2-furfural (2-FAL), 2-furfurol (2-FOL), 5-methylfurfural (5-MF), and 2-acetylfuran (2-AF) [33]. The concentration of 5-HMF is used as a quality indicator of heat processing and freshness of various foodstuffs such as sauces, honey, oils, jams, vegetable products, and fruit-based products [32]. This is because its concentrations tend to elevate during the heating process or long storage period [34]. There are several studies that reported that 5-HMF can be detrimental to human bodies and health due to its cytotoxicity, carcinogenicity, and mutagenicity [35].

Materials and Methods

Chemicals and reagents

All the chemicals and reagents used were of analytical grade. Methanol was purchased from Merck (Darmstadt, Germany). Methanol HPLC grade was purchased from Elite Advanced Material (EAM) (Selangor, Malaysia). Hydrochloric acid (HCl) (37%), nitric acid (HNO_3) (65%), sodium hydroxide (NaOH) pellets, and sodium carbonate were from QRëC (Asia) Sdn. Bhd.; gallic acid was from Fluka (Buchs, Switzerland); and Folin-Ciocalteu's phenol reagent (2N), and 5-HMF standard were from Sigma-Aldrich (St. Louis, MO, USA). Quality control standard 7A elements, 5% HNO_3/trace tartaric acid/trace HF: K (1,000 mg/L); Ag (50 mg/L); Al, B, Ba, Na (100 mg/L); and Si (500 mg/L) in 5% HNO_3/trHF; and quality control standard TruQ™ms, 5% HNO_3/trace tartaric acid/trace HF (1,000 mg/L): As, Be, Ca, Cd, Co, Cr, Cu, Fe, Li, Mg, Mn, Mo, Ni, Pb, Sb, Se, Sr, Ti, Tl, V, and Zn in 5% HNO_3 were purchased from PerkinElmer (USA). Ultrapure water used in the experiments was purified using a Direct-Q®RƐT Direct-Q UV-R water purification system (Millipore, MA, USA).

Honey samples

Twenty honey samples of *Heterotrigona itama* were obtained directly from the beekeepers in Penang and Kedah, Malaysia. Their geographical origins are listed in Table 2. The evaluation of physicochemical profile (pH, free acidity, ash content, TDS, 5-HMF), multi-elemental composition, and antioxidant property were only carried out using the fresh honey samples. The honey samples were stored in the dark at room temperature for six and fifteen months to figure out the consequence of storage duration on the concentration only for 5-HMF.

Table 2. The stingless bee honey species and geographical origins

Preparation of gallic acid standard solutions

Approximately 0.11 g of gallic acid was dissolved in ultrapure water in a 100 mL volumetric flask to produce a stock solution. Then, the stock solution was further diluted to a series of concentrations between 100-1,000 mg/L and marked as standard solutions prior to UV-Vis analysis. A control sample with a concentration of 0.5 mg/L was also prepared to ensure the analysis is properly performed to obtain reliable results.

Preparation of 5-HMF standard and honey sample solutions

Roughly 2,000 mg/L of stock solution was prepared by dissolving 50 mg of 5-HMF with ultrapure water in a 25 mL volumetric flask. The standard solutions (0.05, 0.5, 25, 50 mg/L) were freshly prepared to construct a calibration curve. The calibration curve was obtained by plotting the peak area against the concentrations. The preparation of honey sample was performed according to Moniruzzaman et al.'s study, with slight modification [18]. One gram of honey sample was diluted to 10 mL with ultrapure water. The solution was filtered through a 0.45 μm nylon membrane filter prior to injection into the HPLC.

Multi-elemental analysis

One gram of honey sample was mixed with 10 mL HNO_3 (65%), and the mixture was heated using a hot plate until it was nearly dry. The sample was then diluted to 50 mL with ultrapure water and analyzed using ICP-OES. The following 15 elements were determined using ICP-OES: Ca, K, Na, Ba, Mg, Cd, Cr, Cu, Fe, Ni, Pb, Zn, As, Mn, and Al.

pH analysis

The pH of the honey sample was analyzed based on AOAC Official Method 962.19 (2005) [36]. Two grams of honey sample was dissolved in 15 mL of distilled water, and the pH was measured using a pH meter (Oakton® pH 700 Benchtop). The pH meter was calibrated with a standard buffer solution of pH 1, 4, and 7 prior to the pH determination.

Free acidity

Free acidity was performed according to AOAC Official method 962.19 (2005) [36]. The titrimetric method was used to determine the free acidity of the honey sample. One gram of honey sample was dissolved in 7.5 mL of distilled water. Then, the solution was titrated with 0.1 M NaOH until the pH reached 8.0, and the amount of NaOH used was recorded. Free acidity was expressed as milliequivalent acid per kg of honey (meq/kg).

Ash content

Ash content was measured according to AOAC methods 920.181 (2006) [37]. The crucible was washed with 10% concentrated HCl, rinsed with distilled water, and dried in an oven at 100 ^{o}C for one hour. Then, the crucible was cooled down to room temperature and weighed. Next, 2.5 g of honey sample was weighed in the crucible and heated at 500 ^{o}C in the furnace for two hours. The sample was then cooled and reweighed. The ash content was calculated using the formula below:

$$\text{Ash content (\%)} = (Z - X / Y - X) \times 100 \quad (1)$$

Where X is a weight of empty crucible in g, Y is a sample before ashing + weight of crucible in g, and Z is a after complete ashing, weight of crucible + ash in g

Total dissolved solids

The total dissolved solids were determined by weighing 5 g of honey sample and diluted with 50 mL of distilled water, and measured using conductometer.

Antioxidant property

The Folin-Ciocalteu method based on Gul and Pehlivan [38] was used to determine the total phenolic compound (TPC). Briefly, 1 g of honey sample was dissolved in 5 mL methanol and filtered through Whatman No 1 filter paper. Forty microliter of this solution was mixed with 2.4 mL of ultrapure water and 200 μL of non-diluted Folin-Ciocalteu reagents for three minutes. Then, 0.6 mL of Na_2CO_3 (20%) was added to this mixture, and the mixture was incubated in the dark for two hours at room temperature. The incubated samples were used for TPC determination by using UV-Vis spectrometer. Ultrapure water was used as a blank and reference in UV-Vis analysis. Each sample was scanned at a wavelength of 244.4 nm for one minute. Gallic acid (100-1,000 mg/L) was used to plot a standard calibration curve. The maximum absorbance of the samples and the gallic acid

standards were determined through scanning at a range of 200 nm to 1,100 nm. The TPC was expressed as mg gallic acid equivalents (GAE) per 100 g of honey and calculated using the equation below:

$$\text{TPC (mg } GAE/100g) = \frac{C_{GA}\ x\ V\ x\ DF}{weight\ of\ honey\ sample\ (g)} \quad (2)$$

Where C_{GA} is the concentration of gallic acid from the curve (mg/L), V is the volume of honey sample solution (L), and DF is the dilution factor.

The evaluation of physicochemical profile (pH, free acidity, ash content, TDS, 5-HMF), multi-elemental composition, and antioxidant property were carried out in triplicates.

Instrumentation: UV-Vis spectrophotometer

Lambda 35 UV-Vis Spectrometer used for the TPC determination was from PerkinElmer (Singapore). Oakton® pH 700 Benchtop (USA) pH meter was used to evaluate free acidity and pH measurement. Alpha 800 conductometer was used for the determination of total dissolved solid, while WiseTherm furnace was used for the determination of ash content.

High performance liquid chromatography

Quantitative analysis of 5-HMF was carried out using HPLC unit (Shimadzu, Tokyo, Japan) consisting of a pump (LC-10AT), UV-Vis detector (SPD 10A), injector, and 20 µL sample loops. The HPLC analytical column was an Inertsil ODS C18 column (150 mm, 4.6 mm i.d., 10 µm particle size). Isocratic elution was performed using methanol-water (10:90, v/v) at a flow rate of 1 mL/min and the detector was monitored at a wavelength of 285 nm. The injection volume was 20 µL. The 5-HMF concentrations in the honey samples were calculated by comparing the peak area with the standard solutions after correcting the dilution of the honey samples.

ICP-OES

The ICP-OES used was an Axial Viewed Perkin Elmer Optima 8000 ICP-OES equipped with a Meinherd nebulizer, a cyclonic spray chamber, and ICP Winlab software data system.

HPLC instrumental validation

The instrumental validation (linear range, linearity, precision, limit of detection and quantification, and recovery) in this study is based on the ICH Guidelines [39].

Results and Discussion

HPLC instrumental validation

The instrumental validation for the analysis 5-HMF using HPLC was performed by determining the linear range, linearity, precision, limit of detection (LOD), limit of quantification (LOQ), and recovery. The results are summarized in Table 3.

Table 3. Analytical characteristics of the HPLC method

Parameter	Value
Linear range (mg/L)	0.05-50
Linear equation	y = 493900x + 370074
Correlation coefficient (R^2)	0.9992
Limit of detection (LOD) (µg/L)	0.32
Limit of quantification (LOQ) (µg/L)	0.96
Intra-day precision (% RSD)	0.05-2.70
Inter-day precision (% RSD)	1.38-3.97
Recovery (%)	96.8-99.4

Linear range and linearity

The linearity of the calibration curve of 5-HMF was determined by injecting five standard solution concentrations in the range of 0.05 mg/L to 50 mg/L. The linear regression was obtained by plotting the peak area against the concentration of standard solutions. Good linearity with R^2 of 0.9992 was obtained between the peak area and analyte concentrations.

Precision

The precision of the method was assessed by injecting five times each of the standard solutions (0.05, 5, and 50 mg/L) on the same day (intra-day) and over seven days (inter-day), respectively. Good precision of both intra-day (0.05 to 2.70%) and inter-day (1.38 to 3.97%) was found.

Limit of detection and quantification

The LOD and LOQ values were calculated by dividing the standard deviation of the lowest concentration of 5-HMF (0.05 mg/L) to the slope of regression equation and multiplying the result by 3 and 9, respectively. The LOD and LOQ for 5-HMF were 0.32 mg/L and 0.96 mg/L, respectively.

Recovery

Recovery studies were carried out by spiking two concentrations (0.05 and 5 mg/L) of 5-HMF standards to the honey samples. The data obtained were compared with the blank sample, and the percent recoveries were calculated for both spiked samples. Satisfactory recoveries were obtained (96.8-99.4%).

ICP-OES instrumental validation

The instrumental validation for multi-element analysis using ICP-OES was performed by determining the R^2 of the calibration curve, LOD, and LOQ. Results are summarized in Table 4.

Table 4. Analytical characteristics of the ICP-OES

Element	Range of Calibration Curve (mg/L)	Correlation Coefficient (R^2)	LOD (mg/L)	LOQ (mg/L)
Ca	1-5	0.9996	0.03	0.10
Cd	1-5	0.9991	0.01	0.03
Cr	1-5	0.9990	0.04	0.11
Cu	1-5	0.9998	0.05	0.16
Fe	1-5	0.9993	0.02	0.06
Mg	1-5	0.9992	0.02	0.06
Ni	1-5	0.9994	0.03	0.09
Pb	1-5	0.9996	0.02	0.05
Zn	1-5	0.9993	0.01	0.02
As	1-5	0.9993	0.02	0.07
Mn	1-5	0.9993	0.02	0.07
Al	1-5	0.9820	0.13	0.39
K	5-25	0.9983	0.20	0.59
Na	0.5-2.5	0.9977	0.02	0.05
Ba	0.5-2.5	0.9962	0.01	0.02

Linearity

The linearity of the ICP-OES analysis was determined by injecting five standard concentrations as stated in Table 4. The linear regression of multi-element was obtained by plotting the mean intensity of standard solutions against the concentration of standard solutions. All elements have good linearity with R^2 between 0.9820-0.9998.

Limit of detection and quantification

The LODs and LOQs for all elements were in the range of 0.01 to 0.20 mg/L and 0.02 to 0.59 mg/L, respectively.

Physicochemical properties of stingless bee honey

Table 5 shows the results of the selected physicochemical property of pH, free acidity, ash content, and total dissolved solids. All the measurements were determined in triplicates.

Table 5. Physicochemical properties of the stingless bee honey

Sample	pH	Free Acidity (meq/kg)	Ash Content (g/100g)	Total Dissolved Solid (ppm)	TPC (mg GAE/100 g)

pH analysis

All of the honey samples analyzed in this study were found to be acidic with a range of 3.01 to 3.43 (Table 5). The range of the pH was compliant with the Malaysian Standards for stingless bee honey (pH 2.5-3.8). The pH values obtained from the current study were almost similar to the finding of other regions in Malaysia (pH 2.92-3.71) (Table 6). However, based on the previous study by Selvaraju et al. [40], they found a sample in Penang that has a pH (pH 4.03) higher than the maximum value stated by the Malaysian Standards. The findings proved that despite the different geographical and

botanical sources of the honey samples, their pH was almost within the same range and had no significant difference ($p > 0.05$). This was confirmed by running the pH reading of 20 samples in One-Way ANOVA Test, and the p-value was 0.4028. The result might suggest that stingless bee honey has a similar range of pH regardless of their origin [11]. As reported by Moniruzzaman et al. [41], the high acidity of the honey is caused by the fermentation of sugar into organic acid, which is responsible for honey flavor and stability against microbial spoilage. A low pH value also indicates that the stingless bee honey is more acidic and has more hydrogen ions, which are involved in the formation of other compounds in the honey [11].

Table 6. Physicochemical properties of stingless bee honey produced by *Heterotrigona itama* at different regions in Malaysia

Free acidity

The free acidity of the honey samples was ranged from 65.42 to 184.66 meq/kg (Table 5). The values detected were in a similar range with the previous studies from other regions in Malaysia (Table 6), except for the sample studied by Shamsudin et al. [5] and Zawawi et al. [48] which contained a relatively higher free acidity value (246.3 and 336.2 meq/kg, respectively). The Malaysian Standards did not set a limit for the free acidity in stingless bee honey. Based on the Codex Alimentarius, the free acidity of honey shall not exceed 50 meq/kg. The free acidity of the samples studied were significantly high and did not comply with the Codex standard of honey. Free acidity is a quality parameter related to honey fermentation of sugars to organic acids which depends on the nectar of different floras [43, 49, 50]. Therefore, it can be concluded that the high fermentation of sugars creates the organic acids in the stingless bee honey.

Ash content

The ash content is depending on the amount of minerals present in the honey. The higher the value of ash content, the greater the amount of mineral present in the nectar. The percentage of the ash was measured based on the remaining inorganic residue found after the incineration of the honey sample [46]. The ash content obtained from this study was between 0.07 and 0.61 g/100g. However, analysis on samples 16 to 20 have not carried out due to the constraint of instruments. Nonetheless, for samples 1 to 15, the ash content obtained was aligned with the Malaysian Standards (max 1.0 g/100g). The values were also similar to the previous studies from other regions in Malaysia (0.08-0.47 g/100g) (Table 6) which also complied with the Malaysian Standards.

Total dissolved solids

The total dissolved solids are related to the moisture and sugar content in the honey. In general, honey with high total dissolved solids possesses high sugar content and low moisture content [5]. The total dissolved solids from this study were in the range of 258.83 to 365.67 ppm, except for sample 2 which had a very high value (519.83 ppm). The high value of total dissolved solids of sample 2 is probably due to the high content of organic and inorganic substances, mainly sugars such as glucose and fructose [51]. In other words, the probability of the honey being adulterated with syrup or honeybees which have been fed with sugar syrup is high. From the previous studies, only Moniruzzaman et al. [51] reported the total dissolved solids of Malaysian stingless bee honeys in ppm unit, whereas Shamsudin et al. [5] and Ng et al. [52] reported the total dissolved solids in percent °Brix. In order to record the total dissolved solids in percent °Brix, a digital refractometer is used. The total dissolved solids of Malaysian stingless bee honey from Moniruzzaman et al. [51] ranged from 138.00 to 395.00 ppm.

TPC analysis

The gallic standard solutions and all the samples were scanned from the wavelength of 200 nm to 1100 nm by using UV-Vis spectrometer in order to determine the maximum absorbance. The maximum wavelength was roughly scanned at 244.4 nm for the standard solutions and the sample solutions against the blank solution.

From Table 5, the TPC values varied from 95.0 mg GAE/100 g to 364.9 mg GAE/100 g. The highest TPC was found in sample 16, while the lowest TPC was found in sample 11. However, the TPC found by Abu Bakar et al. [29] (Table 6) showed higher TPC values which were between 357.14 and 520.83 mg GAE/100 g. As the TPC assay is able to identify the total amount of phenolic content in the samples, a high TPC value indicates a greater amount of phenolic content. When the amount of phenolic content of honey is greater, then honey will have better redox properties which leads to higher antioxidant activity.

Analysis of 5-HMF

The concentration of 5-HMF in the honey samples was quantified based on the external standard method using the calibration curve. The standard calibration curve of 5-HMF was constructed using four different concentrations which included 0.05, 1, 10, 50 mg/L of the standard solutions. The baseline separation for 5-HMF was achieved in less than four minutes under the stated experimental conditions.

5-HMF is known as the best indicator for the freshness and quality of the honey which provides information on

degradation, adulteration, and deterioration of the honey [53]. The honey samples used in this study were obtained freshly from the local beekeepers in Kedah and Penang, Malaysia in December 2019. The concentration of 5-HMF present in the fresh honey samples was analyzed after receiving the honey samples from the beekeepers. From the analysis, only honey sample 10 contained a very low concentration (0.31 ± 0.01 mg/kg) of 5-HMF, while the other 19 honey samples were not detected (Table 7). The results obtained from the previous study by our research group are congruent with other studies of different regions and countries where the 5-HMF was not detected or present in a very little amount in fresh stingless bee honey samples (Table 8).

To investigate the consequence of prolonged storage on the concentration of 5-HMF, the honey samples were stored for six months in the dark at room temperature. The honey samples were kept at room temperature to stimulate the common practice that honey is normally stored at room temperature. Besides, the honey samples were stored in the dark in order to prevent excess heat from sunlight; otherwise, the temperature of the honey samples would increase when exposed to sunlight. The increase in temperature of the honey samples would lead to an escalation in the concentration of 5-HMF which will affect the results of the study [54]. After storage for six months, the honey samples were analyzed in July 2020, and the concentrations of 5-HMF were found to have increased to the range of 48.18 ± 1.11 to 192.99 ± 10.39 mg/kg (Table 7). These values exceeded the maximum allowed limit of both Codex Alimentarius Standard (80 mg/kg) and the Malaysian Standard (30 mg/kg). Sample 6 showed a significantly higher concentration of 5-HMF, which might have been influence by the floral source of the honey [53].

Table 7. Concentrations of 5-HMF in honey samples of fresh and different storage durations

Sample	Concentration of 5-HMF (mg/kg)		
	December 2019 (Fresh)	**July 2020 (6 months storage)**	**May 2021 (15 months storage)**
1	N.D.	70.84 ± 0.23	65.10 ± 3.11
2	N.D.	56.20 ± 0.06	38.71 ± 0.91
3	N.D.	49.95 ± 2.13	45.98 ± 1.41
4	N.D.	52.26 ± 0.68	62.45 ± 0.74

The honey samples were then kept for another nine months in the dark at room temperature in order to study the consequence of prolonged storage on the concentration of 5-HMF. The honey samples were analyzed in May 2021, and the results obtained are presented in Table 9. It was observed that all the honey samples contained a high concentration of 5-HMF. The concentration of 5-HMF present in the honey samples were ranging from 38.71 ± 0.91 to 214.38 ± 4.03 mg/kg. This situation shows that the honey samples have violated the allowed limit for the concentration of 5-HMF in the Malaysian Standard and Codex Alimentarius Standard. Thus, this indicates that the honey samples have deteriorated.

Malaysia is a tropical country where the climate is warm and humid all year round [66]. Thus, the concentration of 5-HMF in the honey originating from Malaysia should not exceed 80 mg/kg according to the Codex Alimentarius Standard. The results demonstrate that all the honey samples were within the maximum allowed limit of 5-HMF established by the Codex Alimentarius Standard, except for honey samples 6, 13, 15, 16, 17, and 20. Therefore, this indicates that honey samples 6, 13, 15, 16, 17, and 20 have deteriorated after prolonged storage of another nine months and are not suitable to be consumed.

On the other hand, it was found that the 5-HMF concentration in the honey samples determined in May 2021 fluctuated as compared to the honey samples determined in July 2020. It was noticed that the 5-HMF concentration in some of the honey samples increased, while some decreased. The concentration of 5-HMF increased for honey samples 4, 5, 6, 7, 12, 13, 14, 15, 16, 17, and 20 after prolonged storage. The escalation in the concentration of 5-HMF in the honey samples after prolonged storage is consistent with other earlier studies [54, 58].

The escalation in the concentration of 5-HMF in the honey samples is due to the degradation of the glucose

and fructose under acidic conditions [67, 68]. The longer the duration of storage for the honey samples, the more glucose and fructose are converted to 5-HMF, as stingless bee honey is acidic in nature. Hence, this situation would lead to a higher concentration of 5-HMF [33]. The high concentration of 5-HMF in the honey samples indicates that the honey samples degraded due to prolonged storage. As a result, the high concentration of 5-HMF in the honey samples would decrease the commercial value of the honey.

For honey samples 1, 2, 3, 8, 9, 10, 11, 18, and 19, it was found that the concentration of 5-HMF decreased after prolonged storage. However, large decrease in the concentration of 5-HMF was noticed for honey samples 11 and 19. The concentration of 5-HMF decreased to half when compared with the value quantified in July 2020. The concentration of 5-HMF's decrease in the honey samples could be due to the augmentation of complex processes which favor the decomposition of 5-HMF, whereby it will reduce the formation of 5-HMF [69].

Besides, the concentration of 5-HMF's decrease in the honey samples could also be due to the decomposition of 5-HMF from other products in the diluted honey samples, specifically for the diluted honey samples stored at room temperature. This is proven by the study of Wunderlin et al. [70] whereby the decrease in the 5-HMF band at 284 nm had a simultaneous increase of a new band at 252 nm. Thus, they suggested that the sample solutions containing 5-HMF should be stored in the dark at temperatures ranging from 4 to 8 °C before the sample solutions are analysed. Wunderlin et al. [70] also suggested that the analysis of 5-HMF should be made within six hours after sample preparation in order to prevent the decomposition of 5-HMF in sample solutions.

Furthermore, fructose is known to have a protective effect on the decomposition of 5-HMF [70]. The decomposition of 5-HMF is significant in honey samples without fructose. Therefore, the decrease in 5-HMF observed in a few honey samples in this study could be explained by the lesser amount of fructose in the honey samples which reduces the protective effect of fructose on the decomposition of 5-HMF. This eventually led to the decomposition of 5-HMF in the honey samples. As observed in this study, the 5-HMF concentration in some of the honey samples reduced after prolonged storage in the dark at room temperature for another nine months.

Multi-elemental composition

For the multi-elemental analysis, it was found that the highest concentration of elements was potassium (Table 9). Sample 2 exhibited a very high concentration of potassium (1,623.75 mg/kg), while sample 6 exhibited a very low concentration of potassium (16.13 mg/kg). By excluding these two samples, the average concentration range of potassium was 255.40 mg/kg to 915.50 mg/kg. Calcium, sodium, and aluminum were present in moderate concentrations in the honey with an average concentration range of 36.23 to 272.5 mg/kg, 31.25 to 148.25 mg/kg, and 25.35 to 62.25 mg/kg, respectively. For magnesium, the average range of concentration was 11.14 to 78.38 mg/kg, excluding one sample from Penang (sample 2) that had a relatively high concentration (179.75 mg/kg).

20	255.40 ± 0.06	47.75 ± 0.03	25.35 ± 0.01	78.95 ± 0.04	22.00 ± 0.01	< 0.02

Elements found in low concentrations were iron (< 0.02 to 41.55 mg/kg), copper (< 0.05 to 23.15 mg/kg), manganese (< 0.02 to 13.85 mg/kg), and zinc (< 0.01 to 4.63 mg/kg) (Table 10). The concentration of heavy metals such as arsenic, lead, nickel, barium, cadmium, and chromium were found lower than the LODs values (Table 4). The differences in the multi-element concentrations of the same honey species collected from different locations might be due to the type of soil in which the nectar of the flower was located [71].

Our findings for this species were similar to the values from the study performed by Abu Bakar et al. [29] in Melaka and Johor. The concentrations found for potassium, calcium, magnesium, and zinc were 236.33 to 701.33 mg/kg, 51.83 to 292.67 mg/kg, 18.53 to 50.30 mg/kg, and 4.37 to 5.33 mg/kg, respectively. Another study by Cheng et al. [72] in Selangor, Johor, Terengganu, and Sabah found that the concentrations of potassium, sodium, calcium, magnesium, iron, and zinc were 484.11 mg/L to 761.22 mg/L, 381.47 mg/L to 589.46 mg/L, 141.22 mg/L to 205.98 mg/L, 14.56 mg/L to 41.06 mg/L, 5.98 mg/L to 7.81 mg/L, and 1.02 mg/L to 3.03 mg/L, respectively. They also found that the concentrations of arsenic, lead, and cadmium were below the LODs.

From this study, the highest concentration of potassium was 1623.75 mg/L and the lowest was 16.13 mg/L. The daily recommended intake (Recommended Daily Allowance, RDA) of calcium is based on age, sex, and physio-pathological conditions, generally ranging from 1,000 to 1,200 mg [73]. The World Health Organization (WHO) recommends a potassium daily intake of more than 3,500 mg and a sodium daily intake of less than 2,000 mg [74]. The concentration obtained for these three elements was below the maximum daily intake, therefore it is safe for daily consumption for nutritional values. The concentration of the toxic elements was below the LOD. In terms of food safety, the multi-elemental profile, especially on the toxic elements in the honeys, gave information on the environmental conditions of the harvesting region. Based on the results obtained, our study indicated that there is neither contamination nor environmental pollution in the studied areas.

Conclusion

In this study, the Malaysian stingless bee honey which originated from a particular bee species (*Heterotrigona itama*) from the northern region of Malaysia (Kedah and Penang) was successfully investigated for its physicochemical profile, multi-elemental composition, and antioxidant activity. The antioxidant activity of honey was studied by evaluating their TPC. The pH, free acidity, ash content, total dissolved solids, minerals, and TPC were studied for the fresh honey samples only; whereas the 5-HMF content was investigated for fresh samples, after 6 and 15 months. The findings of ash content, pH, and TPC of all the honey samples were compliant with the advised limit set by Malaysian Standards and previous studies. The free acidity of all the samples and total dissolved solids of sample 2 exceeded the permitted range. The concentration of minerals was observed that their concentration is below the advised daily intake. At the same time, it was observed that the concentration of toxic elements is below the LOD; thus, it is safe to consume these honey samples. The 5-HMF content of all the fresh honey samples was not detected, except sample 10 (0.32 mg/kg). Although 5-HMF was detected in fresh sample 10, it is still low and within the permitted range by Malaysian Standards. Unfortunately, the 5-HMF content of all the honey samples (after 6 and 15 months) exceeded the permitted range. Therefore, it is advised to consume the honey in less than six months. Alternatively, a new study regarding the 5-HMF content of honey samples stored at 4 °C (refrigerator) for different storage periods has to be carried out in order to visualize the change pattern of 5-HMF content in honey. Additionally, the new study has to include the influence of storage period on the physicochemical profile and antioxidant activity of honey, so that the correlation of the parameters can be studied too.

Abstract

Depletion of non-renewable energy sources such as petroleum has triggered researchers to design a green catalyst for the synthesis of biodiesel. Thus, in this study, chicken bones were subjected to calcination-hydration-dehydration treatment to obtain a catalyst of high activity for the production of biodiesel from waste cooking oil (WCO). The physicochemical properties of the synthesized catalysts were analyzed by Fourier Transform Infrared Spectroscopy (FTIR) and N_2 adsorption-desorption. The catalyst prepared via calcination-hydration-dehydration treatment (C900-600) exhibited improved surface area (SBET, 71.14 m^2g^{-1}) and BJH pore diameter of 31.03 nm, in comparison with chicken bone derived catalyst calcined at 900 ˚C (C900) and commercial CaO with 31.72 m^2g^{-1}, 29.35 nm and 2.21 m^2g^{-1}, 15.98 nm, respectively. After 45 min, the activity of 5 wt.% catalysts in the transesterification of WCO with 1:15 oil to methanol ratio at 65 °C, increased as the following trend: C900-600 (92.15%) > C900 (80.63%) > commercial CaO (73.30%). C900-600 was truly a stable and reused catalyst, sustaining its activity of 87.00% even after five consecutive cycles. This research undoubtedly promises a cheap utilization of waste chicken bones for the conversion of WCO into renewable energy sources.

Keywords: waste chicken bones, biodiesel, waste cooking oil, acid value, reusability

Abstrak

Kekurangan sumber tenaga yang tidak boleh diperbaharui seperti petroleum telah mendorong para penyelidik untuk menghasilkan mangkin hijau untuk sintesis biodiesel. Maka, dalam penyelidikan ini, sisa tulang ayam telah dirawat menggunakan kalsinasi-hidrasi-dehidrasi untuk menghasilkan mangkin yang aktif dalam penghasilan biodiesel dari minyak masak terpakai. Ciri fizikokimia mangkin telah dianalisis menggunakan Spektroskopi Inframerah Transformasi Fourier (FTIR) dan N_2 penjerapan-penyahjerapan. Mangkin yang disediakan menggunakan rawatan kalsinasi-hidrasi-dehidrasi (C900-600)menunjukkan peningkatan luas permukaan BET (SBET, 71.14 m^2g^{-1}) dan diameter liang BJH; 31.03 nm, dibandingkan dengan mangkin dari sisa tulang ayam yang dikalsinasi pada suhu 900 ˚C (C900) dan CaO komersial dengan masing-masing merekodkan 31.72 m^2g^{-1}, 29.35 nm dan 2.21 m^2g^{-1}, 15.98 nm. Selepas 45 min, aktiviti mangkin (5% berat) dalam transesterifikasi minyak masak terpakai dengan nisbah minyak dan metanol 1:15 pada 65 °C meningkat berdasarkan tren berikut: C900-600 (92.15%)> C900 (80.63%)> CaO komersial (73.30%). C900-600 merupakan mangkin yang stabil dan boleh digunapakai, mengekalkan aktivitinya sebanyak 87.00% walaupun

setelah lima kekerapan dikitar semula. Penyelidikan ini pasti menjanjikan penggunaan sisa tulang ayam yang murah untuk penukaran minyak masak terpakai menjadi sumber tenaga yang boleh diperbaharui.

Kata kunci: sisa tulang ayam, biodiesel, minyak masak terpakai, nilai asid, kitar semula

Introduction

Growing depletion of non-renewable reserves, sickening environmental issues, and health concerns arising from petroleum-based diesel has positioned biodiesel as an alternative green energy fuel owing to its remarkable properties such as cleaner emission, non-hazard, and offers rapid biodegradability [1]. In biodiesel synthesis, feedstock contributes to 70% to 95% of the overall production cost [2]. This worrying situation draws the attention of global researches to utilise relatively cheap and easily available non-edible oil such as waste cooking oil (WCO). Asian countries, including Malaysia, produce nearly 40,000 tonnes of WCO per annum [3] and it is usually collected from households, fried food outlets, and restaurants [4]. Biodiesel price could be significantly reduced to 50% upon converting WCO into biodiesel [5] and this appears as the best practice to recycle WCO, which will otherwise end-up in palatable water and pose a substantial threat to the environment.

Nowadays, turning waste materials into a catalyst is the most viable way to address the production of biodiesel at a commercial scale. Solid base catalysts involving natural wastes, such as egg shell [6-9], chicken bone [2,10], fusion chicken and fish bone [11], ostrich bone [12], and scallop shell [13], are some of the potential CaO sources for transesterification reaction. For example, Borah et al. [9] have synthesised biodiesel from WCO using Zn doped egg shell derived CaO nanocatalyst that registered a maximum FAME yield of 96.74% after 4 h reaction. Nevertheless, great loss in the activity during the fifth recycle (64.49%) was reported, probably resulting from the leached active Zn species into the reaction medium. Similarly, a longer reaction duration of 5 h was required to reach 100% biodiesel yield over egg shell derived catalyst in the transesterification of WCO [6]. In another work, Dehkordi and Ghasemi [14] demonstrated excellent activity of ZrO_2 CaO in catalysing WCO into 92.1% biodiesel at only 2 h. However, the catalysis requires large catalyst dosage of 10 wt.% and 30 mole excess of methanol. Waste oyster shell employed as a sustainable base heterogeneous catalyst, yielded 87.3% of FAME after 3 h reaction in the presence of 9:1 methanol/WCO molar ratio and 6 wt.% catalyst [15]. However, no reusability study was reported in this work.

Malaysians consume nearly 50 kg of chicken per capita per year, making it rank first and third in Asia and in the world, respectively [16]. With this huge production, large numbers of chicken by-products such as chicken bone are generated and dumped in landfills, ending in poor solid waste management. Chicken bones are made up of organic and inorganic components with 65% (hydroxyapatite), 25 wt.% of protein, and the remaining % of water [17]. They have a high potential to be converted into a value-added product such as CaO based catalyst. However, very scarce studies were focused on chicken bone as a catalyst for biodiesel synthesis. For example, in 2015, Farooq et al. [2] discovered the efficiency of chicken bone as a base catalyst in the triglyceride conversion of WCO and registered a maximum biodiesel yield of 89.33% at optimised reaction conditions of 4 h, methanol to oil molar ratio of 15:1, reaction temperature of 65 °C, and 5 wt.% of catalyst loading.

The performance of Fe impregnated CaO derived chicken bone catalyst was documented by Hantoro Satraidi et al. [18]. The catalyst afforded a biodiesel yield of 22% after 3 h reaction time, with 6:1 of methanol:WCO. In a recent study by AlSharifi and Znad [10], lithium based chicken bone composite converted 96.6% of canola oil into biodiesel after 3 h. In this regard, the world's biodiesel present demand has triggered the search for an active heterogeneous catalyst that offers high yield and excellent properties. As such, in this present work, waste chicken bone was subjected to the calcination-hydration-dehydration technique to enhance the surface area that apparently affects the biodiesel yield. Little literature has shown the importance of the calcination-hydration-dehydration route. For example, CaO derived waste clamshell

prepared via calcination-hydration-dehydration treatment resulted in an enhanced surface area and basicity that greatly affected the biodiesel production from WCO [19]. Similarly, Niju and co-workers [7] reported an improved catalysis of egg shell based CaO catalyst synthesised by the calcination-hydration-dehydration route in the biodiesel synthesis (94.52%) from waste frying oil compared with commercial CaO that gave only 67.57%.

Hence, a lack of publication on the synthesis of CaO derived waste chicken bone catalyst by calcination-hydration-dehydration has encouraged us to prepare a preliminary characterisation of the catalyst using Fourier Transform Infrared Spectroscopy (FTIR) and N_2 sorption analysis. The catalysts were further evaluated in the synthesis of biodiesel from WCO and promised a green conversion of waste materials into value-added products.

Materials and Methods

Raw materials and reagents

The chicken bones and waste cooking oil (WCO) were collected from the cafeteria in Universiti Teknologi MARA (UiTM) Perlis, Malaysia. The chemicals used were CaO (HmbG), 99% anhydrous methanol (HmbG), 98% H_2SO_4 (QREC), sodium sulphate, potassium hydroxide (HmbG chemical), toluene (QREC Asia), phenolphthalein indicator (HmbG), and *n*-hexane (QREC). All the chemicals were used as procured.

Preparation of chicken bone

300 g of waste chicken bones were weighed and boiled in water for 1 h to remove adhering excess tissue and fats. Later, the boiled bones were thoroughly washed with copious amount of water to eliminate meat and other soft tissues [20], and allowed to dry at 110 ℃ for 2 h. The dried bones were crushed into small pieces and subsequently ground using a hammer mill into powder of < 2 mm particle size [21]. Finally, the sample was stored in a closed container to prevent moisture content changes.

Preparation of C900 and C900-600 catalyst

100 g of the powdered sample was placed in a crucible and heated at 900 ℃ for 4 h to obtain hydroxyapatites (HAP). The sample was designated as C900. To prepare C900-600, C900 was refluxed in water at 60 ℃ for 6 h and subsequently filtered and oven dried at 120 ℃ for 24 h [22]. Later, calcination was performed at 600 ℃ for 3 h. This stage allows the conversion of the hydroxide form into an oxide form [22]. For comparison, the commercial CaO catalyst was used.

Catalyst characterisation

The FTIR spectra of the catalysts were collected on a Thermo Electron Corporation Nicolet 380 spectrophotometer at wavenumber ranging from 4000 to 400 cm^{-1} with a resolution of 5 cm^{-1}. In prior analysis, the pellet was prepared with 1:10 w/w KBr:Sample. The surface area (S_{BET}) and BJH pore size distribution were obtained by means of N_2 adsorption-desorption (Micromeritics Instrument Corporation model ASAP 2000) after degassing for 12 h.

Treatment of WCO

The collected WCO was filtered to remove food residues and washed with hot distilled water. Later, it was treated with anhydrous Na_2SO_4 to remove any water content. The molecular weight of fatty acid in oil was determined by GC/MS (Agilent Technologies 6980N).

Acid value (AV) and free fatty acid (FFA) determination

Acid number refers to the quantity of KOH required to titrate 1 g of FFA in sample to its neutral point [23]. The acid number was evaluated according to standard testing procedure ASTM D664 as reported by Corro et al. [24] Briefly, 3 g of WCO was dissolved in 150 mL containing an equal volume of toluene and isopropanol. Then, 1to 2 drops of phenolphthalein were added into the prepared solution and titrated with 0.1 N KOH solution until the colour changed from light yellow to pink. The AV and FFA for feedstock and esterification product were determined as in equations (1) and (2), respectively.

$$Acid\ value\ (AV)\ =\ 56.1\ x\ \frac{M(A-B)}{W} \quad (1)$$

$$FFA\ (\%\ as\ palmitic)\ =\ \frac{A\ x\ M\ x\ 25.6}{W} \quad (2)$$

where M - KOH Concentration (N), A – Volume of KOH

volume required to reach the neutral point (mL), *B* - the volume corresponding to the blank titration (mL), and *W* - Sample weight (g).

Catalytic transesterification and biodiesel production

A two-step transesterification reaction consisting of acid transesterification to reduce the FFA content followed by base transesterification was carried out. Acid transesterification was done following the method by Tan et al. [25], however, with slight modification. In brief, WCO was heated to 110 ℃ overnight to reduce the viscosity. In a 250 mL flask, 50 mL of methanol and 0.1 mL concentrated H_2SO_4 were stirred; and later, 100 mL WCO (preheated at 65 ℃) was transferred and the mixture was stirred at 65 ℃ for 1 h.

Base transesterification and FAME analysis

In a typical run, 5 wt.% of catalyst was added into a three-neck round bottom flask containing 1:15 Oil/MeOH and equipped with a condenser. The reaction was performed at 65 ℃ with continuous stirring (250 rpm) for 1 h. Afterwards, the pre-treated WCO was transferred into the round bottom flask and the reaction was continued for 45 min. Later, the catalyst was filtered off and the reaction mixture containing biodiesel and glycerol at the upper and lower layer, respectively, was allowed to stand in a separating funnel for 24 h, with prior washing using hot distilled water. The water content in biodiesel phase was removed with sodium sulphate. Product composition in biodiesel was identified by GC/MS (Agilent Technologies 6890N, carrier gas: He) with the following temperature program: initial oven temperature of 383 K; ramp of 283 K/min, holding time of 2 min; intermediate temperature of 473 K; final ramp of 278 K/min; and final temperature of 553 K for 9 min. The % conversion was calculated based on equation (3) [24].

$$\%\ Conversion\ = \frac{AV1-AV2}{AV1}\ x\ 100\% \quad (3)$$

where, *AV1*–acid value of raw materials, *AV2*–acid value of transesterification product

Catalyst reusability

Upon completion of each experiment, the spent catalyst was separated from the reaction mixture by centrifugation and washed with *n*-hexane and subsequently subjected to heating at 600 ˚C for 2 h [2]. The recovered catalyst was reused in the transesterification reaction at similar reaction conditions for five consecutive runs.

Results and Discussion

FTIR spectral studies

The FTIR spectra of uncalcined chicken bone, C900, and C900-600 are compared in Figure 1. Broad band at ~ 3419 to 3438 cm^{-1} for all the samples represents the stretching vibration of the hydroxyl group (OH) on the surface, which is often associated with the -OH group of $Ca(OH)_2$ [25].

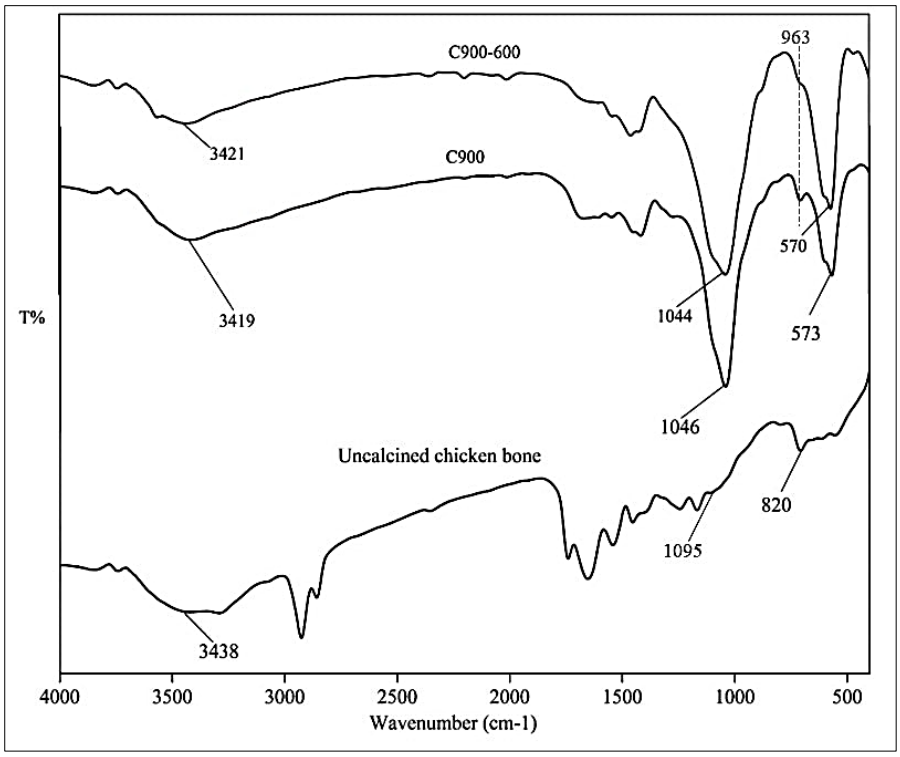

Figure 1. FTIR spectra of the samples

However, the interesting observation to be noted from Figure 1 is the existence of sharp peaks at 1044 to 1095 cm^{-1} and 570 to 573 cm^{-1} for both C900 and C900-600 that evidenced the presence of PO_4^{3-} group, and reflects the O-P-O bonds in calcium phosphate [21]. In addition, the shoulder peak at ~963 cm^{-1} for C900 and C900-600 belongs to PO_4^{3-} that resembles asymmetric stretching vibrations of P–O [24]. According to Corro et al. [24], the peaks at ~3400, 1036 to 1091, and 956 cm^{-1} evidenced the characteristic peaks of hydroxyapatite, which are undoubtedly shown by the calcined samples. Notably, the peaks are more intense for C900-600 compared with C900. This resembles the effectiveness of hydration-dehydration treatment on the chicken bone sample. On the contrary, the IR pattern of uncalcined chicken bone is almost similar to the spectra reported for uncalcined egg shell by Tan et al. [25]. In addition, the shoulder band detected at 820 cm^{-1} for the uncalcined chicken bone is due to CO_3^{2-} [21] and similar vibrations appeared at 1400 to 1500cm^{-1} for all the samples [26].

Textural properties

The S_{BET} and BJH pore diameter of C900-600, C900, and commercial CaO measured from N_2 adsorption-desorption analysis are summarised in Table 1.

Table 1. S_{BET} and BJH pore diameter of C900-600, C900, and commercial CaO

Sample	S_{BET} (m^2/g)	BJH pore diameter (nm)
C900-600	71.14	31.03
C900	31.72	29.35
Commercial CaO	2.21	15.98

According to IUPAC classification, the pore diameters of the synthesised catalysts are classified as mesopores (2 to 50 nm) and accordingly, mesoporous material is most suitable to be used as a catalyst since it allows the diffusion of larger molecules or reactants compared with micropores. It is worth reporting the higher S_{BET} and BJH pore diameter of C900-600 and C900 catalysts than the commercial CaO. To add, the synthesised catalysts in the present work showed greater S_{BET} than the lithium-based chicken bone catalyst prepared by AlSharfi and Znad [10]. The hydration-dehydration treatment significantly improved the surface area and pore diameter of the C900-600 catalyst as shown in Table 1. During dehydration, the removal of attached water molecules from the catalyst lattice might have led to a higher surface area by breaking the crystallite into smaller sizes.

N_2 adsorption-desorption isotherms of the catalysts are compared in Figure 2. Both C900 and C900-600 exhibited Type IV characteristics of mesoporous materials with H1 hysteresis loops, often associated with uniform pores. On contrary, commercial CaO showed a sigmoid type with almost no closure at $P/P_o = 0$ [27].

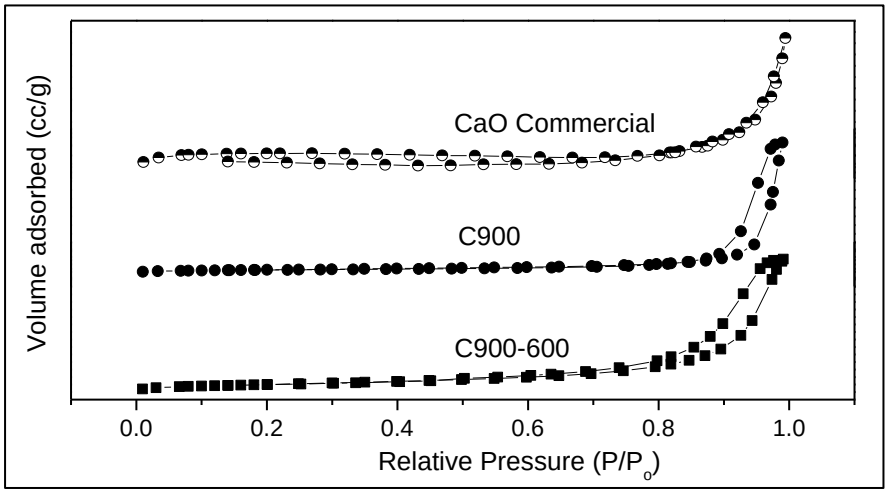

Figure 2. The N_2 adsorption-desorption isotherms of the catalysts

This characteristic is related with materials that have tendencies to swell [27]. Referring Figure 2, the broadening of the hysteresis loop of C900-600 compared to C900 is attributed to its larger pore diameter as evidenced in Table 1.

Production of biodiesel from WCO

The transesterification activity of the catalyst is compared in Table 2. C900-600 gave the maximum conversion of FFA to FAME (92.15%) compared with other catalysts.

Table 2. The activity of the catalysts in the transesterification of WCO

Sample	Acid Value (mg KOH/g)		Biodiesel Conversion (%)
	Initial	After	
C900-600	1.91	0.15	92.15
C900	1.91	0.37	80.63
Commercial CaO	1.91	0.51	73.30

Reaction conditions: Catalyst dosage: 5 wt.%; temperature: 65 °C; Methanol: WCO molar ratio: 15:1; time: 45 min

Higher catalysis of C900-600 can be inferred to its larger surface area and wider BJH pore diameter. Heterogeneous catalysis works on the principle of adsorption of reactants on surface. Thus, theoretically, larger surface area provides greater adsorption sites for the reactants to adsorb and react, which later influences the rate of reaction. In addition, the wider pore diameter of C900-600 eased the diffusion and accessibility of WCO and methanol deep into the active sites, actively participating in the reaction. Higher intensity of functional groups as evidenced through IR studies, have also aided the activity of C900-600 compared with C900. In addition, based on ASTM D-6751 and EN 14214 standards of biodiesel, the transesterification products registered using C900-600 and C900 catalysts were less than 0.5 mg KOH/g, which indicated the perfect fuel for automobiles [28].

Composition of biodiesel

The composition of FAME catalysed by C900-600 is shown in Figure 3 and summarised in Table 3.

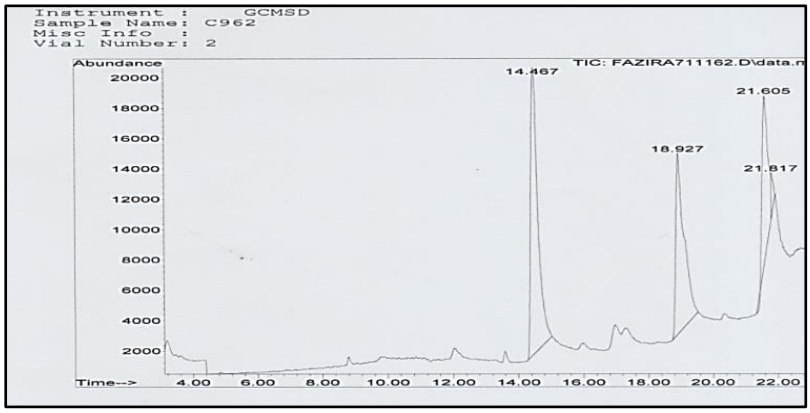

Figure 3. GC-MS profile of the biodiesel synthesised by C900-600

The major FAMEs identified in the synthesised biodiesel are as listed in Table 3. The findings are in accordance with Girish et al. [29], who evaluated the activity of clam shell catalyst in the conversion of waste frying oil.

Table 3. Methyl esters composition of the synthesised biodiesel

Retention Time (min)	Name of Compound	Molecular Formula	Molecular Weight (g/mol)
14.47	Dodecanoic acid methyl ester	$C_{13}H_{26}O_2$	214
18.93	10-Octadecadienoic acid methyl ester	$C_{19}H_{36}O_2$	296
21.61	Docosanoic acid methyl ester	$C_{23}H_{46}O_2$	354

Reusability of C900-600

The key characteristic of a heterogeneous catalyst is the ability to be reused with insignificant loss during the reusability. Figure 4 resembles the trend in the activity of C900-600 after five consecutive runs.

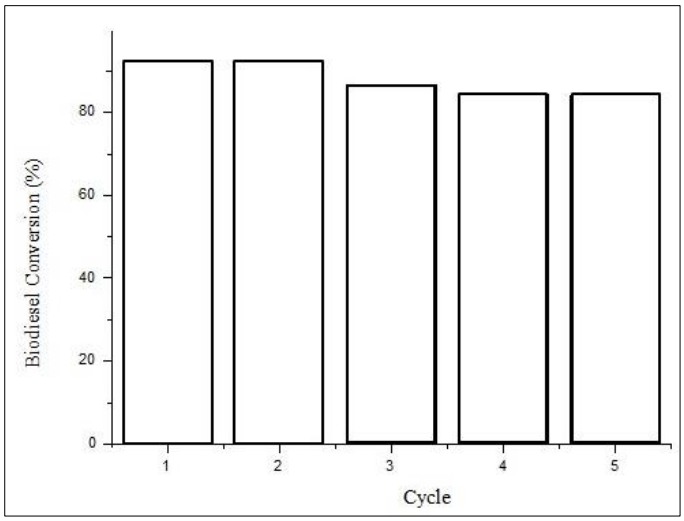

Figure 4. Regeneration activity of C900-600

C900-600 retained its activity up to the second cycle (92.12%), which indicated the high stability of the C900-600 catalyst. However, a slight reduction in the activity was experienced during the third (88.20%) and 87.00% for the subsequent runs. The lowering in the biodiesel conversion could be due to the attachment of unreacted reactants or products at the active sites that might have blocked the active sites and hindered the participation of the catalyst. The findings from this present work correlates well with several studies [7, 22] that demonstrated that the catalyst prepared from calcination-hydration-dehydration treatment can be reused for several runs compared with without treatment.

Conclusion

Heterogeneous CaO catalyst derived from waste chicken bone was synthesised using an improved hydration-dehydration method to cater to the drawbacks of lower surface area and poor activity of reported catalysts for biodiesel synthesis. Enhanced surface area and improved textural properties of C900-600 were the deciding factors for the better catalysis of C900-600 compared with C900. The preliminary characterisation proved the existence of hydroxyapatite, which are the active species for transesterification. However, the strength of basicity of C900-600 and C900 needs to be studied in the future for better insight into the effect of the hydration-dehydration treatment on the catalysis. To conclude, this research has successfully produced an active and recyclable catalyst for the sustainable production of biofuel within 45 min, employing 5 wt.% catalyst at 65 ℃ with insignificant loss of biodiesel after five regeneration studies, comparable to reported literature.

Abstract

Chemical vapour deposition (CVD) of cooking palm oil precursors with a nickel (Ni) catalyst is an established method to produce graphene-based materials. Nonetheless, transferring the graphene sheets from the substrate surface to a selected target substrate presents a major challenge. The utilisation of well-known poly (methyl methacrylate) (PMMA)-assisted graphene transfer promotes defects, impurities, folds, and wrinkles in the graphene sheets, thus affecting its properties. Consequently, the present study demonstrated a polymer-free graphene sheets transfer technique on a Ni substrate derived from cooking palm oil. A dropwise hexane layer substituted the PMMA supporting layer during the etching process to remove the Ni substrate. The quality of the graphene sheet was investigated with optical microscopy by employing a Leica DM1750 M microscope, scanning electron microscopy (SEM) with a Hitachi S-3400N, and Raman spectroscopy utilising a UniDRON automated microscope Raman mapping system with 514 nm laser excitation. Resultantly, macroscopically clean and crack-free graphene sheets were was obtained. Furthermore, the technique was less complicated than the PMMA-assisted transfer technique. The Raman spectra of the polymer-free method also revealed visible graphene peaks, which was absent in the PMMA-transferred samples.

Keywords: graphene, chemical vapour deposition, polymer-free transfer

Abstrak

Kaedah pemendapan wap kimia (CVD) yang menggunakan minyak masak kelapa sawit sebagai prekursor serta nikel sebagai pemangkin dalam proses sintesis bahan berasaskan grafin merupakan teknik yang telah lama dikenali. Namun, cabaran utama dalam menggunakan teknik CVD ini ialah proses pemindahan helaian grafin dari permukaan substrat asal ke substrat baru. Salah

satu kaedah pemindahan yang sering digunakan ialah kaedah pemindahan poli (metil-metakrilat) (PMMA) iaitu sejenis polimer yang akan menyebabkan helaian grafin mengalami kerosakan seperti kotor, berlipat dan berkedut. Oleh yang demikian, kajian ini akan menampilkan suatu teknik pemindahan grafin yang bebas polimer, disintesis di atas substrat nikel menggunakan minyak masak kelapa sawit. Lapisan heksana digunakan sebagai pengganti lapisan PMMA semasa proses penghakisan substrat nikel. Kualiti helaian grafin daripada hasil proses pemindahan ini dikaji menggunakan mikroskop optik (Leica DM1750 M), mikroskop pengimbasan elektron (SEM) dari Hitachi S-3400N dan spektroskopi Raman (system pemetaan mikroskop automatik Raman UniDRON dengan pengujaan laser 514 nm). Dapatan menunjukkan bahawa kaedah ini dapat menghasilkan helaian grafin yang bersih, tidak koyak serta pemprosesan yang tidak rumit berbanding teknik PMMA. Kaedah bebas polimer ini juga dapat menerbitkan puncak grafen menggunakan spektroskopi Raman berbanding kaedah pemindahan PMMA.

Kata kunci: grafin, kaedah pemendapan wap kimia, pemindahan bebas polimer

Introduction

Graphene is a two-dimensional (2D) substance comprising sp^2 carbon atoms in a gigantic aromatic structure [1]. The extraordinary performance of graphene in electrical [2], mechanical [3], and chemical [4] applications are promising, but previous studies revealed several gaps and shortcomings of the material. For instance, high-quality large-area graphene is not defect-free. Generally, graphene is synthesised through various methods, including mechanical, liquid, and chemical exfoliations, thermal decomposition of silicon carbide, chemical synthesis, and chemical vapour deposition (CVD). Among the techniques, CVD has been investigated as an alternative method to overcome inherent limitations in manufacturing large-area graphene with uniform thickness, high crystallinity, and fewer defects [5,6]. Traditional CVD techniques employ purified gaseous precursors, which are expensive, explosive, and require high-temperature growth, and accordingly, carbon waste has become a substitute precursor to synthesising functional carbonaceous material, such as graphene. The capability to fabricate graphene from such economic precursors would be cost-effective and sustainable for practical applications [7].

Recent studies have investigated the utilisation of several renewable natural carbon precursor sources for graphene production, namely camphor [8], reed (grass family) [9], cookies, chocolate, grass, roaches, dog faeces [10], and rice husks [11]. Numerous research reported employing cooking oil to manufacture graphene [12–14]. Most graphene growth via the CVD technique implement a post-grow polymer transfer from the surface catalyst onto the target substrate. The method introduces a complicated process in which a thin polymer layer is deposited on a graphene sheet that acts as a support to remove the metallic substrate by wet etching. The procedure induces defects, wrinkles, impurities, cracks, and stubborn polymer residues [15], which might obstruct the performance of graphene in subsequent applications [16, 17]. The graphene must be free to appreciate its extraordinary properties fully. Consequently, alternative routes of transfer methods such as polymer-free techniques are being explored to resolve the contamination problems [18, 19].

The main objective of the current work was to investigate a polymer-free method for improving the graphene transfer process synthesised from cooking palm oil through the CVD technique. The polymer-free approach employed hexane as a low-viscosity liquid organic layer, which would be very beneficial to stabilise and safeguard the graphene-based sheet generated during the metal substrate wet etching. The present study utilised hexane as the organic layer as it lacks heteroatoms and aromatic groups and is very volatile. Essentially, hexane could serve as a more efficient alternative to the polymer layer deposited on the graphene sheets in most currently practised transfer methods. A comparison study with the poly (methyl methacrylate) (PMMA) transfer method was also performed.

Materials and Methods

The CVD graphene growth

The graphene-based films in the present study were synthesised in a conventional CVD system equipped with a vacuum and argon (Ar) gas purging system. First, nickel (Ni) sheets were cut into 1 cm × 1 cm pieces and subjected to a specific cleaning protocol. Subsequently,

the Ni pieces were loaded into a CVD chamber to eliminate organic contaminations, impurities, and oil to increase the adhesion of the fabricated films on the substrate. The cleaning process began with an ultrasonic bath in ethanol for 10 minutes, followed by rinsing with distilled water. The metal sheets were then cleaned in isopropyl alcohol (IPA) for ten minutes, washed with distilled water, and blown dry with nitrogen (N_2) gas.

Graphene growth was conducted in a conventional thermal CVD furnace with a quartz tube. Two alumina boats were positioned in the heating region of the tube furnace. One boat was filled with a millilitre of cooking palm oil precursor, while the other contained several pieces of Ni sheets. The boat filled with the cooking palm oil precursor was covered with aluminium foil with tiny holes to avoid oil spillage during the heating process. The ends of the quartz tube were sealed. The air and impurities in the tubes were evacuated with a vacuum pump prior to purging with Argon (Ar) gas. The evacuation and Ar purging processes took approximately 30 minutes.

At this point, both boats filled with cooking palm oil and Ni sheets were present during the evacuation process. Subsequently, while the reaction tubes were in the Ar environment, the furnace temperature was raised to 400 ℃ at a 30 ℃ min^{-1} rate. The temperature was maintained for five minutes, during which the cooking palm oil was expected to reach its vaporisation point and flow towards the Ni sheets to start the graphene-based material growth. Subsequently, the furnace was switched off, and the sample was cooled to room temperature. After the effective thermal decomposition mechanism, carbon (C) from the vapourised cooking palm oil was anticipated to disperse evenly on the heated substrate surface.

Polymer-free graphene transfer

Sandpaper mechanical polishing was utilised to eliminate graphene-based material films on the backside of the Ni sheet. The sample was then subjected to metal etching. The graphene-based/Ni was gently placed onto the surface of 0.1 M iron (III) chloride [($FeCl_3$), System ≥ 98%] aqueous solution. Subsequently, the sample was floated (graphene-based side up) atop $FeCl_3$ solution (10 mL) for approximately a few seconds before a layer of hexane (Merck, ≤ 100%) was gently added to the top with a dropper. The hexane layer ensured that the graphene was not torn due to the surface tension associated with the etchant solution.

The Ni etching occurred in the $FeCl_3$ solution for approximately five hours, with the graphene-based sheet layer remaining trapped at the hexane and $FeCl_3$ aqueous solution interface. After etching, only the graphene sheet remained floating between the hexane and $FeCl_3$ solution, whereas the Ni sheet had fully submerged to the bottom of the etchant solution. The graphene sheet was then scooped out with a clean glass slide that was cleaned in a hot acetone bath for 10 minutes, methanol for 5 minutes, and rinsed with distilled water.

The sheet was transferred to a hexane/water interface at one to one ratio. The step was conducted to remove any remaining salt particles and debris from the back of the graphene layer. The graphene sheet was removed with a glass slide and let dry at room temperature after several hours. Fundamentally, the lack of heteroatoms and aromatic groups and volatility and rapid evaporation of hexane enabled the vapourisation and removal of hexane residues at room temperature.

The standard poly (methylmethacrylate) (PMMA) transfer method was performed on a sample set for comparison purposes. According to previous works, the polymer films were designed to protect graphene, which is fragile and could break. The solid support also helps reduce graphene wrinkles from the thermal expansion coefficient between the metal substrate and graphene.

A PMMA layer was spin-coated onto the surface of the graphene/Ni sheet at 1200 rpm for 30 s. Subsequently, the layer was annealed at 80℃ for 15 min to cure it, followed by etching in $FeCl_3$ to eliminate the Ni sheet. After an appropriate etching time, a clean glass slide was employed to scoop out the PMMA/graphene sheet. The sheet was rinsed with distilled water and baked at 60℃ for five minutes. The step was necessary to enhance contact adhesion and eliminate trapped water.

The second layer of PMMA was spin-coated on top of

the PMMA/graphene sheet and let dry at room temperature. Subsequently, the PMMA layer was washed with acetone and rinsed with distilled water. Finally, the graphene sheet was transferred to a clean glass substrate. The second PMMA layer was developed to reduce cracks in the transferred graphene [20]. Without the second layer of PMMA, tension might be imposed, resulting in large cracks on the graphene after the transfer process.

Sample characterisation

Evaluation of the initial quality of the graphene-based sheet was performed through optical microscopy by employing a material analysis microscope Leica DM1750 M. The surface morphology was assessed utilising scanning electron microscopy (SEM) (Hitachi S-3400N). Raman spectroscopy was conducted with UniDRON Automated Microscope Raman mapping system equipped with 514 nm laser excitation.

Results and Discussion

Optical microscopy

Optical microscopy analysed the coverage and distribution of the graphene-based films prior- and post-transfer process. Figure 1 displays the optical images of the graphene-based films on the Ni sheets after the CVD furnace growth process. Yellow, brown, purple, and grey layers covered the Ni sheet entirely. Similar results were reported by [12] as the colour might be the initial information of the graphene-based film structure.

The samples were subjected to two graphene transfer processes following the growth process, the PMMA and polymer-free transfers. Figure 2 illustrates the optical microscopy images of the graphene-based films after being polymer-free transferred on the glass substrate. A complete graphene-based film was obtained after transfer. The films exhibited colourful patterns dominated by grey and yellow. Some brownish colour from $FeCl_3$ residue was observed in the optical images, which was reported commonly occurring in transfer-free methods [21]. The phenomenon might arise from the graphene/Ni sample not correctly floated on the etching solution and correctly trapped in the hexane/ $FeCl_3$ solution interface. Moreover, the "soft support" from the hexane solution might be contaminated with the $FeCl_3$ etching solution.

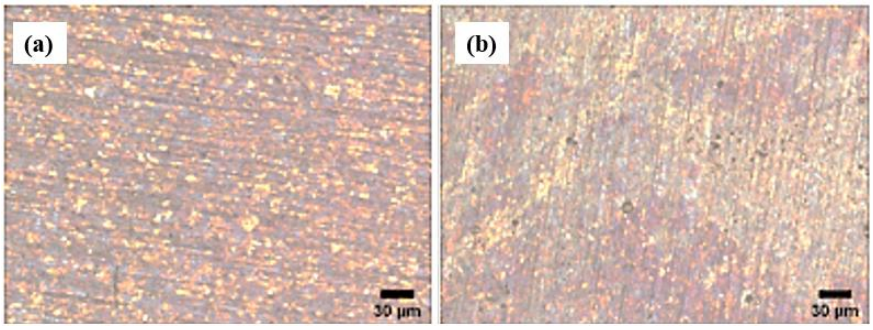

Figure 1. The optical images of two sample pieces of the graphene-based structure on Ni sheet grown at 400 °C

Due to cracks, the graphene-based films transferred with the PMMA technique demonstrated poor film quality. Additionally, some parts of the films were folded during the transfer process. The PMMA transfer process is often intricate, and the free-standing graphene could be broken due to surface tension as it dries [21]. Furthermore, some films failed to attach to the glass substrates, tended to break away, and immediately produced cracks when acetone dissolved the PMMA layer.

Trapped water between the PMMA and graphene and glass substrate throughout the transfer procedure might lead to folded layers and wrinkles. Consequently, the polymer-free transfer method offered a better option for transferring graphene-based films onto the desired substrate. Nonetheless, improvements to minimise the residues might be necessary for future works.

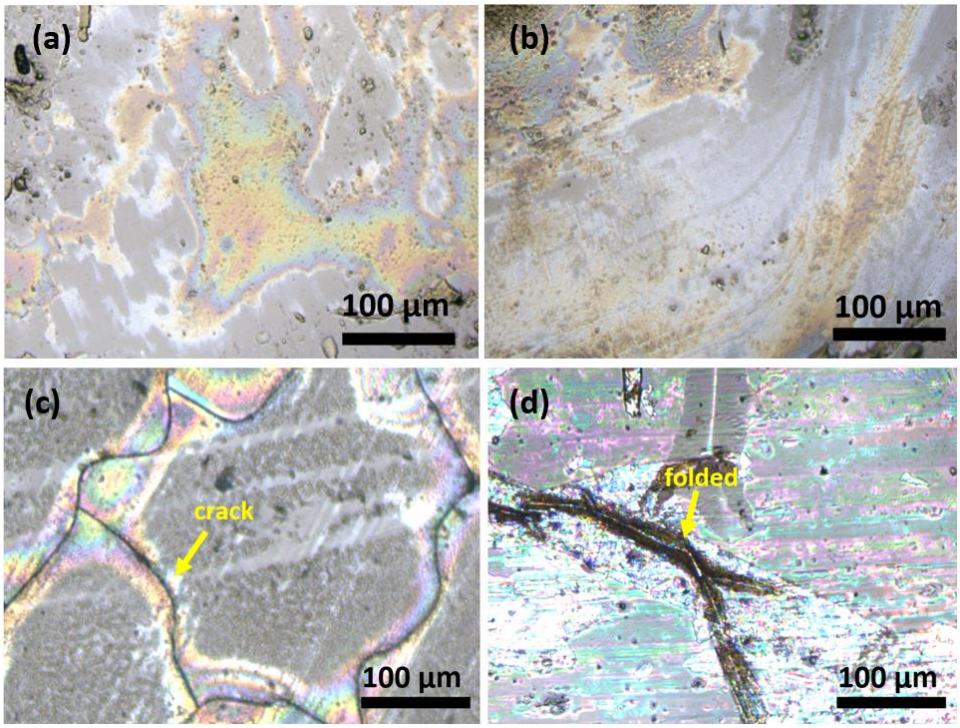

Figure 2. The optical images of the polymer transfer-free samples, denoted (a) and (b), and the PMMA transfer samples, represented by (c) and (d)

Scanning electron microscopy

The graphene films transfer is a crucial process that could affect the quality and performance of graphene in devices. Consequently, SEM was employed to record the surface morphology of the graphene films post-transfer onto the glass substrate. The measurements would further confirm the optical analysis results. Figure 3 exhibits the two specific spots focused on for the SEM assessment.

The PMMA transferred film sample observed suffered folded films and was heavily contaminated with PMMA residue. Although acetone wash was performed several times during the transfer process, the films still contained the residue. Meanwhile, the polymer-free transfer sample demonstrated a much cleaner and smoother surface. The low viscosity of the hexane layer on top of an aqueous etchant layer stabilised and safeguarded the free-standing graphene layer created during the Ni wet etch and water rinse.

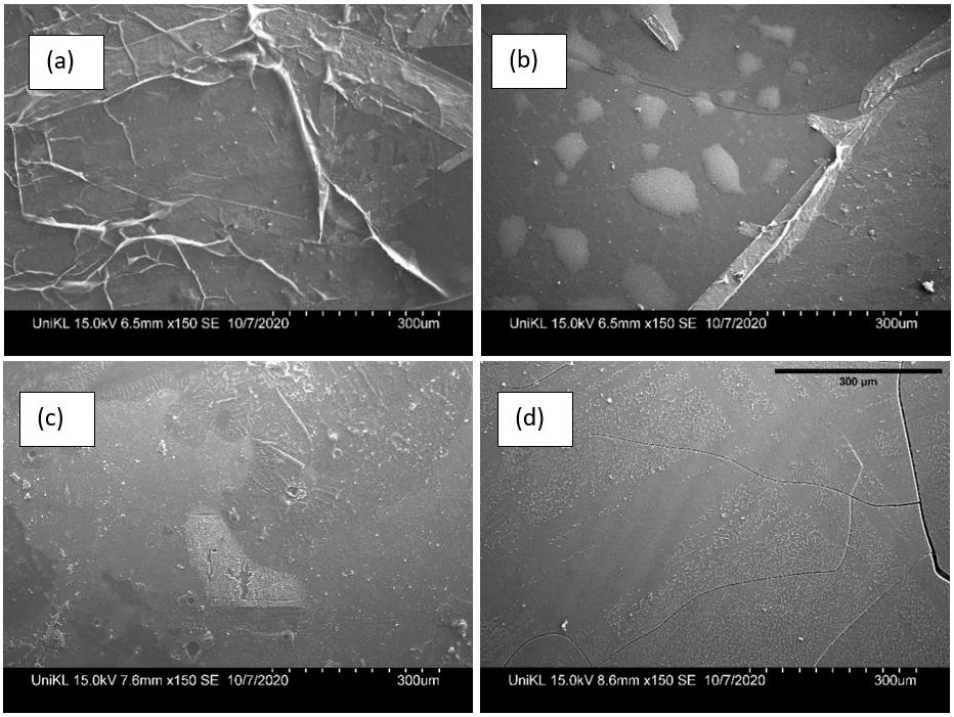

Figure 3. The SEM images of the graphene-based materials (a) and (b) after PMMA and (c) and (d) polymer-free transferred

Fundamentally, the hexane layer substituted the polymer layers currently employed in most graphene transfer procedures. The hexane layer prevented the graphene films from breaking due to the surface tension of the etching solution. The lack of heteroatoms and aromatic groups and high volatility of hexane resulted in no debris left on the graphene surface when transferred to the preferred substrate [19].

Raman spectroscopy

Raman analyses were performed on both samples to examine the synthesised graphene-based films. Figure 4 displays the Raman spectra of the films after being transferred onto the glass substrate utilising two different methods. No graphene structure was formed on the PMMA transfer samples and only PMMA peaks were detected (represented by pink dots). The observation might be due to the PMMA films not being fully dissolved with acetone. The films transferred with the polymer-free method exhibited two peaks that correlated to the D and G bands. The D band was observed at ~1348 cm^{-1}, while the G band was located at ~1543 cm^{-1}. For the sample analysed, the D and G bands demonstrated broad peaks, with no 2D peak, implying that the sample was a graphene oxide (GO) film. A previous study reported similar GO Raman spectra [22].

The D band peak was attributed to the structural defects and disorder of the graphite surfaces [23]. The G band was associated with the radial C-C stretching of the sp^2 bonded carbon [23]. Furthermore, the intensity of the D band peak to the intensity of the G band peak (I_D/I_G) ratio provided details on the defect density of the graphic structure. The I_D/I_G ratio for the GO sample was 0.99. The ratio would be helpful in future studies on the growth kinetics of the films. Shah et al. stated that as the rate of I_D/I_G decreased, the defects in the films were reduced, resulting from nucleation and the joining of the individual nucleation islands [24].

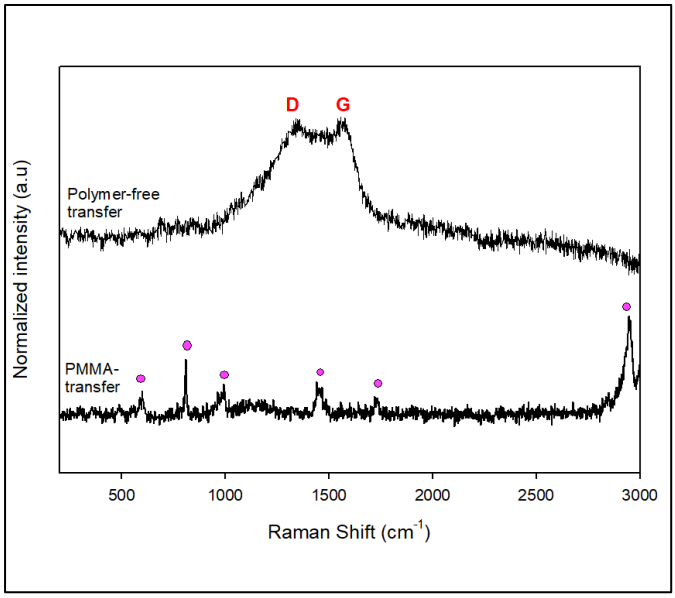

Figure 4. The Raman spectra of the PMMA transferred (bottom) and (above) polymer-free transferred samples

The multiple Raman spectra of four spots on the polymer-free transferred samples are displayed in Figure 5. Two peaks were detected at ~1354 cm^{-1} and ~1540 $cm^{-1,}$ respectively, thus corresponding to D and G peaks. No 2D peak (theoretically at 2670 cm^{-1}) was detected at any spot. Incomplete graphene film formation was observed at spots 1 and 2, which might be due to the lack of energy required for graphene formation to detach and transform the precursor material (hydrocarbon species).

Notably, the low growth temperature of 400°C was insufficient to decompose carbon feedstock from cooking palm oil. Nevertheless, the results might be fundamental in designing a CVD experimental setup. A similar situation was observed in soybean oils-graphene [25]. In the initial stages of the annealing process, the long carbon chains in the soybean oil precursor were thermally detached into methyl and ethyl gaseous carbon atoms. As the growth temperature was increased to 800°C, the carbon-building units began detaching into carbon atoms and dissolve into the Ni bulk. The short duration of the annealing process would then promote carbon atom dissolution in the Ni substrate. In particular, excessive precursor material preceded an oversaturation of deposited carbon in the bulk of the Ni and crystallised the graphite on the Ni surfaces.

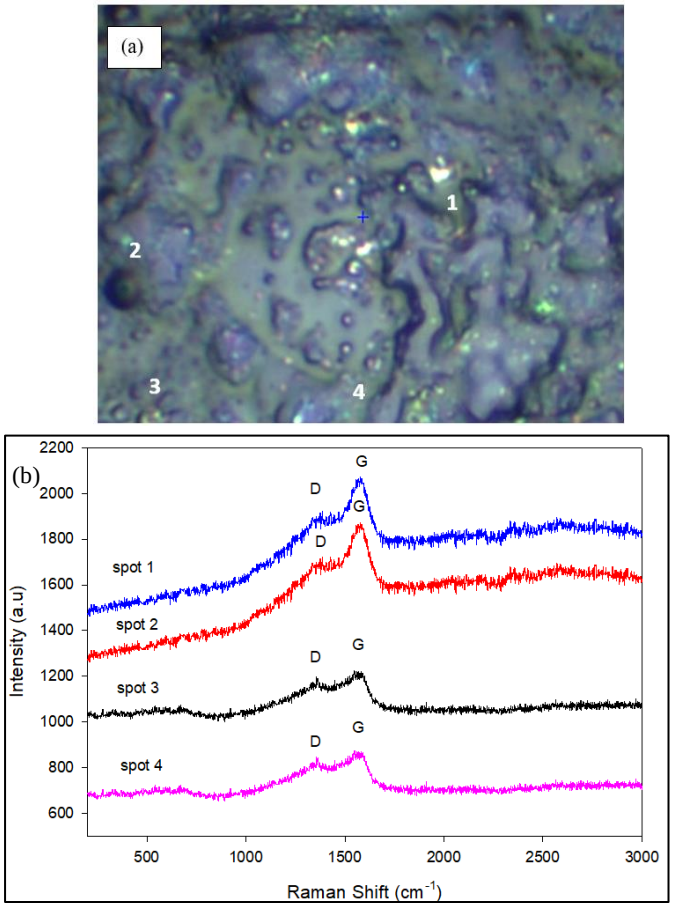

Figure 5. The (a) Four Raman mapping spots and (b) multiple Raman spectrum of the graphene films on a glass substrate of the polymer-free transferred sample

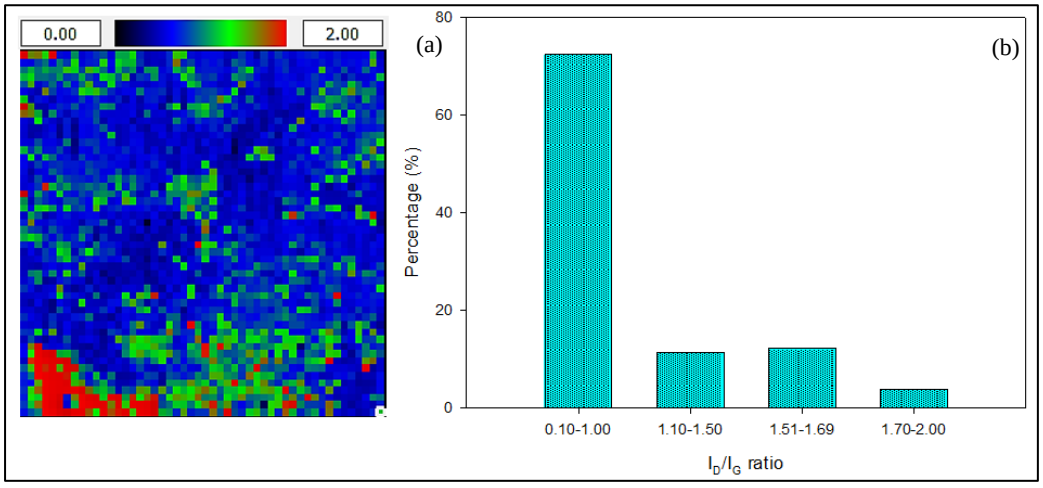

Figure 6. The (a) Raman mapping image of the graphene films on a glass substrate with I_D/I_G ratio within a 2 µm × 2 µm area and (b) histograms of the I_D/I_G ratio intensity percentages

Based on the Raman mapping of the I_D/I_G ratio and the intensity of the GO sample in Figure 6, the grown film was not uniformly distributed on the substrate. The non-uniform colour distribution provided fundamental knowledge of the substrate. The current study employed Ni polycrystalline sheet that was not subjected to polishing and etching treatment. The Ni surfaces in the carbon/polycrystalline Ni combination was densely populated by grain boundaries, particularly interplane grain boundaries, allowing carbon to accumulate throughout the segregation phase. Meanwhile, the single-crystalline surface on Ni (111) was very smooth, with almost no grain boundaries, allowing uniform carbon segregation, forming single-layer graphenes [26].

Histograms derived from the Raman mapping indicated the I_D/I_G ratio percentages. The ratio was divided into four groups, which corresponded to the most prominent family colours in the Raman mapping image, such as blue, dark green, light green, and red. Resultantly, the blue pixels were accounted for a ratio of less than 1.00, while the light green pixels had a 1.10–1.50 ratio, the dark green pixels exhibited a 1.51–1.69 ratio, and the red pixels was at a 1.70–2.00 ratio.

The counted pixels were presented in a histogram as a function of percentage. From the histogram, 70% of the I_D/I_G ratio was denominated by a ratio of less than 1.00. Meanwhile, 12, 11, and 3% corresponded to 1.51–1.69, 1.10–1.50, and 1.70–2.00 ratios, respectively. A high I_D/I_G ratio value corresponded to the high value of defects and disorders in the films [27]. Since 70% of the sample exhibited a ratio of less than 1.00, the film probably has a low value of defect and disorder. Consequently, hexane-assisted transfer promoted a clean graphene layer which might have enhanced the fundamental studies of graphene transfer.

Conclusion

The current study has successfully demonstrated an efficient polymer-free method to transfer graphene-based material sheets onto a substrate. The method was polymer contamination- and wrinkle-free. Compared to the PMMA transfer technique, the polymer-free method was easier to implement and less complicated. A significant advantage of hexane, contradictory to PMMA, was a smaller molecule with its high volatility, simplifying elimination from the graphene. The Raman studies demonstrated fundamental information in developing high-quality graphene-based material for future applications.

Abstract

Microcrystalline cellulose (MCC) was successfully extracted from kenaf bast fiber plant (*Hibiscus cannabinus* L.) and incorporated into PLA biocomposite. The kenaf bast fiber undergone alkali treatment and bleaching prior to acid hydrolysis using 1M HNO_3 in obtaining MCC. Several characterizations on isolated MCC and PLA/MCC biocomposite conducted such as Fourier-transform infrared (FT-IR) spectroscopy and crystallinity index. Further characterization was made on the PLA/MCC biocomposite to study its mechanical and physical properties. FT-IR spectral indicated the successive elimination of non-cellulosic constituents in MCC. Differential scanning calorimetry (DSC) analysis revealed the percentage of crystalline region in the MCC obtained from kenaf bast fiber is higher at 88.53, making it suitable to be used as reinforcement filler in PLA biocomposite. Whilst tensile testing on various loading of PLA/MCC composites showed increment in tensile strength and elastic modulus but decrement in percent elongation. The optimum parameters were found at 9% MCC loading at 18.7 MPa in tensile strength attributed to well mixing of PLA and MCC and 88.53 crystallinity index. The potential application of PLA/MCC biocomposite to be used as food packaging.

Keywords: biocomposite, kenaf, microcrystalline cellulose, polylactic acid

Abstrak

Selulosa mikrohablur (MCC) berjaya diekstrak daripada tumbuhan gentian kulit kenaf (*Hibiscus cannabinus* L.) dan dimasukkan ke dalam biokomposit PLA. Gentian kulit kenaf menjalani rawatan alkali dan pelunturan sebelum dihidrolisis asid menggunakan

1M HNO_3 dalam mendapatkan MCC. Beberapa pencirian pada biokomposit MCC dan PLA/MCC terpencil dijalankan seperti Fourier-transform infrared (FT-IR) dan indeks kehabluran. Pencirian lanjut dibuat pada biokomposit PLA/MCC untuk mengkaji sifat mekanikal dan fizikalnya. Spektrum FT-IR menunjukkan penghapusan berturut-turut juzuk bukan selulosa dalam MCC. Analisis kalorimetri pengimbasan pembezaan (DSC) menunjukkan peratusan kawasan kristal dalam MCC yang diperoleh daripada gentian kulit kenaf adalah lebih tinggi iaitu 88.53, menjadikannya sesuai digunakan sebagai pengisi tetulang dalam biokomposit PLA. Manakala ujian tegangan ke atas pelbagai pemuatan komposit PLA/MCC menunjukkan peningkatan dalam kekuatan tegangan dan modulus keanjalan tetapi penyusutan dalam peratus pemanjangan. Parameter optimum didapati pada 9% pemuatan MCC pada 18.7 MPa dalam kekuatan tegangan yang dikaitkan dengan pencampuran telaga PLA dan MCC dan indeks sistaliniti 88.53. Potensi penggunaan biokomposit PLA adalah untuk digunakan dalam pembungkusan makanan.

Kata kunci: biokomposit, kenaf, selulosa mikrohablur, poli(asid laktik)

Introduction

Poly lactic acid (PLA) is biodegradable and renewable thermoplastic polyesters and one of commercially developed polyester from natural source [1]. It is eco-friendly due to its compostable, biodegradable and consumes carbon dioxide during the production. These advantages make PLA an alternative for other petrochemical-based polymers which mostly non-biodegradable. However, there are many limitations of PLA such as low thermal stability, low impact strength, brittleness and poor elongation. Hence, it is only applicable to products that do not require high performance such as disposable cups, cutlery, plastic bags and food packaging materials [1, 2]. Due to these limitations, many research and studies were done to improve both mechanical and physical properties of composite. Extensive study on the blending between PLA and other biodegradable polymer with reinforcing fillers either natural or even manmade has been carried out. Nano clay, natural fibers, cellulose whiskers and Microcrystalline cellulose (MCC) are among reinforcing filler used in composite preparation. Rice husk, oil palm biomass, kenaf and rice straw are among fibers used as reinforcing filler in composite preparation [2, 3].

MCC is a refined wood pulp which derived from cellulose which appears as inert white crystalline powder with no odor and also tasteless [1]. It is generally applied in composite, pharmaceutical, cosmetics, and food industries. Properties of MCC such as its high crystallinity, stiffness, water insolubility, renewability and biodegradability make them an excellent component for various manufacturing purpose. MCC commonly can be obtained from various woody plants and cotton. However, other new potential sources of MCC such as from kenaf, rice husk, oil palm biomass, rice straw and other plant wastes were investigated since the common woody plants and cotton sources make the production costly. It is believed the lignocelluloses contain cellulose (40-55%), hemicellulose (25-50%) and lignin (10-40%) suitable in obtaining the MCC [4]. Enzymatic, mineral acid or microorganism's hydrolysis are among methods used to isolate MCC. Nevertheless, due to high-cost method and lower crystallinity production of MCC using enzymatic hydrolysis becomes less preferable [5]. Previous researchers found that MCC extracted from various sources through acid hydrolysis process has potential to be used in biocomposite preparation [6].

Kenaf or scientifically known as Hibiscus cannabinus L [7] is a common wild plant found in tropical and subtropical countries such as in Asia and Africa. Kenaf is preferred for industrial purposes as an abundantly available renewable annual fiber crop. It is mainly used as high protein animal feed, building materials, in textiles, fuel and also in the composite preparation [7]. This lignocellulosic fiber plant made up of hemicelluloses, lignin and pectin which help cellulose fibrils to be attached together. Presence of both long outer bast (about 25-40%) that provides high quality pulp and inner short core fiber (about 60-75%) of low-quality pulp makes a unique property in kenaf. Research done by Abdul Khalil et al., [8] found that kenaf core fiber contain higher lignin and holocellulose whilst its bast fibers have higher in α-cellulose and ash content. Recently, many researches were done on extraction of microcrystalline cellulose and cellulose nanocrystals from kenaf bast fibers. The potential end usage of biocomposite obtained is in food packaging since it is

biodegradable and food grade PLA. Many biodegradable polymers such as starch, chitosan, polylactic acid (PLA), and chitin commonly used in food packaging. This is due to their low-cost, flexible and see-through properties [8, 9].

Therefore, this study is focusing on the incorporation of MCC extracted from kenaf fiber in PLA biocomposite since less information recorded on usage of kenaf as one of MCC resources. MCC was characterized to determine its morphology using Scanning Electron Microscope (SEM), determination of degree of crystallinity using Differential Scanning Calorimetry (DSC) and Fourier Transform Infrared (FTIR) to identify the molecular bonds exists. The PLA/MCC (kenaf) biocomposite produced undergone characterization using FTIR and tensile mechanical test to determine its tensile strength, elongation at break, and elastic modulus.

Materials and Methods

PLA was obtained from Toray Malaysia while kenaf was collected from Lembaga Kenaf Malaysia in Kelantan. Analytical grade of sodium hydroxide, NaOH (QRec, 99%) and Sodium hypochlorite, NaOCl (QRec, 5%) was used for alkali treatment and bleaching agents respectively whereas 1M HNO_3 was used in acid hydrolysis process. Chloroform was used to dissolve the PLA for solvent casting method.

Extraction of Microcrystalline Cellulose from Kenaf

10 g of dried kenaf was refluxed with 300 mL of NaOH at 80°C for 1 hour and 30 minutes. After alkali treatment, the kenaf pulp was refluxed at 30°C for 18 minutes using 350 mL of 5% sodium hypochlorite (NaOCl). Again, the solution was refluxed in 83 mL of 1M HNO_3 at 80°C for 30 minutes via mechanical stirring. Then the obtained mixture was filtered, washed several times with distilled water and dried at 105°C in oven until constant weight was achieved [2].

Characterization of MCC (Kenaf)

Functional group that presents in MCC was identified using Perkin Elmer FTIR spectrometer 1650 within wave number range of 4000 cm^{-1} to 400 cm^{-1}. As for DSC measurements, approximately 8-10 mg of MCC sample was run through Perkin Elmer Instruments Pyris DSC to determine its crystalline percentage using rate 5 min at 5°C and heated at rate of 10°C/min until 250°C The percent of crystalline region in the MCC was calculated using Equation 1. T_m was determined from the second scan cycle on the melting peak temperature. Scanning Electron Microscopy (SEM) was conducted via Hitachi Regulus 8220 in Universiti Sains Malaysia to analyse the morphological properties of the selected samples.

$$\text{Percent crystallinity, } X_c = (\Delta Hm \text{ (Treated)})/((\Delta H°m \text{ (Untreated)}) \times 100\% \quad (1)$$

Where, ΔH_m is the MCC obtained after acid hydrolysis (treated kenaf) while $\Delta H°_m$ is the untreated kenaf.

Preparation of PLA/MCC composite

Ten g of PLA was added into 100 mL chloroform to obtain 10% w/v solution in water bath at 60 °C for 2 hours until PLA was completely dissolved. Different amount of MCC (0, 1, 3, 5, 7 and 9 wt.%) was added into 10% w/v solution of PLA and sonicated for 5 minutes to ensure homogenous mixing. Then, casted on glass plates with dimension of 16 cm x 13 cm x 0.5 cm and left to dry at room temperature in 24 hours for complete removal of chloroform.

Characterization and mechanical testing of PLA/MCC biocomposite

The functional groups present in PLA/MCC was identified using Perkin Elmer FTIR spectrometer 1650 within wave number range of 4000 cm^{-1} to 400 cm^{-1}. Tensile testing was carried out using ASTM D882 type V standard test method using Instron Tensile Tester with 5 replicates for each formulation.

Water absorption test for PLA/MCC biocomposite.

ASTM D570 standard test method was used to determine the water absorption properties of PLA/MCC biocomposite. Five replicates of each composite with dimension of 1 cm x 3 cm were made using Equation 2.

Percent water absorption = ([Wet weight - Dry weight])/ (Dry weight) x 100 (2)

Results and Discussion

Fourier transform infrared (FTIR) analysis on isolated MCC

The FTIR spectral obtained were shown in Figure 1. The broad absorption band in at 3409 and 3407 cm^{-1} for untreated kenaf and MCC respectively indicate the presence of –OH group. The –OH groups of untreated kenaf slightly shifted toward lower wavelength after the treatment. This is probably due to weakening of hydrogen bonding in cellulose during acid hydrolysis process [10]. Absorption peaks at 2922 cm^{-1} for untreated kenaf and 2896 cm^{-1} for the MCC is related to CH_2 stretching frequency. The peaks that appeared due to water absorption between 1637 until 1654 cm^{-1} indicates the water presence in the sample [10]. Previous research by Rosa et al. [10] stated that bending modes of water molecules arise due to great interaction between water and cellulose molecules. On the other hand, peaks that appeared within 1035 to 1112 cm^{-1} are due to C-O stretching vibration within the ring of anhydroglucose in cellulose [11, 12]. The absorption peak presents at 1739 cm^{-1} for untreated kenaf is in line with Abdul Khalil et al. [8] and approximate to 1735cm^{-1} [13]. This signifies the presence of C=O stretching vibration of carbonyl group and acetyl group in the hemicelluloses [8]. Whilst for MCC, the absent peak for the C=O stretching indicates a complete removal of hemicelluloses during alkali treatment. The peak at 1424 cm^{-1} in untreated kenaf indicates the presence of lignin (1509-1609 cm^{-1}) whereas it is absent from MCC spectrum proves that lignin had been completely extracted out of the MCC [10].

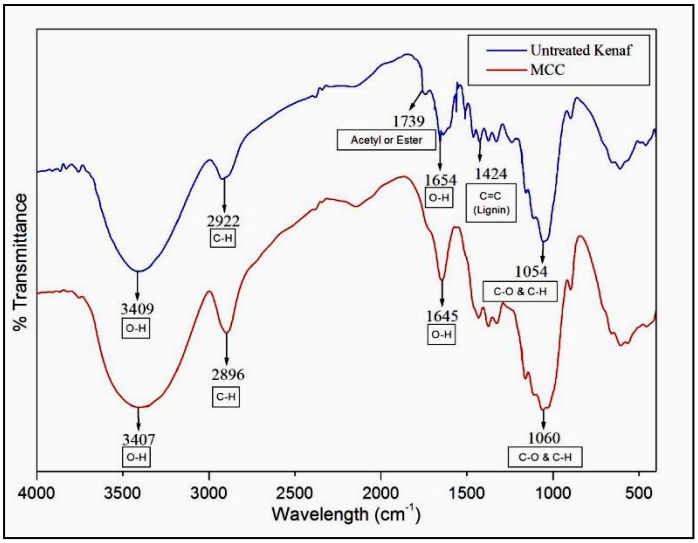

Figure 1. FT-IR spectroscopy for untreated kenaf and MCC from kenaf

FT-IR analysis was performed on pure PLA and PLA/MCC biocomposite in order to determine their interaction and phase behavior. Figure 2 shows the typical FT-IR spectra obtained. The characteristics peak for pure PLA is shown in Figure 2(a). The –OH stretching vibration is apparent at 3316-3843 cm^{-1}while the band observed in between 2850-3000 cm^{-1} is the asymmetric stretching of C-H. The peaks that attributes to C=O stretching vibration of carbonyl appears at 1630-1820 cm^{-1}. Peak that appears in between 1450-1475 cm^{-1} resulted from C-H bending of the -CH_3 group. The C-C bonding of alkane appears at 820-871 cm^{-1} almost similar with peak at 871 cm^{-1} by Haafiz *et* al. [9].

Whilst, PLA/MCC spectra for 1, 3, 5, 7 and 9 wt. % MCC is shown in the same Figure 2. From analysis, there is no new peak present upon gradual addition of MCC into PLA matrix. Haafiz et al. [9] suggest that the

interaction between PLA matrix and MCC most probably involve only physical interaction instead of chemical. Relatively small peaks of pure PLA for –OH stretching and bending that appear at 3200-3400 cm^{-1} gradually absent upon increasing MCC content. Identical result was described by Haafiz et al. [9] in PLA/MCC biocomposite extracted from rice husk.

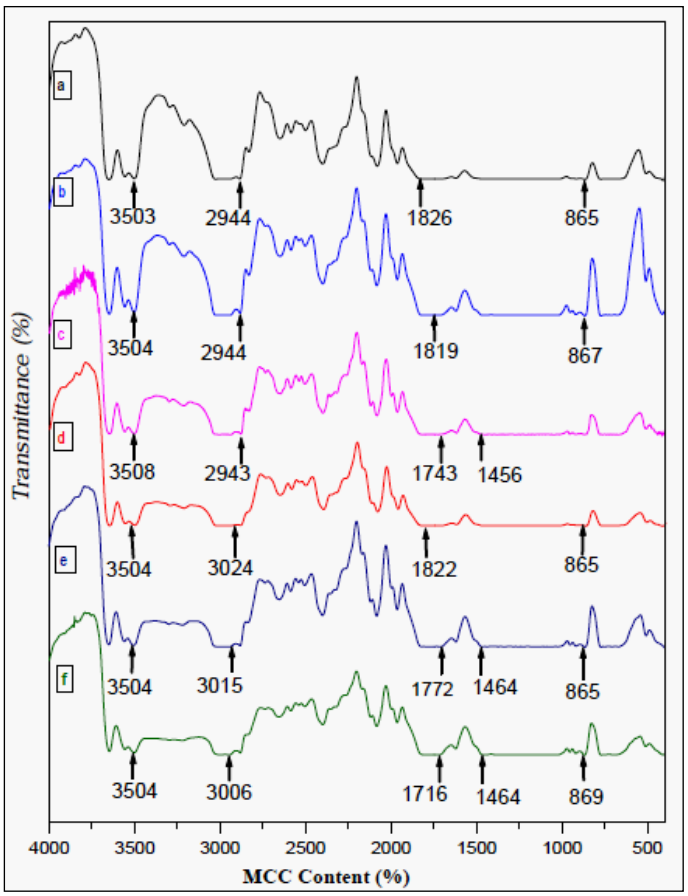

Figure 2. FT-IR spectroscopy for (a) PLA and PLA/MCC composite with different MCC loadings ((b) 1%, (c) 3%, (d) 5%, (e) 7% and (f) 9%)

Differential scanning calorimetry analysis on isolated MCC

Table 1 indicates some thermal characteristics obtained for kenaf, PLA, PLA/MCC. It is shown that melting enthalpies (ΔH_m) obtained for both untreated kenaf bast fiber and MCC extracted from kenaf is 492.38 and 435.89 J/g respectively. The T_m for PLA/MCC composite of 1, 3, 5, 7 and 9 wt. % MCC is in between 152-153°C which is not very different with T_m for pure PLA (152.9°C) due to MCC having nucleating effect on PLA [2]. The degradation of PLA composite lowers its melting point since the length of molecular chains is reduced [14]. It is believed the addition of chemical additives to enhance the PLA for other purpose especially in manufacturing industries decreased the melting point. The percent crystallinity was measured according to formula in Equation. 1. The percentage for crystalline region in MCC calculated is 88.53%. The effect of higher crystallinity in MCC obtained is manifested in increment of tensile and young modulus properties. This indicated physical crosslinking taken place and hindered the mobility of polymer matrix. It is believed highly crystalline MCC acted as nucleating agents and restricted the mobility of the polymer chains

by arranging the crystal lattice structure [1]. The results are in good agreement with SEM images Figure 3(b) showing rough surfaces found at 9 wt.% of PLA/MCC. This is in agreement with Nur Aimi et al. reported that higher crystallinity of the fiber improves the mechanical properties of the composites [15].

Table 1. DSC Characteristic of kenaf, MCC, PLA and PLA/MCC biocomposite

Characteristics	Kenaf	MCC	PLA	PLA/MCC (9%)
Melting Temperature T_m(0c)	80.38	74.83	168	153
Glass transition Temperature T_g(0c)	45	55	58	63

Scanning electron microscope image analysis

Fracture surfaces of pure PLA and PLA/MCC composite for 9 wt.% were analyzed using SEM to investigate the morphology of microcrystalline cellulose embedded in the PLA matrix. Smooth fracture surface can be observed on the pure PLA as shown in Figure 3(a) which can be categorized as ductile fracture due to amorphous property of PLA itself. Whilst, uneven fracture shown for both composite filled MCC (Figure 3b). Smooth fracture surface can be observed on the pure PLA as shown in Figure 3a. Mukherjee et al. [16] suggested that uneven fracture of composites possibly take place after the addition of MCC cause a significant deformation on PLA matrix as compared. It is also indicating that more force is needed to fail the samples during testing.

Through observation, the diameter of 5 and 9 wt.% MCC content measured is approximately 25.55 μm and 17.69 μm respectively (Figure 3(c) and (d)) and there is no significant filler agglomeration observed. This is the evidence of good interaction between MCC and the PLA matrix that helps to reinforce the composite as it manifested in tensile strength and modulus. In addition, only a little irregularity in the MCC shape found in both samples which is a good feature for filler. According to Yussuf et al. [17], the irregularities shape of filler in polymer matrix lowers the mechanical strength of the composite because it reduces the ability of filler to transfer the applied stress from the polymer matrix [16]. Since the size of MCC is small enough to lower the irregularities shape in the composite, mechanical properties of the PLA/MCC composite are enhanced.

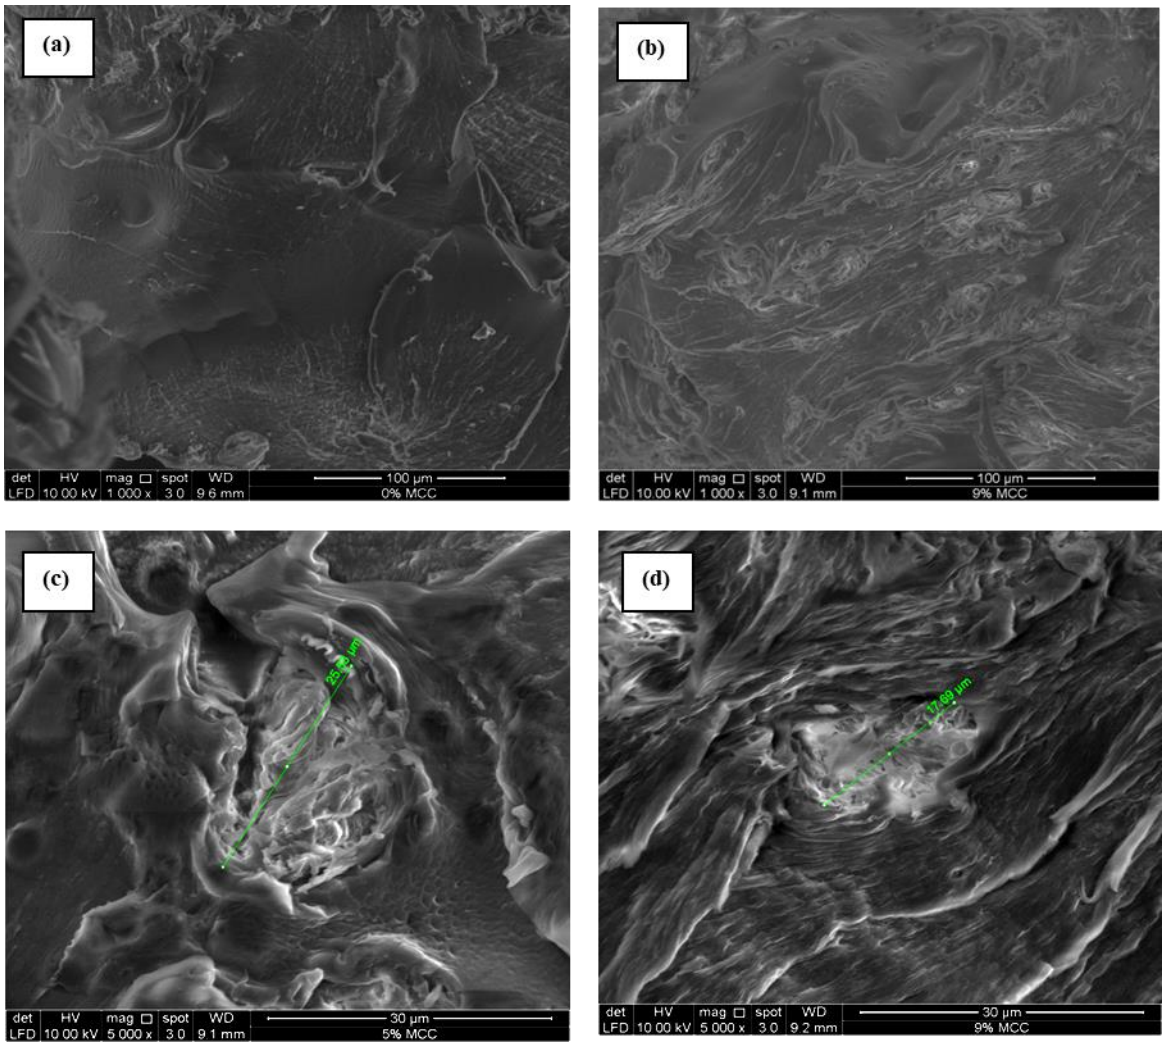

Figure 3. (a) Scanning electron micrographs of fractured surface of pure PLA at 1000, (b) 9 wt.% PLA/MCC at 1000x, (c) 5 wt.% PLA/MCC biocomposite at 5000x, and (d) 9 wt.% PLA/MCC biocomposite at 5000x

Tensile properties of PLA/MCC (kenaf) biocomposite

The tensile strength of PLA/MCC blends is higher than that of pure PLA as shown in Figure 4. For 1 and 3 wt. % composites, slight increment of tensile strength can be observed compared to the pure PLA. Whereas, at 5 to 9 wt.% MCC contents in PLA composite shows higher tensile strength which is 1.2 to 1.4-fold greater than the pure PLA due to good dispersion between MCC and PLA resulting in good interaction between them. Previous study by Haafiz et. al. indicates that MCC have higher tendency to agglomerate which makes it interact and distributed poorly in PLA matrix [9]. As proven by analysis under SEM, no significant agglomeration observed in all the composites thus it can be suggested that the interaction and distribution of MCC in the PLA matrix is good. Furthermore, it can be seen from the SEM fractography there is good interaction between PLA and MCC. This is because of the MCC possess a high aspect ratio giving way to better interaction and finally increased the tensile strength. Figure 5 illustrate the result for elastic modulus. PLA/MCC blends of 1, 3 and 5 wt.% MCC in PLA show improvement compared to the pure PLA with order of 217.94, 226.83 and 236.52 MPa correspondingly. Nevertheless, as MCC contents increased more than 5 wt.%, the elastic modulus

maintained at average value approximately at 237 MPa. According to Haafiz et al. the increasing of MCC loading may be attributed by common filler/polymer features such as increasing rigidity effect, hydrogen bonding and also the percentage of crystalline region in the filler [9].

On contrary, PLA/MCC blend shows a gradual reduction for percent elongation when more MCC added as shown in Figure 6. The values then retained between 39 to 40% elongation for 5, 7 and 9 wt.% MCC loading with average of 3.2-fold lower than pure PLA. This might due to properties of MCC itself which possess strong hydrophilic properties compared to PLA that slightly hydrophilic cause poor interfacial adhesion between them [14]. Stiffening action by MCC may cause the restriction on chain movement of PLA molecules during testing [17]. In contrast, PLA/MCC blend shows a gradual reduction for percent elongation when more MCC added as shown in Figure 6. The values then retained between 39 to 40% elongation for 5, 7 and 9 wt.% MCC loading with average of 3.2-fold lower than pure PLA. This might due to properties of MCC itself which possess strong hydrophilic properties compared to PLA that slightly hydrophilic cause poor interfacial adhesion between them [12]. Stiffening action by MCC may cause the restriction on chain movement of PLA molecules during testing [15].

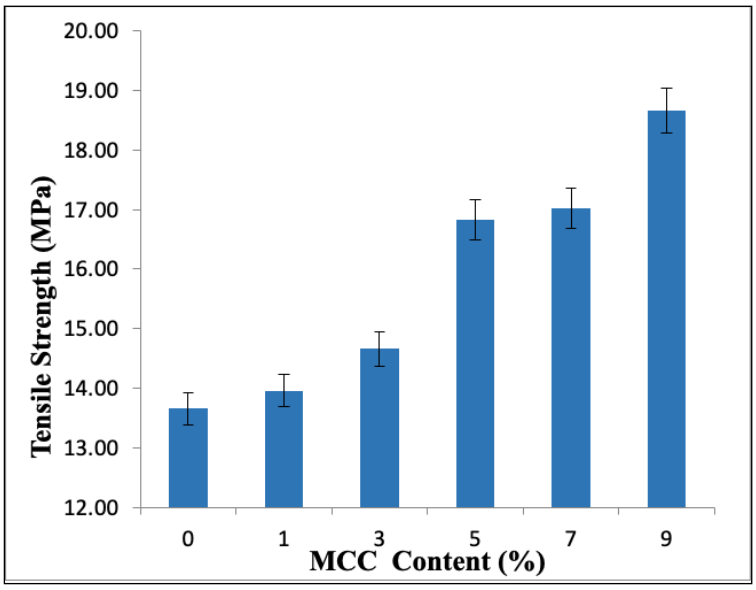

Figure 4. The effect of MCC content on the Tensile strength of PLA biocomposite

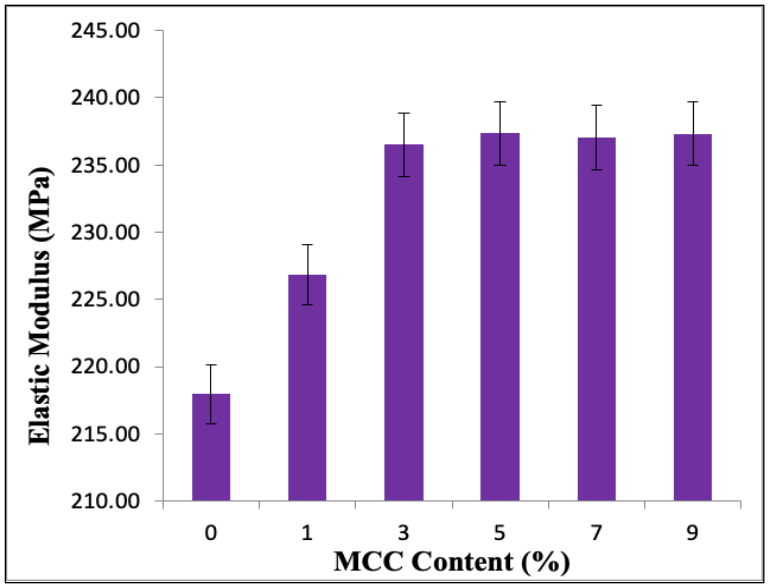

Figure 5. The effect of MCC content on the tensile modulus of PLA biocomposite

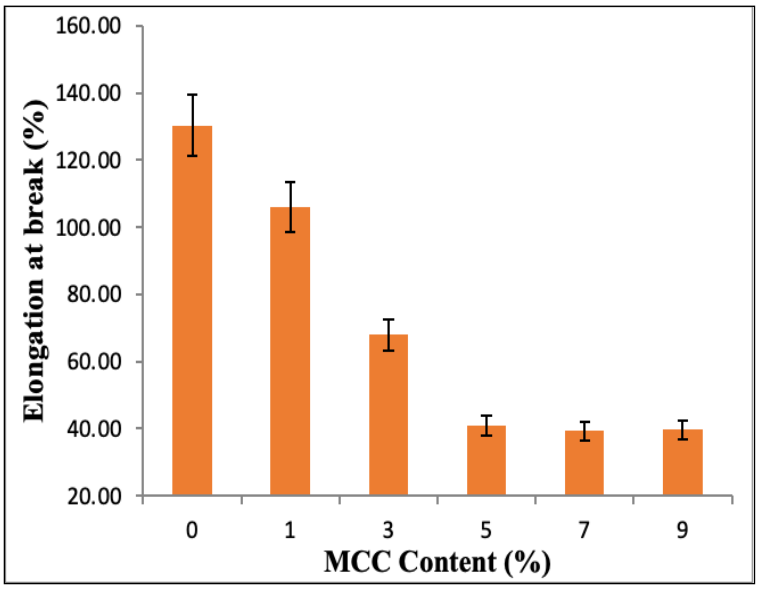

Figure 6. The effect of MCC content on the elongation at break of PLA biocomposite

Water immersion testing

The percentage of water absorption and thickness swelling of PLA/MCC composites increases upon MCC addition as shown in Figure 7 and 8. However, the water absorption does not linearly increase and might due to dispersion of MCC in the matrix not good enough for some of the composite. For an example the percentage of water absorption for 1% MCC is closer to pure PLA compared to 3 wt. % MCC. Based on the result obtained, it shows significant increment in the water absorption and thickness swelling with the increasing of MCC content after 1 % loading. It gives a better picture that

addition of MCC in the composite will help to boost the degradation of PLA since water is one of the important aspects in hydrolysis process as mentioned by Rocca-Smith et al. [18]. The process is the hydrolysis induced by water penetration and diffusion is where the penetration water into the PLA is driving force the biodegradability of the PLA [19]. From the result obtained also show that pure PLA have low water absorption capability. So that beside the mechanical improvement, addition of MCC into the PLA also can contributed to the degradability of the material which significantly important aspect as bio-based thermoplastic.

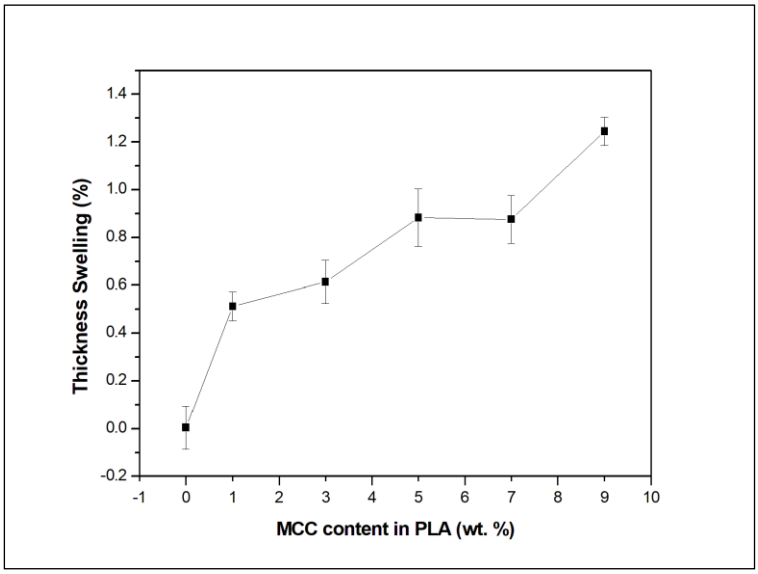

Figure 8. Thickness Swelling of Various MMC PLA Biocomposite

Conclusion

The finding from the research shows that MCC from kenaf bast fiber has been successfully isolated and characterized. The uniqueness of the research is the combination of MCC isolated from kenaf and PLA in biocomposite preparation since it possesses the biodegradability and renewability properties. In addition, Cellulose was purified using general chemical treatments which are alkali treatment and bleaching. The alkali treatment was used to remove hemicelluloses whilst bleaching was done for delignification purpose. Extraction of MCC from the treated kenaf fiber was done via acid hydrolysis 1M HNO_3. Characterization using FT-IR spectrum obtained for both kenaf and MCC proved a successful elimination of hemicelluloses and lignin from MCC. The analysis under DSC shows that percent crystallinity of MCC is high which validated that acid hydrolysis does not alter the crystal structure of cellulose in the kenaf fiber. The isolation of MCC from kenaf by means of acid hydrolysis is sufficient to produce high crystalline MCC. PLA/MCC biocomposite was successfully fabricated with addition of 1, 3, 5, 7, and 9 wt.% MCC through solvent casting technique. FTIR spectra of showed insignificant changes in the peak position of PLA/MCC biocomposite suggest that PLA matrix and MCC only physically interacted. Mechanical properties of PLA/MCC biocomposite proved an increasing tensile strength and elastic modulus due to stiffening action of MCC upon increasing MCC content. Conversely, elongation at break decreased when MCC content increased. This caused by brittleness property of crystalline region in MCC causing subsequent restriction on the biocomposite chain movement. Observation under SEM revealed a good dispersion of MCC in PLA matrix which gave reason for the increasing in tensile strength of the biocomposite. Physical test was done upon PLA/MCC to determine the water absorption properties of the biocomposite. Upon addition of MCC, water absorption of the composite showed increment as MCC content added due to hydrophilic properties of MCC which important for degradability of PLA. Thus, it can be concluded that addition of 1 to 9 wt. % MCC into PLA matrix gave significant effect.

Abstract

Dilution of gas was deployed to investigate the surface morphology and the surface topography of Silicon Carbide (SiC) film deposited using Very High Frequency – Plasma Enhanced Chemical Vapour Deposition (VHF-PECVD) technique. The deposition process of SiC thin film was performed with 150 MHz excitation frequency and 20 W radio frequency (RF) power. The argon and hydrogen carrier gas dilution was set to 5 sccm. Silane (SiH_4) and methane (CH_4) functioned as precursor gases and their flow rates were fixed at 2 and 8 sccm, respectively. Direct observations revealed that the surface morphology of deposited nanostructured-silicon carbide (ns-SiC) films in all samples had layer-island structure with varied island density and size formation above the critical layer thickness. Next, surface topography and roughness of the deposited SiC films were examined using Atomic Force Microscopy (AFM) in non-contact mode. As a result, all samples displayed different roughness, surface topography structure, and average grain diameter.

Keywords: silicon carbide, plasma enhanced chemical vapour deposition, dilution gas

Abstrak

Pencairan gas digunakan untuk menyiasat morfologi permukaan dan topografi permukaan filem silikon karbida (SiC) yang dimendap menggunakan kaedah Frekuensi Sangat Tinggi – Pemendapan Wap Kimia Dipertingkatkan Plasma (VHF-PECVD). VHF-PECVD dikendalikan menggunakan frekuensi pengujaan 150 MHz pada kuasa gelombang radio (RF) 20 W. Sementara itu, pencairan gas pembawa argon dan hidrogen ditetapkan kepada 5 sccm. Gas pendahulu silane (SiH_4) dan metana (CH_4) masing-masing ditetapkan pada 2 dan 8 sccm. Pemerhatian langsung mendedahkan bahawa morfologi filem nanostruktur-silikon karbida (ns-SiC) yang dideposit dalam semua sampel mempamer sktruktur lapisan-pulau dengan ketumpatan pulau yang berbeza dan pembentukan saiz di atas ketebalan lapisan kritikal. Topografi permukaan dan kekasaran filem SiC yang dimendap diperiksa dengan Mikroskopi Daya Atom (AFM) dalam mod bukan sentuhan. Hasil kajian menunjukkan bahawa semua sampel mempunyai kekasaran struktur topografi permukaan dan diameter butiran purata yang berbeza.

Introduction

Nanoscience and nanomaterial are the fastest growing research areas to date since the introduction to nanotechnology by Richard Feynman [1]. Material properties improve when the material is reduced to nanoscale [2-7]. The cutting-edge trend of nanomaterial applications includes electronic devices for extreme environments such as high temperature, high corrosion, high nuclear radiation, and high electromagnetic radiation - the importance of using unique material as resource in extreme conditions. Silicon carbide (SiC) is a relatively new semiconductor material that has been gaining popularity in high-frequency and high-power applications. Since several decades ago, SiC has been identified as a potential material for use in extreme conditions due to its mechanical properties, chemical inertness, thermal stability, high oxidation resistance, high hardness, large band gap, and relatively lightweight [1, 8-11]. In fact, SiC has a crucial role in some optoelectronic device applications [11-13], including light-emitting diodes (LEDs), electroluminescent devices [14], and thermoelectric cooling (TEC) devices [15]. Nevertheless, low-quality material has hindered the development of high-quality devices [16].

Several methods that can be used to synthesise SiC thin films are hot wall chemical vapour deposition (HWCVD), plasma enhanced CVD (PECVD), electron cyclotron resonance CVD (ECR-CVD), magnetron sputtering, pulsed laser deposition (PLD), ion implantation, and molecular beam epitaxy (MBE) [8, 17]. Many studies revealed that high-quality thin films and nanostructured-SiC (ns-SiC) can be produced using higher radio frequency (RF) PECVD at lower temperature. Notably, PECVD with RF exceeding 13.56 MHz is classified as very high frequency (VHF-PECVD) [19].

The VHF-PECVD technique was employed in this study at 150 MHz plasma excitation frequency to deposit SiC film. The effect of dilution gas on SiC film was examined and characterised by using FTIR spectroscopy, FESEM, and AFM. Notably, high excitation frequency of PECVD has some advantages over conventional PECVD, including higher deposition rate, less defect and better-quality films, higher electron density, lower plasma potential, and lower impact of ion bombardment when compared to conventional PECVD [19]. However, no study has assessed SiC film synthesised with RF-PECVD at a frequency exceeding 100 MHz with SiH_4 and CH_4 precursors at low temperature. The ns-SiC thin film should successfully grow using VHF-PECVD at the said excitation frequency.

Materials and Methods

First, Si [100] substrates were thoroughly cleaned with ethanol and followed by organic cleaning in ultrasonic bath for 10 minutes. Next, the substrates were immersed in acetone for 10 minutes in ultrasonic bath. To remove the remaining contaminant particles, the substrates were submerged in 50% sulphuric acid (H_2SO_4) before another ultrasonic bath for 10 minutes. The oxide layer on the substrate surface was stripped off by immersing in 50% fluoric acid (HF). Finally, the substrates were rinsed with deionised (DI) water and blow-dried with N_2 gas. The substrates were then ready to be placed in the process chamber.

The substrates were labelled as samples A, B, and C. Sample A was diluted with the mixture of argon and hydrogen gases, while sample B was diluted only with hydrogen gas, and sample C without dilution of gas mixture. Substrate temperature, RF power, deposition time, and SiH_4 flow rate were fixed at 400 °C, 20 W, 15 minutes, and 2 sccm, respectively, for all samples A-C. The growth parameters for samples A-C are summarised in Table 1.

Table 1. Gas dilution growth parameter

Sample	Power (W)	Temperature (°C)	Argon Flow Rate (sccm)	Hydrogen (sccm)	Silane Flow Rate (sccm)	Methane Flow Rate (sccm)	Deposition Time (min)
A			5	5			
B	20	400	-	5	2	8	15
C			-	-			

Results and Discussion

Both chemical composition and bonding structure of Si C thin film samples were verified using IR spectroscop y. This technique has been vastly used to qualitatively a ssess the type of chemical bonding present in thin film materials, including a-Si:H, a-SiO_2, a-SiNx:H, a-SiCx: H, and a-C:H. In fact, IR spectroscopy is used to quanti tatively determine the concentration of terminal hydrog en bonds (Si-H, C-H, O-H, & N-H) and network bonds (Si-C, Si-O, Si-N, P-O, & B-O) present in thin film mat erials.

Figure 1 illustrates the IR spectrum for samples A-C in two regions ranging from 650 to 1500 cm^{-1} and 1800 to 3000 cm^{-1}. The sharp peaks observed at 1500-1800 cm^{-1} range are attributed to O-H water vapour vibration in t he air during the measurement [20, 25]. Moreover, sign als of the deposited thin film were noted at 650-1500 c m^{-1} and 1800-3000 cm^{-1}, in comparison to the blank Si wafer.

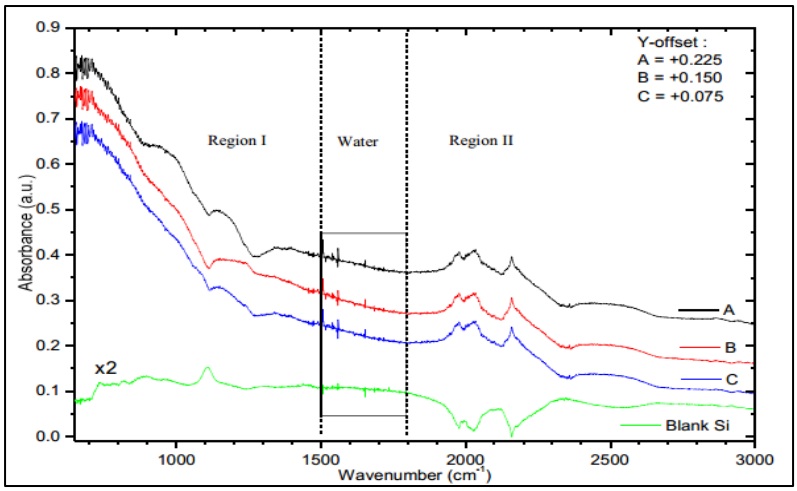

Figure 1. Comparison of IR spectrum between Si wafer and samples A-C

Spectra in regions (I) and (II) revealed the following vibrational bands: absorption band at ~ 650-1000 cm^{-1} is correlated to Si-C stretching [18, 21, 26-28]. The band at ~ 1000-1150 cm^{-1} is ascribed to Si-O-Si asymmetry and symmetry stretching vibration band or Si-CH_2-Si wagging mode [18, 21, 26, 28]. At ~ 1000 cm^{-1}, the band corresponds to Si-CH_n bending mode [24, 27]. In most samples, lower intensity absorption bands in the range of 1200-1500 cm^{-1} were detected. A shoulder at ~ 1250 cm^{-1} is linked with Si-CH_3 stretching mode [26] or Si-CH_n wagging mode [24]. The symmetry and asymmetry C-H_n bending and stretching modes are associated with ~ 1250-1500 cm^{-1} and 2700-3000 cm^{-1} bands, respectively [20-22, 26-27]. The Si-H_n stretching mode is assigned to the band from ~ 1850 cm^{-1} to 2300 cm^{-1} [21]. The small sharp peak at ~ 2350 cm^{-1} is attributed to CO_2 in the atmosphere [24, 27]. All the peaks verified that all the deposited thin film samples possessed Si-C

network bonds.

Scanning electron microscopy

Figures 2 (a-c) illustrate the overall surface morphology of the thin films, with inset images zooming in on the flat region for samples A-C respectively. Next, Figures 2 (i-iii) portray the cross-sectional morphology for samples A-C respectively. In sample A, the thin film had the largest island diameter at less than 1 µm and the film thickness was roughly ~ 397 nm. The island diameter in sample B was similar to that of sample A. However, the size exceeded 1 µm when agglomeration occurred among the islands. Sample B had thinner film thickness than sample A at 337 nm. Without argon gas during deposition, the density of island nucleation displayed an increase in sample B, when compared to sample A. Meanwhile, sample C showed the highest density of island nucleation above the film surface after attaining critical thickness. Notably, island formation increased in sample B and island density was higher in sample C. Therefore, dilution gas was proven effective to reduce the C-H network, which is ascribed to the high dissociation of methane on the films [23]. The film thickness values obtained from FESEM were 397 nm, 337 nm, and 357 nm for samples A-C respectively.

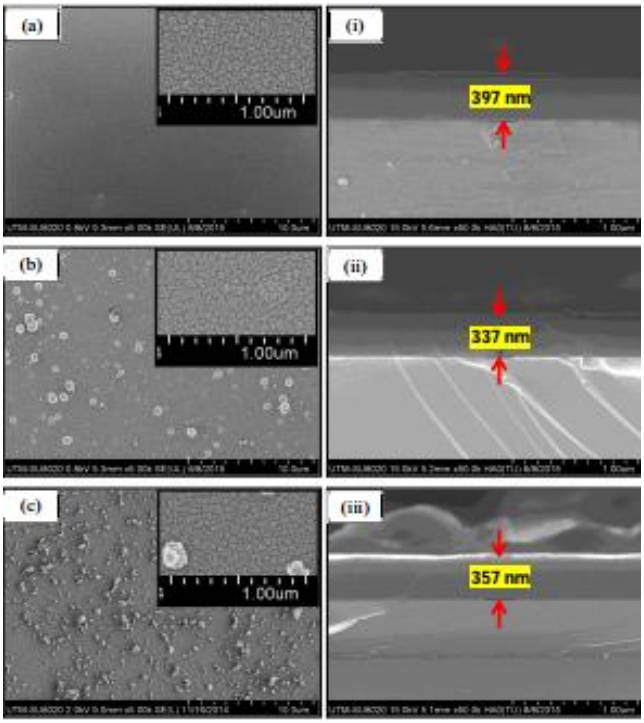

Figure 2. FESEM images of surface morphology ((a), (b), & (c)) and cross-sectional view ((i), (ii), & (iii)) of SiC films grown with different types of gas carriers for samples A, B, and C, respectively

Atomic force microscopy

Figure 3 shows high resolution surface topography of AFM images for samples A-C represented in root-mean-square roughness (R_{rms}). Sample B had smoother surface with R_{rms} of 0.798 nm, when compared to samples A and C with R_{rms} values of 1.505 nm and 1.599 nm, respectively. Dilution gas influenced the formation of different grain structure shapes, including triangular base pyramid [29, 31], square plateaus [30, 32], and semi-square plateaus for samples A-C respectively. This result is ascribed to the phase transition from amorphous to crystalline phase when hydrogen and argon were added during the deposition process [23]. Upon comparing the R_{rms} values of samples A and B, higher surface roughness in sample A is attributed to the effect of argon ion bombardment on film surface, although the

deposition pressure in sample A was lower than that of sample B. Hydrogen ions that existed in sample B deposition process could have less ion bombardment effect due to high electronegativity of H ion to have reaction in gas space with other reactants, when compared to the behaviour of argon ions as inert gas naturally. The mean diameter value of triangular pyramid island was ~ 81 nm and sample B showed well definite square plateaus of ~ 120 nm wide (based). For sample C, it had no perfect square plateau shape of each grain and the average wide of grain was ~ 140 nm.

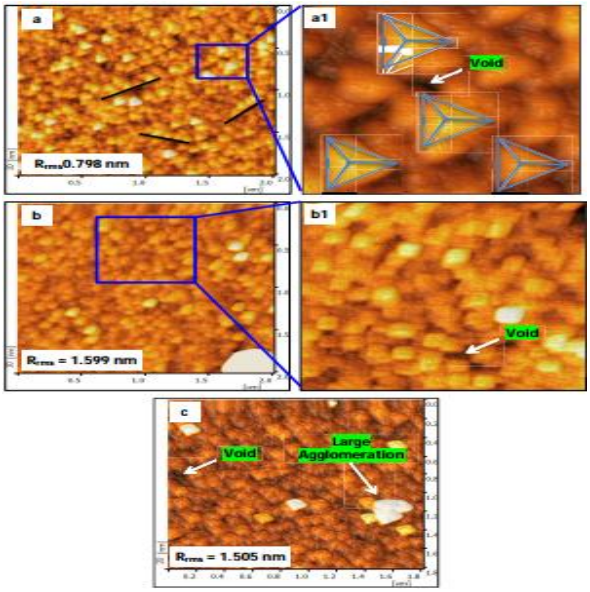

Figure 3. AFM images of the surface topography of SiC films grown with different types of gas carriers for samples A, B, and C represented by (a & a1), (b & b1), and (c), respectively

Conclusion

In conclusion, the surface morphology of the deposited ns-SiC films revealed a layer-island structure with varied island density and size formation above the critical layer thickness in all samples. Both surface topography and roughness of the deposited SiC films were assessed using non-contact AFM mode. The results revealed that all samples had different roughness, surface topography structure, and average grain diameter. Thin film deposited with dilution gas had a very smooth surface with the lowest R_{rms} value of 0.798 nm. Notably, dilution gas had affected the formation of different grain structure shapes. Nonetheless, the role of argon gas in changing the grain structure from square plateaus to triangular base pyramid demands further investigation.

Abstract

This two-dimensional (2-D) carbon structure, known as graphene, has tremendous potential due to its unique properties. This research intends to identify the existing knowledge gap because of the lack of substantial studies and prior comparisons in bilayer graphene and bring to light any pertinent differences between monolayer and bilayer graphene in this field. So, a density functional theory (DFT) study was done using a Quantum Espresso package for analysing the structural properties of mono- and bi-layer graphene. Generalised gradient approximation (GGA) under Perdew-Burke-Ernzerhof (PBE) of the DFT study and pseudopotential method was employed in this research. The monolayer and bilayer graphene have successfully predicted the bandgap and the Density of states (DOS), proving the zero-gap semiconductor tag. Furthermore, the band structure of the monolayer graphene illustrated a toroidal like shape, whereas the bilayer graphene projected a hyperbolic type of band-structure. The hybridisation of graphene was identified as sp^2 in which the bilayer graphene consumed more time for the orbital hybridisation compared to that of the monolayer. Therefore, this study is able to obtain the band gap vale for monolayer and bilayer graphene and provide a detail studies related to bilayer graphene beneficial for semiconductor applications.

Keywords: density functional theory, graphene, quantum espresso, structural properties, bandgap

Abstrak

Struktur karbon dua dimensi (2-D) ini, yang dikenali sebagai grafin, berpotensi besar kerana sifatnya yang unik. Penyelidikan ini mengatasi ketiadaan pengetahuan yang ada kerana kekurangan nilai teori yang signifikan dalam struktur jalur dwi lapisan dan perbandingan yang jelas dari lapisan tunggal dan lapisan dwi grafin dalam kajian sebelumnya. Oleh itu, kajian teori fungsi ketumpatan (DFT) dilakukan menggunakan pakej espresso kuantum untuk menganalisis sifat struktur grafin lapisan tunggal dan lapisan dwi. Kaedah gradien umum (GGA) di bawah Perdew-Burke-Ernzerhof (PBE) kajian DFT dan kaedah pseudopotensial digunakan dalam penyelidikan ini. Struktur jalur dan ketumpatan telah berjaya diramalkan oleh kajian grafin lapisan tunggal dan lapisan dwi, yang membuktikan tanda semikonduktor jurang sifar. Tambahan pula, struktur pita bentuk yang digambarkan untuk grafin lapisan tunggal adalah toroidal manakala grafin dwi lapisan mengunjurkan jenis struktur pita hiperbolik. Hibridisasi grafin dikenal pasti sebagai sp^2 di mana grafin dwi lapisan menggunakan lebih banyak masa untuk hibridisasi orbit berbanding dengan grafin lapisan tunggal. Oleh itu, kajian ini dapat memperoleh nilai jurang jalur untuk grafin lapisan tunggal dan dwi lapisan serta menyediakan kajian terperinci berkaitan grafin dwilapisan yang bermanfaat untuk aplikasi semikonduktor.

Kata kunci: teori fungsi ketumpatan, grafin, espresso kuantum, sifat struktur, jurang jalur

Introduction

Carbon-based materials have advanced at a breakneck pace over the last few decades, particularly in the previous decade. For instance, carbon nanotubes, carbon nanofibers, graphene and carbon sponges [1] are carbon-based materials. The fullerene discovery, the carbon nanotubes, and the graphene have dramatically increased the variety of carbon-based materials available to researchers. The critical experiments of Novoselov and Geim in isolating graphene and identifying its basic properties sparked a surge in interest in graphene [2]. Graphene, as mentioned previously, is a carbon nanomaterial of zero-bandgap [3–4], a planar two-dimensional (2-D) hexagonal lattice [5-14], and sp2 bonded carbon atom [8, 15-17]. These carbon atoms are bound to the of their neighbours in the graphene lattice by σ bonds. The particles in the lattice each have a π orbital [18], which helps form an independent electron network. Graphene has strong electrical conductivity[5, 6, 8, 10-12, 14, 16, 19, 20], because of freedom of the π electrons in 2-D plane of a graphene sheet.

Electron transfer occurs at room temperature and below, resulting in low resistance and high conductivity due to the material's unique band structure [21]. It is said that a two-dimensional (2-D) sheet of crystals is entirely stable, as it is slightly wavy rather than flat. The high-expanded surface area [4, 5, 7, 16, 21-22], electrical conductivity [5, 6, 8, 10-12, 14, 16, 19-20], high-velocity and high absorption rate[23] of graphene add to each other to yield a lot of these properties. To top it all of this, it also has exceptional electrical properties such as low noise and high mobility [5, 7, 9, 21, 24-25]. Great attention has recently been directed toward electronic devices such as biosensors [6, 7, 12, 15], radio frequency (RF) transistors [6], and flexible displays. Aside from this, graphene has a wide range of possible uses in photonics, electronics, optical, and photonic technologies such as electrochemical energy storage [3]. Due to its unique physical properties, monolayer and bilayer graphene-based quantum electronic devices are in-demand today [26]. DFT is very accurate in predicting atomic structures, properties and phonon spectrums [27]. Several interpretations of good accordance between DFT simulations and observational study demonstrate that DFT is highly appropriate and precise for infinitesimal investigations of physics and chemistry. Knowledge of density of states and electronic bandgap is valuable when modelling materials for energy applications, such as graphene.

The experimental value of monolayer graphene from the study of Jeon et al. is reported to be 0.2eV [28]. Zhang and Quhe et al. have found the experimental value of band gap for bilayer graphene and is said to be 0.25eV [29-30]. To investigate the properties of a finite-size graphene sheet, Banerjee et al. experimented with various possible defects and edge effects and used software such as MOLDEN and GAMESS-US [31]. However, this software can be used for generating the molecular and electronic structure only, unlike Quantum Espresso that can calculate the structural and other electrical properties of graphene. Besides, Abbood and co-workers [32] used Gaussian 09 package to study electronic and electrical graphene sheets. Gaussian software utilises local basis functions rather than plane-wave to compute them, so it is more challenging to find basis functions.

In a study done by Geng and co-workers, DFT calculations using CASTEP software was utilised to evaluate the DFT aspects of the interface between graphene and ZnO [33]. Zhu and co-workers also used CASTEP software to study the electronic properties of nano-structural ZnO [34]. Although CASTEP can be used as one of the DFT studies, it has drawbacks at the price as it is licensed software, unlike Quantum Espresso (QE), an open-source code. QE is an open-source quantum mechanical software package with high performance capable of supporting various applications at the nanoscale level, including the design of materials, structural optimisation, and the simulation of atomic electronic structures, all based on DFT theory. The past research proves that Quantum Espresso is the best for studying and analysing the properties of graphene sheets among the other software. Pashangpour and co-workers also used Quantum Espresso to investigate the structural and electronic properties while adhering to Density Functional Theory (DFT) [35]. However, his study has not discovered the value of the bandgap for monolayer and bilayer graphene (AA or AB stacking).

Investing substantial time over the years has taken place to enhance the Quantum Espresso distribution by advancing computational methods, theoretical studies, and property calculations and improving interoperability with external codes [36]. High performance was one of the main motivations behind the Quantum Espresso

project's inception [37]. Past research proves that Quantum Espresso is the best for studying and analysing the properties of graphene sheets among the other software. However, detailed studies of monolayer and bilayer graphene are not discovered using Quantum Espresso. Therefore, this research attempts to do detailed studies on monolayer and bilayer graphene using the DFT study with the Quantum Espresso package.

Computational Details

Density Functional Theory (DFT) [38-44] and the generalised gradient approximation (GGA) known as Perdew-Burke-Ernzerhof (PBE) were used in the PWSCF code to obtain the first-principles calculations. The input files are created using PW Graphical User Interface (GUI) in Quantum Espresso software package under Linux 64-bit. Kohn Sham orbitals are expanded in a plane-wave basis set. Norm-conserving (NC) and ultra-soft (US) forms make up most of the pseudopotentials used in plane-wave electronic structure codes. Thus, this allows for a much lower cut-off in the basis set, which results in a much better cut-off, faster computational efficiency and increased accuracy. Fermi-distribution smoothing was performed using a Monkhorst & Pack (10 × 10 × 1) particular point grid used to perform Brillouin zone integrations, using Gaussian smearing technique with a smearing width of 0.01 Rydberg (Ry).

For monolayer graphene, the energy cut-off (80Ry) and the charge density (320Ry) are set, while for bilayer graphene, these values are 40Ry and 225Ry, respectively. With the ultra-soft pseudopotential of bilayer graphene, using lower cut-off energy is preferable. Variable cell relaxation calculation was done to obtain the optimised cell lattice vectors by introducing Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm as the type of ion dynamics. Relaxation calculation was also performed to get the optimised atomic coordinates essential for other following calculations. Burai Software, a GUI for Quantum Espresso (QE) was used to obtain the unit cell and lattice structure of monolayer and bilayer graphene.

K points were chosen to be *automatic* for Self-Consistent Field (SCF) and non-SCF calculations, whereas k points were set to 'crystal_b' for band calculations. To calculate the density of states (DOS) calculation, grids of (24 × 24 × 1) and (11 × 11 × 3) for monolayer and bilayer graphene, respectively, were used using non-self-consistent field type. The number of bands was set to be 8 for monolayer graphene whereas 16 for bilayer graphene. Another feature of Brillouin zone is that they have been fine-tuned to obtain band structure. XCRYSDEN was used to find paths along the primitive Brillouin zone using k-path selection. After locating symmetrical points on the selection set, the symmetrical points are used for the band calculation. The selected high symmetrical points are tabulated in Table 1 and Table 2 for monolayer and bilayer graphene, respectively. The Quantum Espresso software package computed the bandgap, highest occupied molecular orbital (HOMO), lowest unoccupied molecular orbital (LUMO), and Fermi energy. In order to obtain information about the orbitals, the projected band structure calculation was done.

Result and Discussion

Structural properties

Monolayer and bilayer graphene atomic geometries are optimized as the initial step. This type of calculation is done so that other analysis uses these optimized atomic coordinates, which is beneficial for less or defect-free structure and structural optimization. The bond length between C-C is 1.4214Å which is in excellent agreement with the experimental value of bond length 1.42 Å [45], and the bond angle of C-C-C is 120°. The unit cell and hexagonal lattice structure in 2-D and 3-D viewed in XCRYSDEN for monolayer graphene and bilayer graphene are illustrated in Figure 1 and Figure 2, respectively. The unit cell of monolayer graphene contains two carbon atoms, whereas four carbon atoms are reported to be for bilayer graphene with a lattice constant of 2.467 Å. The AB bilayer is 3.35 Å apart, which is in the range of interlayer distance by past researchers [46-47]. In addition, the shape of the unit cell of monolayer and bilayer graphene is said to be in a lozenge shape. The lattice structure of the monolayer can be seen to be as a single layer of atoms with the axis of direction given in Figure 1(b) & (d). Therefore, these structures are proven accordingly as monolayer graphene, which is in excellent agreement with the experimental design [48]. The lattice structure of the bilayer can be seen to be stacked up as double or two layers of atoms with the axis of direction given in Figure 2(b) & (d). Therefore, these structures are verified accordingly as bilayer graphene, which is in excellent agreement with the experimental design [49]. In AB bilayer graphene, half of the carbon atoms in the upper layer are located above the centres of the lower-layer hexagons. AB bilayer graphene is the most stable [50], and it has a wide range of applications because of its stable characteristics.

The charge density of graphene is visualized under Visualization for Electronic & Structural Analysis (VESTA) software illustrated in Figure 3. Color in the 4 edges of this figure refers to electrostatic potential, where green represents positive charge and orange represents negative charge. The arrow in Figure 3 indicates the yellow color in the unit cell, indicating graphene's charge density. The charge distribution is equally transmitted in the graphene unit cell, implying a minimal structure defect. The output file details are tabulated in Table 3, in which the input file of PP.X was used for data analysis and plotting purposes. The space group of the graphene is P1, where P indicates primitive lattice type and the symbol P 1 refers to triclinic Bravais lattice. The lattice constant is in excellent agreement with the theoretical value of 2.47 Å [42]. The grid size was changed from a smooth grid of (10 x 10 x 1) to a denser grid of (27 x 27 x 216) to view the charge density. Dense grids of k-points are needed for periodic structures.

Electronic properties (density of states)

The density of states represents the number of electron states per unit volume per unit energy. In DOS calculation, the type of calculation used was non-SCF. The solution field minimizes the density charge functional until a predefined limit in the energy difference between two consecutive steps. The non-SCF analysis used a denser grid (24 × 24 × 1) for monolayer graphene and a grid (11 × 11 × 3) for bilayer graphene. Grid size here indicates the lattice size. *nbnd* is specified in this type of calculation, and it represents the number of bands where electron value 8 and 16 is included for monolayer and bilayer graphene respectively. The Brillouin zone is divided into a tetrahedron. The energies of the corners of each tetrahedron are used to calculate the eigen energies. These values are then interpolated to obtain the overall eigen energy. It follows the trapezoidal rule for approximating the integral of single-variable functions, making the tetrahedron method similar. Therefore, the type of occupation was

set to '*tetrahedra*' as this is applicable for accuracy in non-SCF calculation. Figure 4 and Figure 5 illustrate the density of states (DOS) for mono- and bi-layer graphene.

The Fermi energy was set to zero in the axis. It can be interpreted from those figures, the DOS is near 0, around the energy of 0. Since the cones are connected at an infinitely small point with no range or extent in the E-k space of band structure, the density of states is 0 for both monolayer and bilayer graphene. Therefore, there are no states at this point, so DOS is zero. In other words, we can say that the DOS of graphene increases linearly with energy. The bilayer graphene also shows zero DOS because layers' stacking (AB) is through planes and not edges in this study. Figure 6 shows the shapes formed by the bonds between carbon atoms (edge stacking pattern).

AB stacking of bilayer used in this research is of one structure only, which is zigzag pattern similar to plane AB stacking. The AB stacking of bilayer through armchair or zigzag nanoribbons (narrow strips of graphene) has specific DOS and bandgap because it depends on the edge orientation. This value is due to the stacking of layers through edges which can modify the electronic properties of graphene. For instance, in the armchair pattern, the bandgap is dependent on the nanoribbon width, unlike the zigzag pattern. The zigzag structure supports localized states [51-52], resulting in covalent bond formation, bonding and anti-bonding states. Moreover, the zigzag pattern, similar to plane AB stacking, possesses metallic behavior regardless of graphene nanoribbon width [53]. Consequently, the DOS and band gap is still zero for the zigzag pattern. To study the edge stacking in bilayer graphene, LDA should be used. However, GGA was used in this study instead of LDA because GGA gives a minor error and is more accurate in illustrating structural or electronic properties. LDA underestimate the bond length and over-bind, which causes a more significant interatomic force constant (IFC) to be generated [54].

***Electronic* properties (projected band structure)**

The results obtained from the projected band structure are illustrated in Figure 7 for monolayer graphene and Fig. 8 for bilayer graphene, respectively. Two and four atoms were specified for monolayer and bilayer graphene, respectively, based on their unit cell. Therefore, the monolayer has eight atomic states, and the bilayer has sixteen atomic states.

a) $l = 0$ indicates the s orbital
b) $l = 1$ refers to the p orbital
c) $m = -1, 0, 1$ refers to the magnetic quantum number (p_x , p_y , p_z)

The results projected in Figure 7 and Figure 8 concludes that graphene has s and 2p orbitals. The total charge in Figure 8 and Figure 10 for monolayer and bilayer graphene recorded 4.0497 and 3.9553, which gives a value of 4.0 when rounded off to one decimal place. This total charge here represents the number of valence electrons. The spilling parameter setting represents what percentage of the total density is not projected by these schematics. As the spilling parameter gets closer to zero, the representation is more accurate. Therefore, both mono- and bi-layer graphene recorded a value of 0.01, which is in excellent agreement with the accuracy range. Carbon with 6 electrons has $1s^2$, $2s^2$, $2p^2$ ground-state electron configuration, whereby two is in the inner shell, and four are in the outer shell. In graphene, each carbon atom is connected to three other carbon atoms on the two-dimensional plane, leaving one outer shell electron available for chemical bonding. Carbon atoms in graphene have sp^2 hybridized, which means the mixture of a single 2s orbital with two 2p orbitals. The diagram in Figure 9 is the representation of sp^2 hybridization with 120º spacing. Therefore, the orbitals (2s, $2p_x$, $2p_y$) results in trigonal planar (120º apart) structure with the formation of σ bond between carbon atoms. Because of this arrangement, the hexagonal structure of graphene was formed. Carbon's robust lattice structure is due to the σ bond. Since the Pauli principle is in effect, these bands have a filled shell. A valence band is therefore formed. $p_z$orbital covalently bound to carbon atoms occurs along the graphene plane [55]. This $p_z$orbital constitutes the π bond. When joining together, the π bonds form the π band (bonding) and π^* bands (anti-bonding). The π band is half-filled since every p orbital contains one extra electron and is not doped [50]. Most graphene's remarkable electronic properties are credited to these bands because they have a half-filled band that enables free-moving electrons. Because bilayers are hybrids between s orbitals and p_z orbitals, the hybridization is more time-consuming than for monolayer graphene. Therefore, the hybridization for bilayer graphene is more complicated than monolayer graphene.

Besides, the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) can provide information on the chemical stability [56–58]. The gap between the highest energy HOMO and LUMO orbitals is where most likely excited states can be found. Therefore, it is crucial to know the energy gap. Conjugated π orbital systems allow for the transfer of energy more freely within a molecule, helping to keep it stable. Better molecular stability is associated with higher HOMO-LUMO gaps. Monolayer and bilayer graphene have recorded values of 2.034eV and 1.877eV, respectively, for (HOMO - LUMO) gap. Consequently, monolayer graphene is more stable molecularly in this study. HOMO – LUMO gap value from theoretical study reported to be in range of 2.2eV to 3.1eV for graphene quantum dot [59]. However, there's no value reported in experimental study for monolayer and bilayer graphene.

Electronic properties (band structure)

Figure 10 illustrates band structure for monolayer and bilayer graphene obtained from the band calculation explained in methodology. The band structure where two cones touching at the Dirac point is presented in Figure 11. The dispersion of the bands can be visualized from the result as two cones that intersect at the Dirac point. Electron and holes are expected to have the same properties at the Dirac point. The orthogonal π and π^* do not interact, so the crossing of band-structure is possible. The yellow circle in Figure 10 shows the intersection of the valence band (VB) and conduction band (CB) clearer. Results show that graphene is a zero-gap semiconductor because the VB and CB intersect at the Dirac point. Graphene's zero bandgap originates from the carbon-rich environment of the unit cell. In short, electron flow can happen at the top of the VB without any external stimulus, so electrons from the VB can flow into the CB at lower energy.

Graphene's outstanding electrical properties are due to its use of zero-mass, low-energy carriers that behave as relativistic Dirac fermions [55]. An independent energy-independent group velocity is seen in the low energy excitations of graphene's linear dispersion, meaning zero effective mass. Moreover, being massless allows an electron to quickly move within the graphene, which means graphene has high electron mobility. The difference in band structure for both monolayer and bilayer graphene is that monolayer graphene has a toroidal-like shape and exhibits a band state density that approaches zero at the Dirac point. Besides, the density of states rises exponentially from zero energy with bilayer graphene, showing a hyperbolic band structure. Gapless band structure in AB-stacked bilayer graphene results in massive Dirac quasi-particles classified as Dirac Fermions in monolayer graphene [53].

Electron transfer from VB to CB is vital for current to flow. Therefore, electrical conductivity is heavily influenced by the bandgap of the material. In the absence of a semiconducting bandgap, semiconducting materials are impossible. This absence means that applications where graphene performs well, such as high-frequency analogue electronics and transparent conductive films, will be compromised. While silicon-based electronics dimensional scaling is approaching its limit, graphene semiconducting with a sizable bandgap might become the next generation's silicon alternative. Even though symmetry is commonly associated with geometry, it can also be disrupted through stacking two graphene layers in a Bernal stacking (AB stacking) [60]. Bilayer graphene sheets have two valence and conduction bands since they contain four atoms in a unit cell. Bilayer structure offers a new stacking order to fine-tune the electronic properties because of weak interlayer van der Waals interactions (forces). Consequently, modifying bilayer stacked graphene is suitable for fine-tunable electronic circuits or field-effect transistor (FET) applications. Bilayer graphene has been extremely promising since doping or an external electric field could open the energy gap [42,50]. Furthermore, applying external voltage and strain to bilayer graphene can increase the electron's mass [53].

Conclusion

The Density Functional Theory (DFT) study involved a detailed theoretical investigation of monolayer and bilayer. Ultrasoft and norm-conserving pseudopotentials approaches were used in the calculations. Therefore, both Brillouin zone sampling parameters (10 × 10 × 1, k-point) and plane-wave monolayer and bilayer graphene parameters (320eV and 225eV, respectively) were optimized. The results of this study were computed using the open-source Quantum Espresso software package that incorporates the electronic structure software. Using the Broyden-Fletcher-Goldfarb-Shanno (BFGS) force and energy minimization method, monolayer and bilayer graphene were calculated to have a stable geometry. Graphene's very stable lattice and unit cell structure were discerned and observed using XCRYSDEN. The density of states and band gap have been calculated using the band calculation for ground-state properties. In both cases of graphene, zero DOS and 0eV for bandgap were recorded. Using this information, proving the properties of zero-gap semiconductor tags for graphene has been made possible. The shape of the band structure for monolayer graphene differs from bilayer graphene. sp^2 hybridization of graphene is the same for monolayer and bilayer graphene but more time consuming for bilayer. Monolayer graphene is more stable molecularly than bilayer graphene due to having a larger (HOMO – LUMO) gap. Therefore, it is reasonable to assume that results given by Quantum Espresso are reliable, given that the software has proven accurate in both electronic and structural analyses. At times, the absence of a zero-bandgap semiconductor material can hinder the use of electronic and optical devices. Expanding the study to AB stacked bilayer offers tremendous potential for application in devices due to its ability to tune the bandgap. The usage of graphene should not be restricted because it is a promising material. Stacking bilayer graphene with armchair and zigzag edges results in a bandgap value different from the bandgap obtained in this study. This subject is essential and requires more study from a theoretical and experimental perspective.

Abstract

This research proposes reduced graphene oxide (rGO) functionalized with nanoparticles (NPs) from gold (Au), silver (Ag) and platinum (Pt) as a sensing material for the detection of acetic acid gas at low concentrations, from 1 to 5 part per million (ppm). The rGO was functionalized with NPs at different sputtering durations (15 sec and 75 sec) and relative frequency (RF) power (30W and 70W) to study the enhancement of sensing properties. The sensors were exposed to acetic acid from 1 to 5 ppm in the presence of 20% relative humidity (RH) and at 30 °C room temperature. In this work, the Au NPs/rGO (30W 15s), Ag NPs/rGO (30W 15s) and Pt NPs/rGO (70W 15s) sensors were reported to have a good response with sheet resistance, (R_s) at values: 327.2, 453.844 and 201.084 Ω/sq, respectively, compared with the reference sensor, rGO at only R_s, 529.614 Ω/sq. The three sensors had also recorded high R^2 values compared to the reference rGO (0.9448) with values of 0.993, 0.966 and 0.995 for Au/rGO (30W 15s), Ag/rGO (30W 15s) and Pt/rGO (70W 15s), respectively. Thus, the functionalization of rGO with nanoparticles can enhance the sensor's electrical properties and generate good responses for acetic acid gas detection at low concentrations.

Keywords: reduced graphene oxide, functionalization, nanoparticle, response, sensitivity, gas detection.

Abstrak

Penyelidikan ini mencadangkan grafin oksida terkurang (rGO) dan kefungsiannya dengan nanopartikel (NPs) daripada emas (Au), perak (Ag) dan platinum (Pt) sebagai bahan penderiaan untuk pengesanan gas asid asetik pada kepekatan rendah. NPs telah difungsikan dengan rGO pada tempoh percikan yang berbeza (15 saat dan 75 saat) dan kuasa frekuensi relatif (RF) (30W dan 70W) untuk mengkaji peningkatan sifat penderiaan peranti penderia. Penderia didedahkan dengan asid asetik dari 1 hingga 5 bahagian per juta (ppm) kepekatan dengan kehadiran 20% Kelembapan Relatif (RH) dan pada suhu bilik 30 °C. Dalam kerja ini, penderia Au NPs/rGO (30W 15s), Ag NPs/rGO (30W 15s) dan Pt NPs/rGO (70W 15s) dilaporkan mempunyai tindak balas yang baik dengan nilai rintangan lembaran, Rs yang diukur; 327.2, 453.844 dan 201.084 Ω/sq, masing-masing, dengan nilai yang lebih rendah daripada penderia rujukan, rGO sahaja iaitu 529.614 Ω/sq. Ketiga-tiga penderia itu juga mencatatkan nilai R^2 yang lebih tinggi berbanding rGO rujukan (0.9448) dengan nilai masing-masing 0.993, 0.966 dan 0.995 untuk Au NPs/rGO (30W 15s), Ag NPs/rGO (30W 15s) dan Pt NPs/rGO (70W 15s). Oleh itu, kefungsian rGO dengan nanopartikel boleh meningkatkan sifat elektrik sensor dan menjana tindak balas yang baik untuk pengesanan gas asid asetik pada kepekatan rendah.

Introduction

Graphene is a two-dimensional crystalline material that has become a promising sensing element due to its unique properties of having high surface area [1], fast electrical transport, zero bandgap semiconductor [2] and high electron mobility at room temperature [3]. The properties of graphene demonstrate its potential for gas sensing applications with high sensitivity, which is mainly related to the resistivity and adsorption sites of the surface material.

Graphene oxide (GO) and reduced graphene oxide (rGO) derived from graphene can further improve the performance of a material as a sensing element [4]. GO and rGO have good electrical conductivity and sensitive surface adsorbates compared to graphene only due to the crystal defects and oxygen functionalization on its edge and basal [5-6]. A large number of functional groups and defects on rGO provide abundance adsorption sites [7]. Metal oxide nanoparticles such as gold (Au), silver (Ag) and platinum (Pt) have been functionalized with graphene or rGO to enhance the sensitivity of the surface material. Metal nanoparticles are reported to be an excellent catalyst due to their high ratio of surface atoms which increase the subsequent interaction of targeted gases with the absorbed oxygen species on the sensing surface [2,8].

In the medical field, the detection of a volatile organic compound (VOC) through breath analysis has been used as a quick and non-invasive diagnostic procedure to monitor human health. There are hundreds of VOCs used as preclinical biomarkers in diagnosing various pulmonary diseases as they are linked to metabolic activity in the body and provide information about an individual's health [9]. Many gasses were studied for VOC detection such as acetone, toluene, isoprene, acetaldehyde, ethanol, acetic acid, phenol and 2-propanol [10-11]. Acetic acid is a natural biomarker that is correlated with metabolic acids. It is an indicator of airways acidification for a patient with gastroesophageal reflux and cystic fibrosis disease [12]. Thus, a non-invasive approach for the detection of VOC as a breath biomarker is expected to improve health monitoring and early diagnosis [9].

In this study, we report the functionalized rGO with Au NPs, Ag NPs, and Pt NPs as a thin film on resistive VOC sensors for acetic acid detection. Different sputtering durations and powers during the deposition of the nanoparticle on the rGO thin film were tested to study the consequences on the sensing properties. The electrical parameters of the sensing materials, such as sheet resistivity and conductivity, were measured using hall effect measurement. Furthermore, the sensor sensing behavior was determined and studied from the detection of acetic acid gas (1 to 5 ppm) in the presence of 20% relative humidity (RH) at room temperature. The result from this study highlights the material that has suitable fabrication parameters with good performance and sensitivity to low concentrations of acetic acid at room temperature.

Materials and Methods

The rGO was derived from GO films as mentioned in [12]. The rGO layer was spin-coated and reduced at a

temperature of more than 700 °C. Then, the rGO was patterned as sensing material on top of a titanium/platinum (Ti/Pt) interdigitated electrode (IDE) that was deposited on a silicon dioxide/silicon (SiO_2/Si) substrate. The sensor was then loaded into a vacuum deposition chamber for Au NPs (99.99% purity) and sputtered at the duration of 15 sec and 75 sec. The sputtering was carried out in an Ar environment at 0.005 mbar with RF power of 30W and 70W. The lift-off process was done by soaking the sensors in acetone solutions where the photoresist on pads was removed. This process was repeated for Ag and Pt nanoparticles functionalization. The sensor's design is illustrated in Figure 1 and the details of the parameter are described in Table 1.

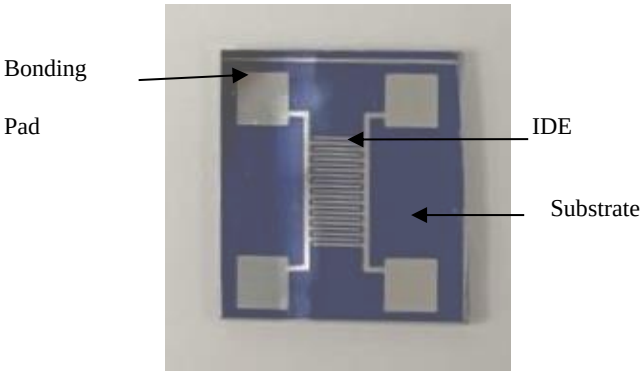

Figure 1. Image of the VOC sensor

Table 1. List of Samples and Parameters of the VOC Sensors

Sample No.	Nanoparticles	Power (WRF)	Time (sec)	Remarks
1	Reference rGO film			Bare rGO
2	Au	30	15	Au NPs/rGO (30W 15s)
3	Au	30	75	Au NPs/rGO (30W 75s)
4	Au	70	15	Au NPs/rGO (70W 15s)
5	Au	70	75	Au NPs/rGO (70W 75s)
6	Ag	30	15	Ag NPs/rGO (30W 15s)
7	Ag	30	75	Ag NPs/rGO (30W 75s)
8	Ag	70	15	Ag NPs/rGO (70W 15s)
9	Ag	70	75	Ag NPs/rGO (70W 75s)
10	Pt	30	15	Pt NPs/rGO (30W 15s)
11	Pt	30	75	Pt NPs/rGO (30W 75s)

13	Pt	70	75	Pt NPs/rGO (70W 75s)

***rGO= reduced graphene oxide, Au NPs = Gold nanoparticle, Ag NPs = Silver nanoparticle, Pt NPs = Platinum nanoparticle**

The electrical properties of the sensors were obtained using hall effect measurement (Ecopia HMS-5300) at room temperature before proceeding with the VOC gas detection test. The experimental setup for the gas sensing system is illustrated in Figure 2. The procedure was the same as mentioned in the previous study [13].

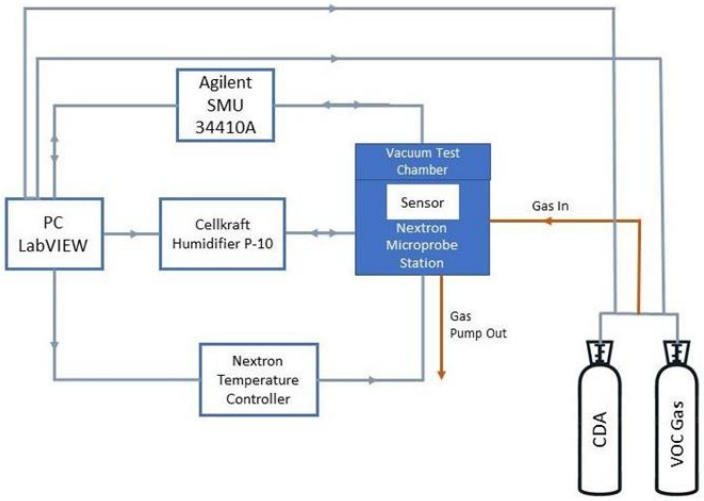

Figure 2. Schematic diagram of the experimental setup for gas detection system

The sensor was put on a sample stage in the Nextron microprobe station. Then, gas testing measurement was applied with a clean exposure method at 20% RH and at room temperature, 30℃. The flow of clean dry air (CDA) was maintained at 1 L/min for 3 min to stabilize the baseline reading for the sensor. Next, the VOC gas was exposed to the sensor at 1ppm for 30 sec. Then, the gas purged out and the CDA was allowed to flow again in 30 sec. The method was repeated by increasing the gas concentration with 1 to 5 ppm. Changes in resistance reading as the signal output were used to measure the sensor response and sensitivity (S) using the formula below [14, 15]:

$$\Delta R = R_{air} - R_{gas} \quad (1)$$

$$\text{Sensitivity (S)} = R_{air}/R_{gas} \quad (2)$$

$$\text{Response} = \frac{\Delta R}{R_{gas}} \times 100\ (\%) \quad (3)$$

Where R_{air} is an average resistance in CDA only, without VOC gas. R_{gas} is an average resistance with the exposure of VOC gas.

Results and Discussion

Surface morphology

Figure 3 shows the FESEM images of rGO thin film sputtered with Au NPs/rGO, Ag NPs/rGO and Pt NPs/rGO for parameters 30W 15 sec, 30W 75 sec, 70W 15 sec and 70W 75 sec with 200k applied magnification for each device. Based on Figure 3, the grain size was increased with the increase of time and power. Good particle formation can be found at 15 sec to 75 sec duration of nanoparticle sputtering. The nanoparticle size for Au and Ag had become bigger as the power and sputtering duration increased. Meanwhile, the grain size for Ag NPs/rGO at 70W began to agglomerate into large entities and become irregular in shape. This may be due to the coalescence of nanoparticles at a longer sputtering duration [16]. Pt NPs still showed a smaller size at 30W and 70W, and the grain size cannot be seen clearly as it was fully deposited onto the rGO thin film compared with Au and Ag NPs.

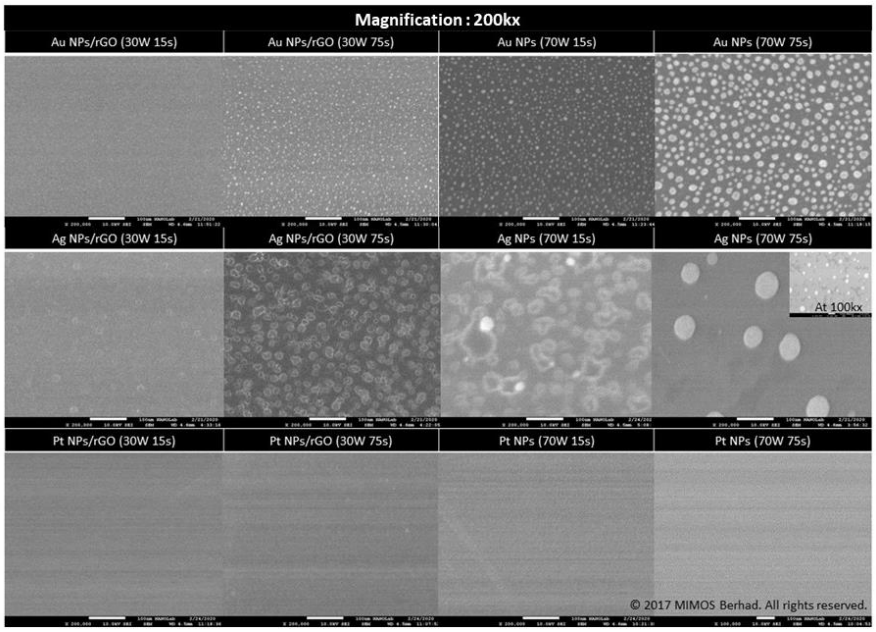

Figure 3. FESEM image of nanoparticle Au, Ag and Pt on rGO thin film after 15 sec and 75 sec sputtering at 30W and 70W

Hall effect measurement analysis

Electrical properties such as average sheet resistivity, Rs, average resistance, R and conductivity, σ of thin film on the samples were obtained from the hall effect measurement and are listed in Table 2. Functionalized NPs except Ag NPS/rGO at 70W had shown lower resistivity compared with the reference sensor, the thin film with rGO only. The NPs' functionalization on the rGO thin film was varied with power and sputtering duration. The variation caused defect concentrations on the thin film and increased the electrical properties of NPs functionalized rGO rather than the thin film of the rGO only [17].

Table 2. List of electrical properties for the VOC sensor

Sensor	Average Resistance Sheet, Rs, (Ω/sq)	Average Resistance, R (Ω)	Conductivity, σ (S/cm)
rGO	529.61	0.000201	4964.56
Au NPs/rGO (30W 15s)	327.20	0.000129	7732.44
Au NPs/rGO (30W 75s)	394.16	0.000154	6475.38
Au NPs/rGO (70W 15s)	394.43	0.000155	6471.26
Au NPs/rGO (70W 75s)	394.84	0.000154	6497.20
Ag NPs/rGO (30W 15s)	453.84	0.000176	5689.86
Ag NPs/rGO (30W 75s)	467.94	0.000181	5518.76
Ag NPs/rGO (70W 15s)	793.39	0.000300	3331.94

Pt NPs/rGO (30W 15s)	270.02	0.000109	9163.50
Pt NPs/rGO (30W 75s)	286.96	0.000116	8595.58
Pt NPs/rGO (70W 15s)	201.08	0.000085	11758.20
Pt NPs/rGO (70W 75s)	426.37	0.000166	6032.040

Figure 4 plots the average sheet resistivity, R_s value for Au NPs/rGO, Ag NPs/rGO and Pt NPs/rGO films at the different parameters. The bare rGO film marked as a reference sensor has a R_s value of 529.61 Ω/sq. Meanwhile, for rGO functionalized with Au, Ag and Pt, the NPs showed a decrease in the Rs value except for Ag NPs at 70 W. The sensor with thin film Au NPs/rGO, Ag NPs/rGO and Pt NPs/rGO at 30W and 15 sec had the R_s value decrease to 327.2, 453. 84 and 270.02 Ω/sq, respectively. However, Ag NPs/rGO at 70W at sputtering time 15 sec to 75 sec showed a gradual increase in the sheet resistivity from 793.39 Ω/sq to 3641.00 Ω/sq, which may be due to the increment of the grain size for Ag NPs at high power. The increment of power and sputtering time during functionalization had increased the grain size of the NPs (refer to Figure 3), thus increasing the sheet resistivity of the thin film. The increased grain size of the nanoparticle had affected the resistivity of the device as the grain boundaries act as scattering centers for the electron [18].

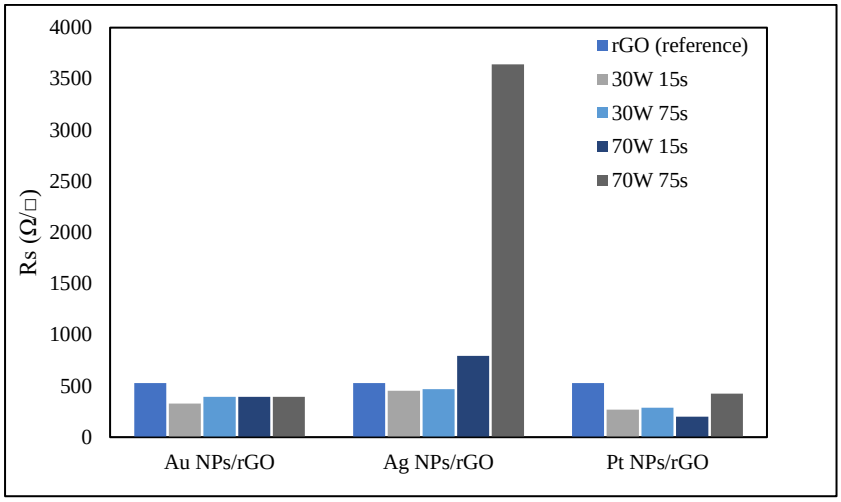

Figure 4. The sheet resistivity of the rGO and the functionalization with nanoparticles at four different parameters

Sensor response measurement

The response from the reference sensor during exposure to acetic acid is shown in Figure 5. At first, when the CDA was exposed to the chamber, the resistance increased due to the removal of electrons that took place by oxygen absorption in the depletion layer. At this phase, the sensor also showed a drift in baseline reading. Drift in sensor response occurs due to many factors, such as the age of the sensor or variation from environmental conditions. For this sensor, the source of the sensor drift may come from the temperature or humidity changes in the chamber [19].

Next, when the acetic acid was purged into the chamber, resistance from the rGO sensing layer began to decrease. This is because the gas molecules reacted with the adsorbed oxygen ions and the electrons were absorbed back into the conduction band [17]. The sensor with rGO and NPs functionalized rGO acted as an n-type semiconductor. Thus, the resistance decreased as the acetic acid acted as a reducing gas on the sensing element.

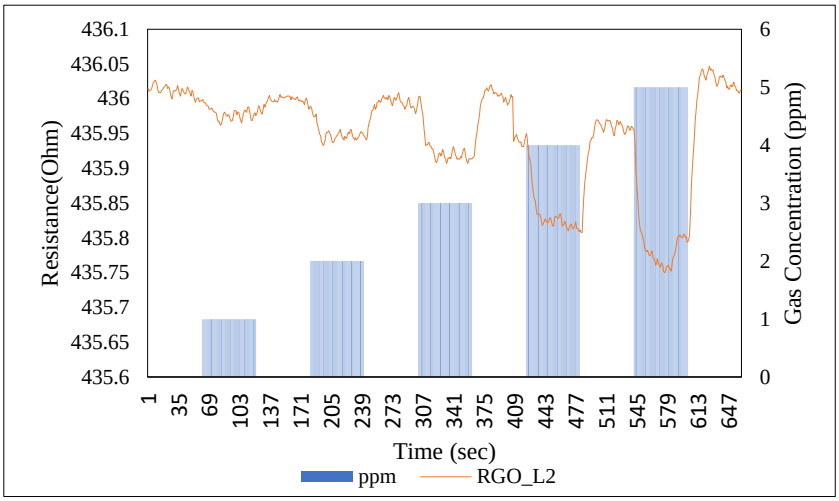

Figure 5. Response rGO thin film-based VOC Sensor on 1 to 5 ppm of acetic acid

Figure 6 shows the average sensitivity for functionalized rGO with a) Au NPs, b) Ag NPs and c) Pt NPs. The sensitivity of the sensor increased as the concentration increased. Meanwhile, Figure 7 showed the R^2 value for the linearity of the sensor response that corresponds with the gas concentration. For sensor selection, the sensor response and the R^2 value were compared for each sensor.

Based on the result in Figure 6a, the Au NPs/rGO sensors had low sensitivity with acetic acid compared with the reference sensor. However, the linearity of the sensor response based on Figure 7 showed that Au NPs/rGO at 30W and 15 sec had R^2 value 0.9869, which was the highest among the others, followed by Au NPs/rGO at 70W and 75 sec. The sheet resistivity for Au NPs was also the lowest at 30W and 15 sec at 327.20 Ω/sq. The sensor conductivity for Au NPs at 30W reached maximum at low sputtering duration, while at high sputtering duration, it was good at high power.

Next, for Ag NPs functionalization, parameter 70W and 75 sec showed a good response compared to the reference sensor. Even though the Ag NPs/rGO (70W 75s) sensor had the highest R_s with 3641 Ω/sq, the sensitivity of the sensors was higher based on the result in Figure 6b. The sensitivity of the Ag NPs functionalized rGO was higher than pure rGO because the attachment of the Ag nanoparticle onto the rGO led to more active sites such as defects and oxygen functional group for adsorption of VOC molecules [20]. Besides that, the agglomerate grain size of Ag NP on the rGO thin film caused it to become more sensitive with the acetic acid. Based on Chen Zhou et al. in their study in 2012, a decrease in the grain size of the nanoparticle on the thin film was reported to be low in electrical and thermal conductivities [21].

Next, for the Pt NPs/rGO sensor in Figure 6c, the sensitivity with the acetic acid was the same as Au NPs which is lower than the pure rGO. The grain size of the nanoparticle can be seen clearly as Ag NPs, however the R^2 value for the Pt NPs/rGO sensor at high power (70W) had a high R^2 value compared to the pure rGO and Pt NPs/rGO at 30W. Based on the hall effect measurement, Pt NPs had low R_s value compared to the pure rGO. However, a good linearity of the sensor response was observed at high power for Pt NPs at 15 sec and 75 sec with 0.9948 and 0.9842, respectively. The Rs value for Pt NPs/rGO at 30W 15 sec had increased from 270.02 to 286.96 Ω/sq. The lowest R^2 value for the Pt NPs at low power can be affected by the duration of sputtering. Pt is commonly used as an electrode as it has high chemical stability and is more stable at high temperature [17], thus, the sensor's sensitivity can be seen as good at high temperature.

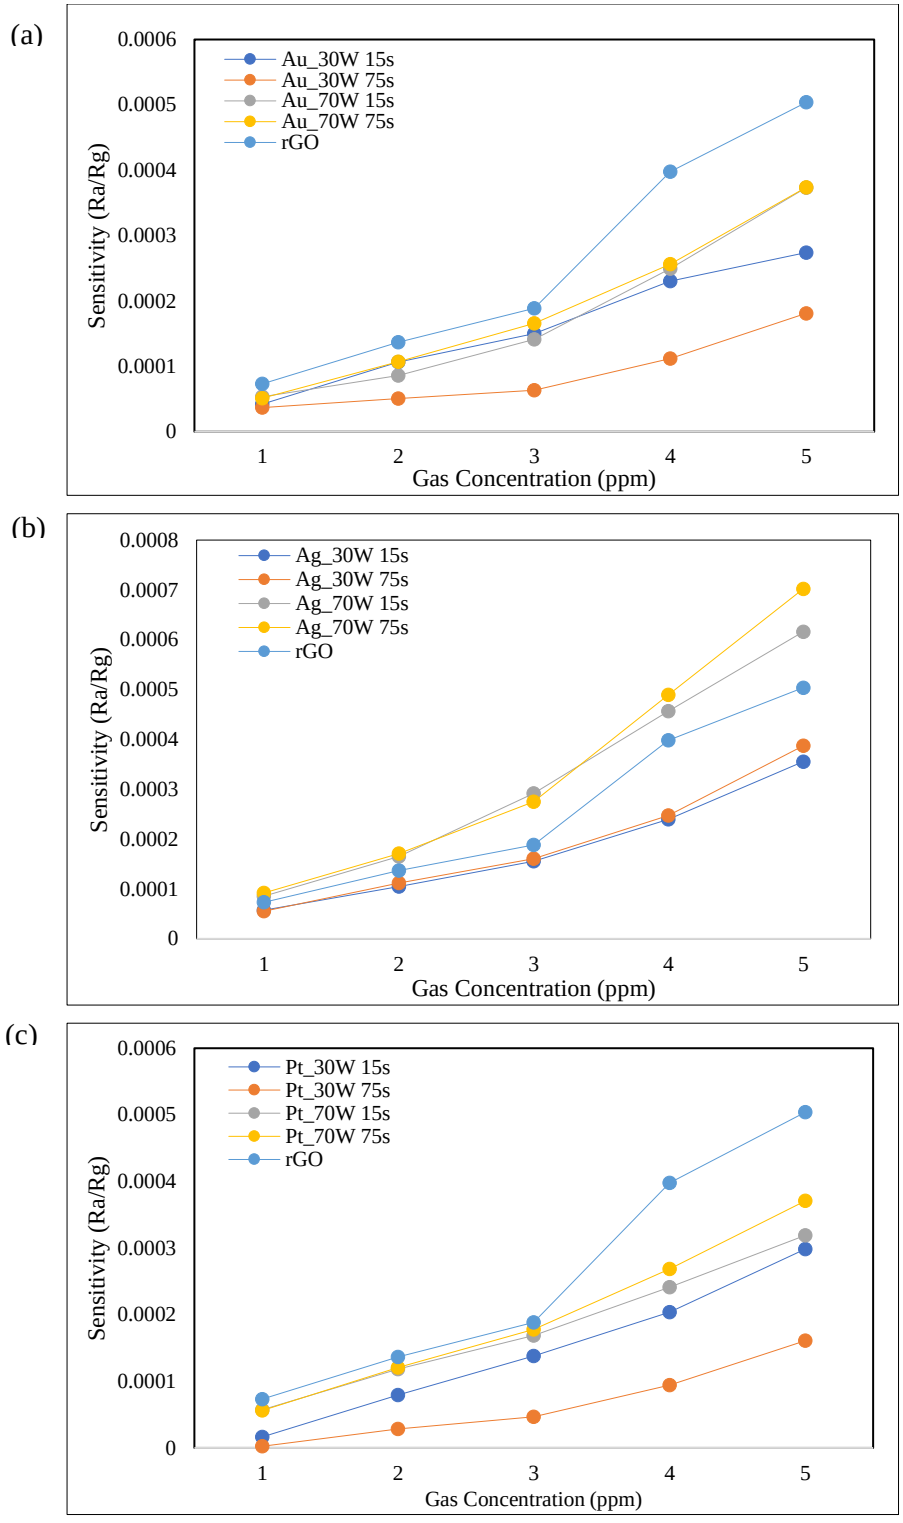

Figure 6. Sensitivity for functionalized rGO with a) Au NPs, b) Ag NPs and c) Pt NPs sensors

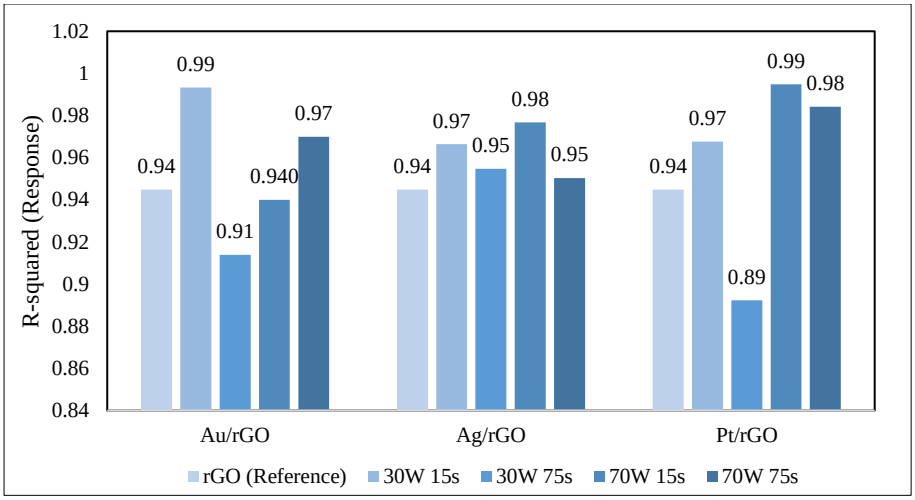

Figure 7. The R^2 value for the sensors on the detection of acetic acid

Conclusion

In this work, the n-type material was separately analyzed to detect reducing gas. The VOC sensors of rGO functionalized with NPs can detect low concentrations of acetic acid at a low operating temperature. The sensitivity results were compared between metal nanoparticles at different powers and durations. However, the cause of sensitivity for different types of nanoparticle functionalization rGOs were affected by different reasons. For Au NPs, the sensitivity of the sensor was influenced by the resistivity of the thin film, while for Ag NPs, the agglomerate of the grain size was more affected. For Pt NPs, high power made the sensor more sensitive to acetic acid. Hence, the study for these sensors can be taken further by varying the sputtering duration at each power and comparing it with more types of gas so that the effect of the nanoparticle on rGO thin film can be understood better and thus can be used for sensor selection.

Abstract

This work describes the gas sensing performance of undoped zinc oxide (ZnO) and ZnO doped with 2 atomic% aluminum (ZnO: Al 2% at.) prepared via the thermal oxidation of zinc (Zn) and Al metal. The prepared films exhibited a polycrystalline structure of the hexagonal ZnO structure. The element composition shows the presence of Zn, O and Al, with Al percentage of approximately 2.2% at. The current-voltage characteristic was used to study the effect of the low hydrogen (H_2) concentrations on the sensing properties of ZnO and ZnO: Al. The maximum response of the undoped ZnO was approximately 100 at an operating temperature of 400 ℃ and increased to approximately 2000 at an operating temperature of 300 ℃ after doping with 2% at. Al. The current study reveals the promising potential for the Al-doped ZnO for low H_2 gas concentrations, as there was an enhancement in the response and reduction in the operating temperature of the doped ZnO with Al.

Abstrak

Kerja ini menerangkan prestasi penderiaan gas untuk zink oksida (ZnO) tanpa dop dan ZnO terdop 2 atom% aluminum (ZnO: Al 2% at.) yang disediakan melalui pengoksidaan terma logam zink (Zn) dan Al. Filem yang disediakan mempunyai struktur polikristal iaitu struktur heksagonal ZnO. Komposisi unsur menunjukkan kehadiran Zn, O dan Al, dengan peratusan Al pada anggaran 2.2% at. Ciri Arus-Voltan telah digunakan untuk mengkaji kesan kepekatan hidrogen (H_2) rendah terhadap sifat penderiaan ZnO dan ZnO:Al. Gerakbalas maksimum ZnO tanpa dop dalam anggaran 100 pada suhu operasi 400℃ dan meningkat kepada 2000 pada suhu operasi 300℃ setelah didop dengan Al. Kajian semasa menunjukkan ZnO terdop Al mempunyai potensi baik pada kepekatan gas H_2 yang rendah, di mana pengayaan dalam respons dan pengurangan dalam operasi suhu terhadap ZnO didop Bersama Al.

Introduction

Recently, metal oxide semiconductor gas sensors have attracted considerable attention due to their applications in integrated circuit processes [1-3]. It is known that semiconductor sensors have been widely used and studied owing to their low cost, small size, and reliability [4-6]. However, the performance of the gas sensors based on metal oxide semiconductors showed drawbacks, as they need high operating temperatures and show a relatively low sensitivity.

The modification and the improvements in the metal oxide semiconductor gas sensors performance can be approached with different paths. Surface modification [7, 8] and doping process [9, 10] are among them. Recently, extensive studies on the doping process and its effect on the gas sensing performance of the metal oxide semiconductor were conducted. Elements such as chromium [10], indium [11], magnesium [12] aluminum (Al) [13-16] and others [17] have been carried out for different gas sensing applications. Aluminium was the most studied element for doping ZnO for several applications, such as conductive transparent layers [18]. In addition, the Al is inexpensive metal and abundant as compared with the other doped elements.

There are many published reports on the application of aluminum as a dopant for ZnO based gas sensors. Paraguay et al. [19] prepared ethanol vapor sensors based on ZnO, and different metals such as tin, indium, Al, iron and copper were used as dopants. No difference in operating temperature was observed. However, the ethanol vapor sensor based on ZnO doped with tin shows the highest sensitivity for ethanol vapor. Hijri et al. [13] prepared ZnO doped with 1-5% atomic Al nanoparticles via sol-gel process. The working operating temperature was in the range of 250-300 ^{o}C. The sensors based on ZnO: Al manifested a higher response than the undoped ZnO sensor in carbon monoxide environment. Zan et al. [20] synthesized ZnO: Al (0.1/0.075/0.05/0.025 mol/L) via a hydrothermal method. Different nanostructure morphologies were prepared, and the operating temperatures of the prepared ZnO: Al nanostructures were almost the same, despite the fact that different nanostructure morphologies were prepared. However, the sensitivity of the disk shape structures was the heights compared to other nanostructure morphologies. Several gases were demonstrated in the study, such as ammonia, carbon monoxide, and H_2. The chemical bath deposition method was conducted to prepare ethanol vapor sensors based on undoped ZnO and doped ZnO: Al. The optimum performance of the prepared sensor was for the sample with Al concentration equal to 2.90 at% [21]. The prepared ethanol sensor was operated at 300^{o}C as a working temperature. Furthermore, Yoo et. al [16] reported on the sensing of acetone by Al-doped ZnO for breath analysis applications. It was reported that doping ZnO with 1 at% Al will enhance the detection performance of the ZnO nanoparticles.

Hydrogen is one of the most gasses demonstrated for their importance as one of the resources of clean energy [22, 23]. H_2 gas is considered as one of the flammable gasses with a wide range of flammability in the air, which is about 4–75% by volume. The lowest limit of H_2 concentration in the atmosphere to cause an explosion is 4.65%, making it one of the most flammable gasses [24]. Sensors with the ability to detect low levels of H_2 ranging from 0.1 ppm to 100 ppm are required for applications involving leak detection in hydrogen fuel systems [23, 25].

Currently, there are few studies regarding the gas sensing properties of ZnO films prepared by oxidation as well as the process of doping it. Furthermore, the effect of the applied bias voltage on the gas sensing performance of the undoped and doped ZnO:Al was not explored wildly. In this study, we prepared zinc oxide (ZnO) and aluminum doped zinc oxide (ZnO: Al) through the thermal oxidation of dc sputtered Zn metal. The aim of this study is to enhance the sensing properties of the ZnO gas sensor through the doping process for H_2 gas sensors.

Materials and Methods

Silicon n-type wafer with (1 0 0) orientation was used as a substrate. Initially, the cleaning process of the wafer is

according to the RCA (Radio Corporation of America) method [26]. A silicon dioxide (SiO_2) thick layer is grown through a thermal oxidation process. Platinum (Pt) is used as a heating element and electrode. The pattern of the heating element and electrodes was carried out using the photolithography technique. Zn metal and Zn + Al thin films were coated using the A306 dc sputtering unit from Edwards. The target was high purity Zn metal target with a purity of >99.99% (diameter 7.62 cm) from (Xiamen Advanced and High-tech Material Co. Ltd, China) for the first batch of samples, while a high purity 2 cm Al rod (99.99% from Sigma-Aldrich (M) Sdn Bhd, Malaysia) with a diameter of 2 mm attached on top of the Zn target for the doped Zn. After reaching a pressure below 1 x 10^{-5} mbar, Ar gas was introduced into the chamber through a needle valve. During this process, the working pressure was held constant at approximately 4.5 x 10^{-2} mbar, and the dc power was maintained at 250 W.

The oxidation process was performed using a controlled tube furnace from Lenton. Both samples were inserted at room temperature, which was subsequently raised up to 400 ℃ at the rate of 5℃.min^{-1} with a constant flow rate of high purity (99.98%) oxygen. The oxidation time was 30 min. The film's color changed to white after the oxidation process. The thickness of the produced films was (300 ± 20) nm as measured by Filmetrics F20 optical reflectometer (based on the optical interference method). PANalytical X-ray diffractometer (HR-XRD) is used to obtain the crystal structure of the prepared films. The diffraction angles were in the range of 20° - 60°. A scanning electron microscope (SEM JEOL model JSM-6460 LV) with an energy dispersion spectroscopy (EDS type INCAx from OXFORD instrument) was used for structure, surface morphology, and elemental analysis of the prepared samples. Atomic force microscope (AFM) was also used for the morphology of the prepared samples' surface.

The current-voltage (I-V) characteristic of the sensor was measured using a programmable KEITHLEY Electrometer – model 617, which also supplied the voltage V ranging from -2 to 2 volts. A DC power supply was used for supplying the voltage to the heating element at the operating temperature between 50 ℃ to 450 ℃. A calibrated K - type thermocouple was mounted on the device to determine the operating temperature of the sensor. After 3 min of turning on the gas flow, the measurements were commenced to ensure a homogeneous distribution of the gas under study inside the chamber. The output current was collected as a function of different H_2 concentration (0-120) ppm. The test chamber was made of stainless steel, creating a volume of about 8200 cm^3. Highly grade 2% H_2 balanced in nitrogen (MOX-LINDE GASES SDN BHD, Malaysia) was used as a test gas. The measurements were taken at room temperature at humidity and temperature of 62% and 25℃, respectively.

Results and Discussion

Structure and elements analysis

The X-ray diffraction patterns of the 30-min thermal oxidation of Zn metal and Al-doped Zn are depicted in Figure 1. The pattern shows the polycrystalline nature of the prepared samples. Furthermore, there was no evidence of Zn metal in both prepared undoped and doped ZnO films, which confirmed the complete conversion of Zn metal to ZnO. The Bragg angles appear at 31.8°, 34.3°, 36.2°, and 56.8°, which belong to the (100), (002), (101) and (102) phases of ZnO (JCPDS card no. 36-1451), respectively. The decrease in the peak's intensity after doping with Al is also worth noting. This might be attributed to the existence of Al_2O_3 grains that interrupt the nucleation of the structure growth [27]. The EDX values for ZnO and ZnO: Al are shown in Table 1, along with their corresponding elemental compositions. It is clear that the Zn:O ratio is almost identical, and that the Al concentration is approximately 2.2at%.

Table 1. The element percentage of the ZnO and ZnO:Al samples prepared through the 30-minute thermal oxidation of Zn and Zn:Al

Elements	Atomic (%)	
	ZnO	ZnO: Al
O	52.48	52.17
Zn	47.52	45.65
Al	-	2.20

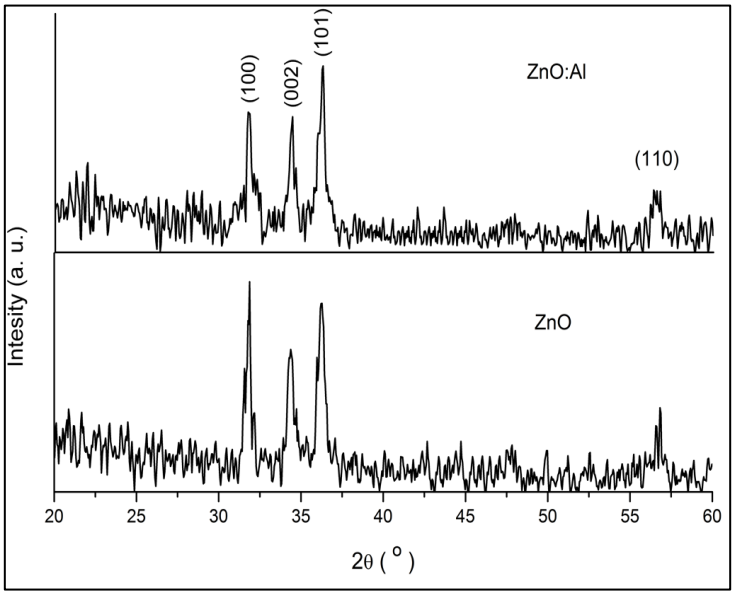

Figure 1. HR-XRD of ZnO and ZnO: Al samples after a 30-minute thermal oxidation at 400 ℃

The SEM and AFM micrographs of the surface of both sensors are depicted in Figure 2. It can be observed that the undoped ZnO surface appears to be more condensed as compared to the doped one, which demonstrated a porous microstructure with larger grains. The enhancement of the ZnO: Al grains size is due to the segregation of Al content into the grain boundaries [28]. The AFM micrograph also confirms that the doped ZnO possesses a rougher surface as compared to the undoped one. The root mean square of surface roughness measured by AFM for the undoped ZnO was 45 nm, which increased to 78 nm for the doped ZnO with 2.2at% Al. Surface roughness and less compact structure may be attributed to the migration of Al dopants towards the grain boundary, where they react with oxygen atoms and segregate as Al_2O_3 [29].

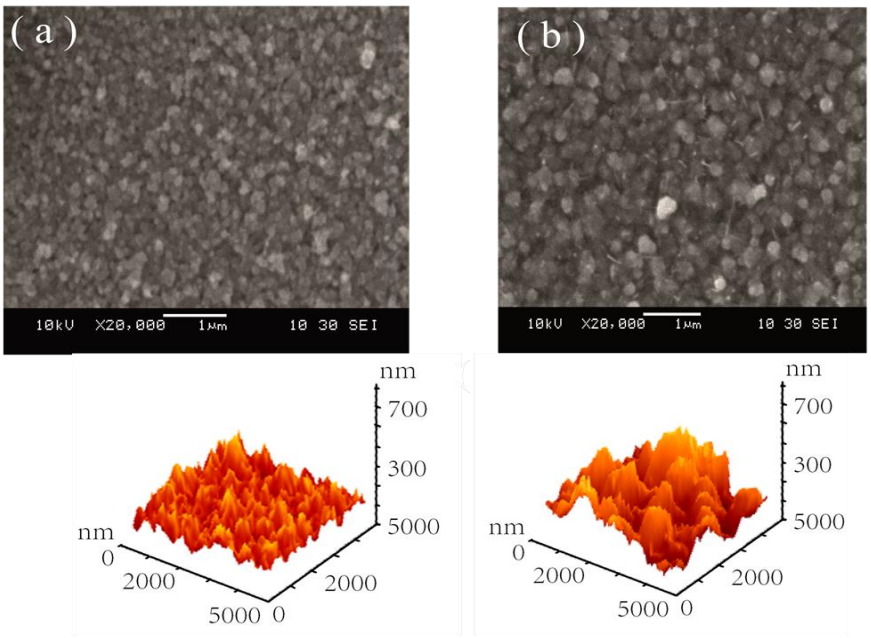

Figure 2. The SEM and AFM micrographs for both (a) ZnO and (b) ZnO: Al were prepared through the thermal oxidation of Zn metal; the bar length is 1 μm

The current-voltage characterization

The resistance of both prepared gas sensors samples in the temperature range starting from room temperature up to 450 ℃ is measured in an air atmosphere, and the results are shown in Figure 3. It is worth noting that the resistance of both sensing materials decreased along with the temperature. This indicates the semiconductor behavior of both prepared samples. Moreover, the resistance of the ZnO: Al was lower than that of undoped ZnO in the temperature range from 50 ℃ to around 250 ℃. The lower baseline resistance could be attributed to the higher charge carrier concentration resulting from the donor nature of the substitution of Al^{3+} on Zn^{2+} sites [28, 30]. These results are comparable with those published [13, 31]. The decrease in sheet resistance at 100-250 ℃ was due to the thermal excitation of electrons into the conduction band. Furthermore, it has been reported that undoped ZnO undergoes a reduction process as the temperature rises to form oxygen vacancies, which are immediately ionized to donate electrons to the conduction band [32, 33]. The next regime of the behavior (above 250℃) exhibited a positive temperature coefficient of resistance (PTCR) for the ZnO sample. However, for the ZnO: Al sample, PTCR appeared in the temperature ranging from 250 – 350 ℃ before giving way to the negative temperature coefficient (NTCR) of the resistance regime at temperatures above 350 ℃. The PTCR regime in the ZnO sample is probably due to the thermal desorption of the (OH^-) layer [34] or the adsorption of various oxygen molecules on the ZnO surface [30].

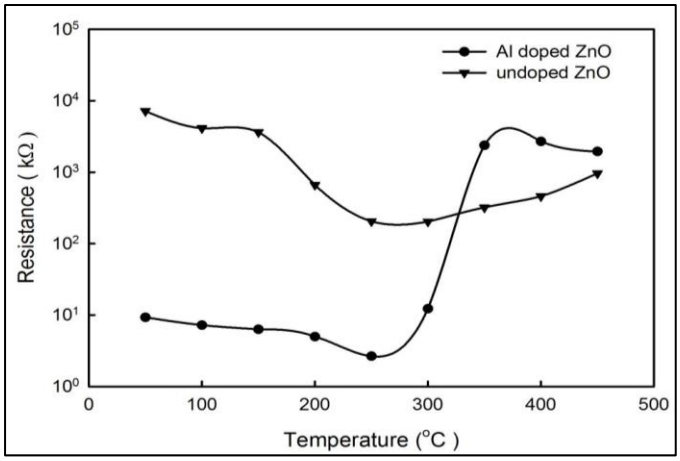

Figure 3. The electrical resistance behavior of the ZnO and ZnO: Al samples

In order to evaluate the quality of the manufactured sensors as well as determine the optimum operating temperature, both sensors were exposed to a fixed concentration of H_2 (100 ppm), while the temperature was varied between 100℃ and 450℃ with a step of 50℃ (there was the insignificant response at temperature lower than 100℃ for both samples). The quality levels of both ZnO and ZnO: Al sensors were estimated by measuring their response (Equation 1), which can be calculated by the ratio of the resistance in the air (Ra) and resistance in the hydrogen gas atmosphere (R_g) [34]:

$$S = \frac{Ra}{Rg} \quad (1)$$

Figure 4 (semi-log graph) reveals the response of both prepared sensors as a function of the operating temperatures. In both cases, the response to the 100 ppm H_2 was increased with the temperature. The maximum response of the undoped ZnO was approximately 100 and occurred at 400℃, and it was approximately 2100 at an operating temperature of 300℃ for the doped ZnO:Al gas sensors. It is, therefore, concluded that the optimum operating temperature is 400℃ and 300 ℃ for the undoped ZnO and doped ZnO:Al gas sensors, respectively.

The reaction rate between the gas under test with the surface absorbed oxygen species is low at low operating temperatures. This is probably due to the high activation energy barrier of the surface reaction. Increasing the operating temperature will enhance the sensor response, which probably is due to the sufficient thermal energy to overcome the barrier height. According to Krishnakumar et al. [35], Patil and Patil [36] and Barreca et al. [8], the adsorbed oxygen may desorb from the surface at higher temperatures (the adsorbed oxygen will not be enough to react with the gas). This will result in decreasing the gas response at higher temperatures. It is obvious that the ZnO: Al sensor has a much lower operating temperature and higher response than that of the undoped ZnO sensor.

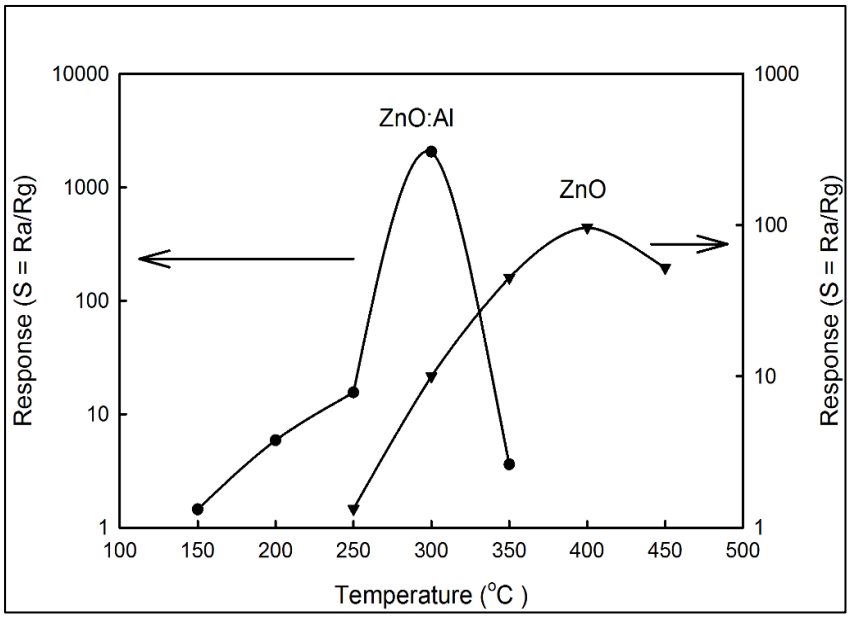

Figure 4. The operating temperature of the ZnO: Al and ZnO gas sensors.

We believe that the enhancement of the gas response at lower operating temperatures is due to the incorporation of the Al metal. Consequently, the surface activity is enhanced as Al has lower ionization energy than the Zn [10]. Furthermore, the modification in the surface nature may consider another factor that might enhance the response of the doped ZnO gas sensor. The increase in the roughness of the surface will result in an increase in the surface to volume ratio, which will allow the gas to penetrate more through the sensitive area of the oxide. On the other hand, the surface is usually dense for the undoped ZnO, and the sensing reactions are restricted to the surface.

Several authors [37, 38] have observed the occurrence of shifting operating temperature by doping; it was found that such an effect is related to the changes in the reaction equilibrium, which strongly depend on operating temperature [38]. Figure 5 shows the current-voltage characteristic of both the undoped and doped ZnO with 2% at. Al in H_2 atmosphere with the concentration ranging from 40 to 160 ppm. The operating temperatures were fixed at 400 ^oC and 300 ^oC for the undoped and doped ZnO, respectively. The figure shows that the current magnitude for both sensors increased as the gas concentrations increased. Furthermore, the current values of the doped ZnO are becoming higher than the undoped ZnO.

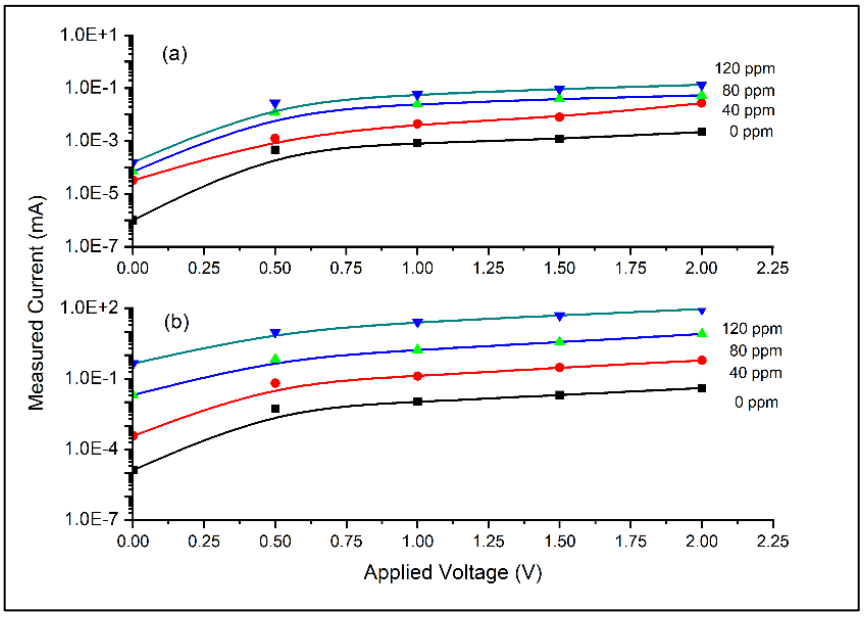

Figure 5. The I-V characteristic of (a) ZnO and (b) ZnO: Al in the H_2 atmosphere with concentration ranging from 40 to 160 ppm

It is well accepted that the detection of reduction gases over the metal oxide surface involves an adsorption−oxidation−desorption process [39]. Here, the oxygen molecules play an important role in this process. Upon the exposure of the metal oxide in the air at elevated temperatures (higher than 200℃, oxygen molecules are adsorbed over at surface of the oxide, and the formation of oxygen ions (O^-, O^{2-} or O^{-2}) will accrue (Equation 2-5), by attracting electrons from the conduction band of the metal oxide. The reaction can be summarized as follow [37];

$$O_2(gas) \Leftrightarrow O_2(adsorbed) \quad (2)$$

$$O_2(ads) + \bar{e} \Leftrightarrow O_2^-(ads) \quad (3)$$

$$O_2^-(ads) + \bar{e} \Leftrightarrow 2O^-(ads) \quad (4)$$

$$O^-(ads) + \bar{e} \Leftrightarrow O^{-2}(ads) \quad (5)$$

This will form a space-charge depletion layer on the surface of the oxide resulting in a reduction of the carrier concentration. When the sensors are exposed to a reducing gas (in this case is H_2), the H_2 gas reacts with the adsorbed oxygen ions on the sensor's surface, and as a result, the electrons will be released back into the conduction band, causing an increase in the produced current, as can be expected (Equation 6) from the following reaction between the hydrogen gas molecules and the adsorbed oxygen:

$$H_2 + O^- \rightarrow H_2O(gas) + e^- \quad (6)$$

As the doping content of Al increases the carrier concentration, this will result in a higher output current as compared to the undoped ZnO gas sensor. The behavior of both undoped ZnO and doped ZnO:Al with the H_2 concentrations from (0 - 120) ppm at a bias voltage of 2V is depicted in Figure 6. It can be observed

that the sensor's measured current increased when exposed to hydrogen up to 120 ppm with a good linearity that proves the suitability of using the ZnO for low hydrogen concentrations.

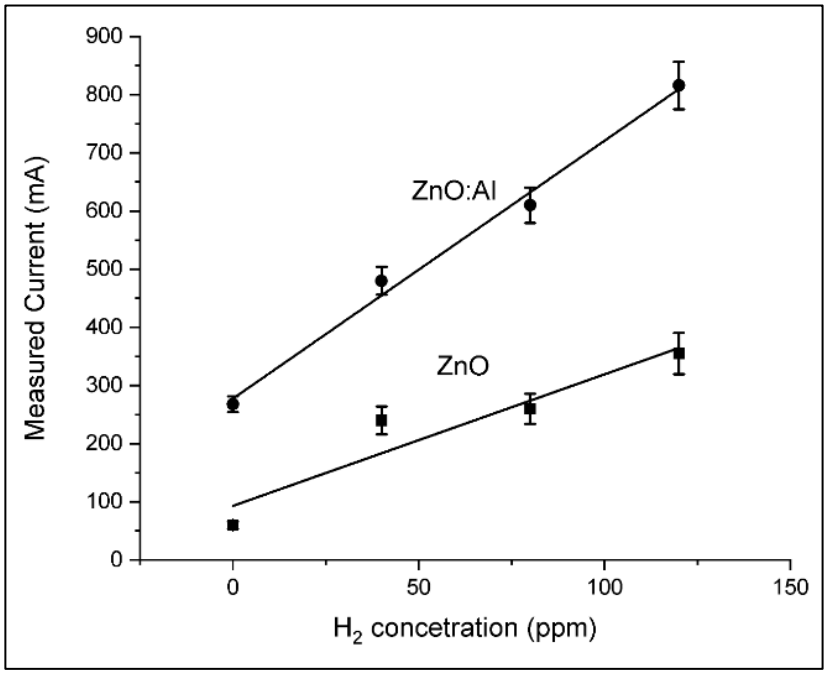

Figure 6. The response of the measured current for ZnO and ZnO: Al when exposed to the H2 atmosphere for different concentration levels. The operating temperature of the undoped and doped ZnO was 400 ℃ and 300 ℃, respectively, and the applied voltage was fixed at 2V

Conclusion

In this study, undoped ZnO and doped ZnO: Al gas sensors were successfully prepared by the thermal oxidation of the Zn metal at 400℃. It was also found that the operating temperature was reduced, and the sensitivity was higher for the doped ZnO: Al sensor. The I – V characteristic of both samples show a significant response for the measured H_2 concentration range. Due to the increase in the carrier concentration of the Al doped ZnO, the enhancement of response was noticed. The results show a potential application of the Al doped ZnO for low range H_2 concentration gas sensors.

Abstract

Tyramine (TYR) in foods have been regarded as a quality indicator of food freshness for assessing microbial action, which potentially affects human health. Enzyme-based electrochemical biosensor technology represents an excessively massive field that significantly impacts food quality control with incredible potential and rapid tools. Thus, this study aimed to immobilize tyrosinase (tyro) over single-wall carbon nanotubes (SWCNTs) onto the screen-printed carbon electrode (SPCE) in the detection of TYR. The characteristics and electrochemical behaviour of the modified SPCEs were investigated by Fourier transformed infrared spectroscopy (FTIR), cyclic voltammetry (CV) and differential pulse voltammetry (DPV). Under optimum experimental conditions, Tyro-SWCNT-COOH/SPCE biosensor exhibit good performance at scan rate 50 mVs^{-1} (range of 10 to 500 mVs^{-1}), pH 8.0 (range of 7.0 – 10.0), 8 µL enzyme tyrosinase (range of 2 to 10 µL), and 0.5 mg/mL SWCNTs (range of 0.2 - 3.0 mg/ml). The modified SPCEs was successfully applied for tyramine (TYR) determination with a detection limit (LOD) of 0.02 mM.

Keywords: tyrosinase, tyramine, screen-printed electrode, single-walled carbon nanotube

Abstrak

Tiramin (TYR) dalam makanan telah dianggap sebagai penunjuk kualiti kesegaran makanan untuk menilai tindakan mikrob yang berpotensi menjejaskan kesihatan manusia. Teknologi biosensor elektrokimia berasaskan enzim mewakili bidang yang luas dimana mampu memberi kesan ketara terhadap kawalan kualiti makanan dengan potensi dan alat pantas yang luar biasa. Oleh itu, matlamat kajian ini adalah untuk mengalihkan tirosinase (tyro) ke atas tiubnano karbon berdinding tunggal (SWCNT) ke elektrod karbon bercetak skrin (SPCE) dalam pengesanan tiramin (TYR). Ciri-ciri dan tingkah laku elektrokimia SPCE yang diubah suai telah disiasat oleh spektroskopi inframerah (FTIR), voltammetri kitaran (CV) dan voltammetri nadi pembezaan (DPV). Di bawah keadaan percubaan optimum, biosensor Tyro-SWCNT-COOH/SPCE mempamerkan prestasi yang baik pada kadar imbasan 50 mVs^{-1} (julat 10 hingga 500 mVs^{-1}), pH 8.0 (julat 7.0 – 10.0), 8 µl enzim tirosinase (julat daripada 2 hingga 10 µl), dan 0.5 mg/ml

SWCNTs (julat 0.2 – 3.0 mg/ml). SPCE yang diubah suai telah berjaya digunakan untuk penentuan tiramine (TYR) dengan had pengesanan (LOD) sebanyak 0.02 mM.

Kata kunci: tirosinase, tiramin, elektrod bercetak skrin, tiub nano karbon berdinding tunggal

Introduction

Tyramine (TYR) is one of the most abundant compounds in a group of biogenic amines (BAs) that are present in a variety of foods due to their capability to show the activity of certain microorganisms such as *Enterobacteriaceae,* including *E. coli* [1–3]. Today, food safety and quality are the main concerns among consumers and health agencies worldwide [4]. Furthermore, TYR can affect human health by stimulating the release of catecholamines from the sympathetic nervous system, which can increase heart rate and blood pressure, which can lead to migraines, hypertension, cardiac failure, and cause serious intoxication effects when ingested in large quantities [5–8]. Due to their toxicity to human health, the optimization parameter for modification of the electrode in the detection of TYR is important.

The demand for safer food quality has promoted more research into BAs quantification over the past few years. Previous work deals with the development of a sensitive and easily fabricated electrochemical biosensor for TYR detection using tyrosinase (tyro) on a glassy carbon electrode [9], such as electrochemical deposition of poly-(8-anilino-1-naphthalene sulphonic acid) attached with gold nanoparticles (AuNP) on gold electrodes (AuE) by polymerization of the monomer [10,11]. However, amongst all of the modified electrodes, screen-printed electrode (SPCE) is the most suitable to be used based on electrochemical analysis in environmental, clinical or agricultural food areas due to its versatility of fabrication, affordability, nontoxic and customizability with nanomaterials and biological elements such as enzymes resulting in the high surface area of the modified electrode [12].

Nanomaterials such as single-wall carbon nanotubes (SWCNT) play an important part in the recent development of enzyme-based biosensors providing advantages such as high catalytic efficiency, rapid response times [13] and enzymes processed with nanoparticles employed to overcome the inherent drawbacks of enzymes [14]. SWCNT is also very good at adsorption, electrical, mechanical, and thermal properties, and it has a lot of surface area, which makes it a good material for the fabrication of electrochemical biosensors and allows them to stay in harsh chemical environments [15]. In addition, SWCNTs that functionalize with carboxylic acid groups (-COOH) help to mitigate this disadvantage by affording the possibility of further chemical derivatization [16].

Enzyme tyro is commonly used to determine analytes containing phenolic compounds [17–19]. Carbon nanotubes act as conductive material and have been commonly used as common approaches for the immobilization of tyro onto various substrates [20]. In previous work by Apetrei, an amperometric TYR biosensor has been developed by immobilizing enzyme tyro on SWCNT-COOH thin film of SPCE electrodes for detection of TYR level in fish products by using amperometric techniques [21]. Other than that, studied by da Silva, the same enzyme tyro was used using a modification of the glassy carbon electrode (GCE) [22].

However, there are only a few reports on tyro immobilized on SPCE with a synthesis of SWCNT-COOH on TYR determination. As a result, more detailed research on the immobilization of tyro over the activated surface of SWCNT-COOH modified SPCE in the detection of TYR is required to determine the best parameter for developing the novel electrode. Thus, in this study, the effect of various compositions on the modification of the electrode Tyro-SWCNT-COOH/SPCE in the detection of TYR was investigated. The optimization focused on the effect of scan rate, pH of the buffer, amount of enzyme and concentration of SWCNT-COOH that contributed to giving the optimum condition of the biosensor in the experiment.

Materials and Methods

Apparatus

Tyrosinase from mushroom (EC 1.14.18.1) ≥1000 unit/mg, carbon nanotube, and single-walled, ≥98%

carbon basis, n-hydroxysuccinimide (NHS), potassium hexacyanoferrate (III) reagentplus®, tyramine, sodium phosphate dibasic (Na_2HPO_4), sodium phosphate monobasic (NaH_2PO_4) were purchased from Sigma Aldrich (St. Louis, MO, USA). Nitric acid (HNO_3) (65%) and sulphuric acid (H_2SO_4) (95-98%) were purchased from R&M Chemicals. The 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) is from G-Bioscience, USA and potassium chloride (KCl) is from Friendemann Schmidt. The stock solution of enzyme tyrosinase and EDC/NHS coupling agent has been aliquoted and stored at -20°C. All reagents used in this research are analytical grade and used without further purification. Water purified with a Milli-Q system (Millipore Milli-Q, Badford, MA, USA) was used for the preparation of all aqueous solutions.

Chemicals and instrumentations

The weight balance and pH measurements (Mettler Toledo) using a pH meter were employed for all pH measurements and calibrated with buffer pH 4, 7 and 10. Elmasonic EASY 120 H was used for ultrasonication of solution, and Beckman counter centrifuges Allegra 64R was used in ultracentrifuge precipitate separation. The electrochemical measurements were obtained using the Autolab (Ecochemie, Utrecht, The Netherlands) potentiostat incorporated with a general-purpose electrochemical system (NOVA 2.1.4), connected to a computer for data processing. The characterization of SWCNT-COOH was carried out using Fourier transform infrared (FTIR) (Perkin Elmer).

Electrodes and electrochemical cell

The electrochemical experiments were carried out using a screen-printed carbon electrode (SPCE) purchased from Rapid Lab Sdn Bhd (Bangi, Malaysia), which was made up of carbon as the working electrode (diameter: 5 mm), silver chloride (AgCl) as the reference electrode and carbon as counter electrodes. Measurement and electrochemical characterization were carried out using cyclic voltammetry (CV), and differential pulse voltammetry (DPV). CV was registered from -0.6 to 1.0 V at a scan rate of 0.05 Vs^{-1} (except otherwise indicated). DPV was registered from 0.0 to 1.0 V with a scan rate of 0.05 Vs^{-1} and a potential of 0.5 V (except otherwise indicated).

Synthesis of SWCNT-COOH

The amount of 200 mg of SWCNTs was dissolved in 200 mL of concentrated sulphuric acid (H_2SO_4) and nitric acid (HNO_3) with a ratio of 3:1. The mixture then undergoes sonication for 6 hours at 60 °C. The solution was allowed to cool, then distilled water was added, and left overnight. The solution was then ultracentrifuged (35000 rpm), the sedimental black solution was collected, and distilled water was used to control the pH until it reached neutral pH 7. After that, the black sedimental solution was collected using a vacuum filtration assembly with (0.45 µm pore size) filter paper. The filtered SWCNT-COOH bedding was dried in an oven overnight at 50ºC, and the obtained SWCNT-COOH powder was characterized using FTIR.

Biosensor fabrication

The 12 µL of 0.5 mg/mL SWCNT-COOH solution was drop cast onto the pre-treated SPCE surface and dried at room temperature for 30 minutes. The 10 µL of 0.5 M EDC/NHS solution was dropped onto the dried SWCNT-COOH/SPCE. After 30 minutes, 10 µL of enzyme tyrosinase solution (2 mg/ml, 200 units activity) was dropped gently onto the SWCNT-COOH/SPCE at 4ºC for 15 minutes, and the electrode was rinsed with PBS to remove the unbonded enzyme. Each analysis was repeated three times.

Immobilization of tyrosinase on SWCNT-COOH/SPCE

Immobilized enzymes onto an SPCE using EDC/NHS coupling were prepared by dissolving 0.048 g of EDC (0.25 M) and 0.029 g of NHS (0.25 M) into a 1 mL polypropylene microcentrifuge tube and 0.05 M phosphate buffer solution (PBS) at pH 7.0 up until the mark. The prepared solution was then stored in the freezer.

Optimization procedure

The parameters that were investigated for the optimization of the modified electrode are the effect of pH of the electrolyte (pH 7.0, 8.0, 9.0 and 10.0), effects of SWCNT-COOH concentration (0.2, 0.5, 1.0. 1.5, 2.0 and 3.0 mg/mL) and the amount of enzyme (2, 4, 6, 8 and 10 µL) by keeping other parameters fixed and changing one factor at a time. All the measurements

were run three times, and the error bars show the standard deviation of the three measurements. The electrochemical response of the biosensor was carried out at 0.50 V in phosphate buffer solution (PBS) at 50 mM in the presence of tyramine (TYR) (0.05 M) using differential pulse voltammetry (DPV) by observing the peak current (ΔI_p) response. For the immobilization of the enzyme, tyro was prepared in a solution of 2 mg/ml as a stock solution (activity 2000 units) before being diluted to 0.2 mg/mL (200 units activity) as a working solution. Six different concentrations of enzyme tyro (≥1000 U/mg) ranging between 2, 4, 6, 8 and 10 µL were used in the fabrication of the biosensor and were directly immobilized onto SWCNT-COOH/SPCE after drop cast of EDC/NHS that act as an immobilization holder.

Result and Discussion

Biosensor fabrication

The biocatalytic performance of an immobilized enzyme system depends mostly on the intrinsic properties of both the biomolecule and its support. Single-walled carbon nanotubes (SWCNTs) possess unique features for tyrosinase (tyro) immobilization by adsorption after drop-casting as the first layer on a screen-printed carbon electrode (SPCE). Thus, the optimum concentration condition of SWCNT-COOH was studied on the DPV peak current (ΔI_p) response of modified electrode tyro-SWCNT-COOH/SPCE at 0.2, 0.5, 1.0. 1.5, 2.0 and 3.0 mg/mL SWCNT-COOH towards TYR determination. The resulting biosensor was denoted as Tyro-SWCNTCOOH/SPCE, as shown in Figure 1. The first layer of modification involves SWCNT-COOH to form a thin solid drop solution onto the flat surface of SPCEs, followed by evaporation of the solution. After that, the enzyme tyro was immobilized over SWCNT-COOH by an adsorption process.

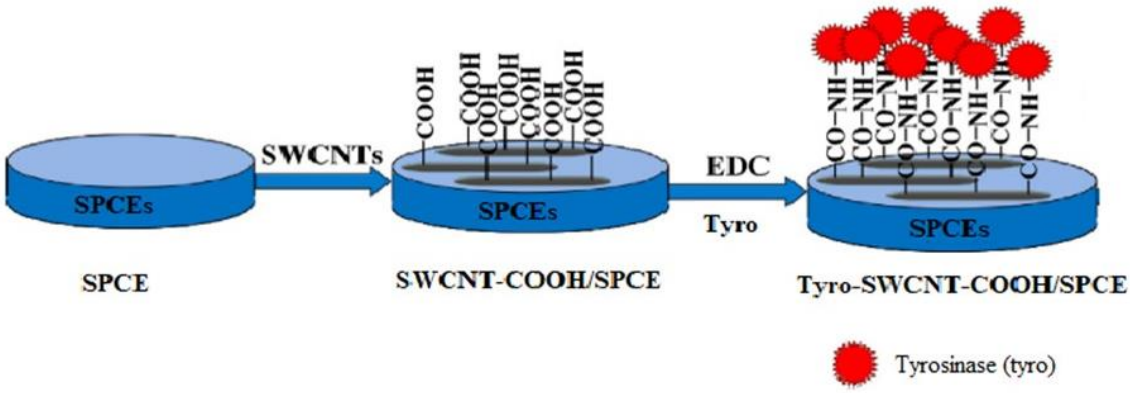

Figure 1. Proposed schematic reaction of the tyrosinase study on the single-walled carbon nanotube carboxyl functionalized (SWCNT-COOH) modified electrode for detection of tyramine (TYR)

Figure 2(a) shows carboxyl functionalized single-walled carbon nanotube (SWCNTCOOH) using the acid treatment method. Chemical manipulation becomes difficult when pristine CNTs are inherently insoluble in organic solvents. Thus, functionalizing the pristine CNTs with carboxylic acid groups will help to mitigate this disadvantage by affording the possibility of further chemical derivatization.

Effective immobilization of the enzymes is a crucial step in the development of high-performance biosensors. In this study, immobilization of tyro onto SWCNT-COOH/SPCE was employed using EDC/NHS coupling to activate the carboxyl groups of SWCNT-COOH that have been drop cast as the first layer of modification. The EDC/NHS activation method can minimize any adverse effects on the bioactivity of target molecules; thus, it was preferred due to its high conversion efficiency and excellent biocompatibility [23].

The EDC/NHS used in this study was 0.25/0.25 M, where the equal amount of EDC/NHS = 0.25/0.25 M shows the most effective concentration for the carboxyl group [24]. The -COOH functionalized groups on the sidewalk of the SWCNT will be used as the precursor for diimidation for the formation of amide bonds with the amine groups of the enzyme. This will be successfully achieved through the reaction of carboxylic acid groups with EDC/NHS to form an amine-reactive ester group that finally bonds to the -NH group in the enzyme, so that the enzyme is immobilized on the electrode. The conjugation of the enzyme reaction pathway onto SWCNTs is shown in the mechanism given in Figure 2(b).

2(a) 2(b)

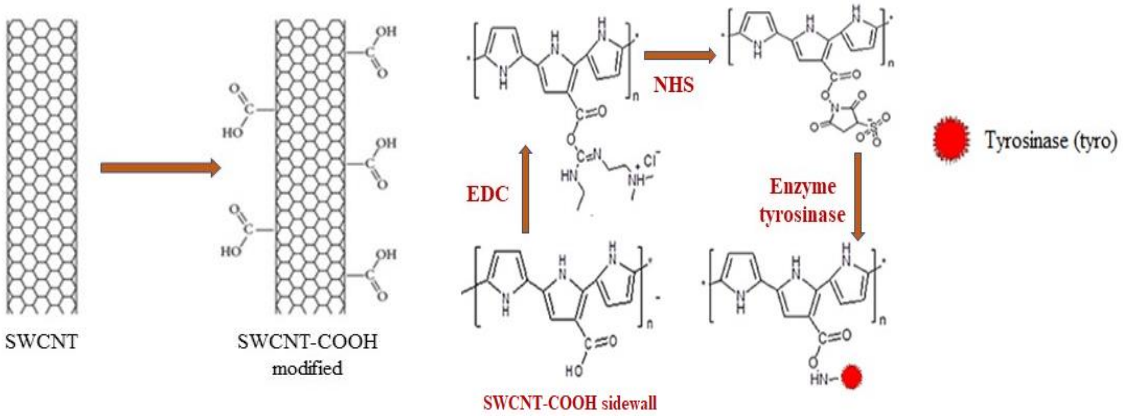

Figure 2. (a) Carboxyl functionalized single-walled carbon nanotube (SWCNT) using an acid treatment method, (b) The EDC/NHS coupling method's mechanism.

Characterizations of the modified electrode

Figure 3 shows the comparison of the total reflection infrared spectra in a range of 4000 - 1000 cm^{-1} for (a) pristine SWCNT and (b) functionalized SWCNT after being treated with H_2SO_4 and HNO_3 acid treatment method, producing SWCNT-COOH. It can be clearly shown that there is a broad peak representing the O-H stretching of hydroxyl groups from carboxyl groups (O=C-OH and C-OH) at about 3296 cm^{-1} [25]. During purification, the partial oxidation reaction occurs, causing the carboxyl group to be present on the surface of pristine SWCNT [26]. The apparent peaks at 1750 cm^{-1} and 1055 cm^{-1} are contributed by the presence of C=O and C-O stretching vibration of the carboxyl group (-COOH), respectively [27]. Meanwhile, the C-H stretch modes of H-C=O in the carbonyl group also indicate the presence of a long-chain alkyl molecule that is attributed to peak 2920 cm^{-1} [28].

FTIR spectra were used to ensure the presence of carboxyl functionalized group -COOH on SWCNT to indicate the successfulness of the synthesis of SWCNT to SWCNT-COOH using the acid treatment method in this study [29]. The functionalization method was used to improve interfacial interactions with nanotubes and to produce a well-dispersed SWCNT composition to drop the SWCNT-COOH dispersion on SPCE during the modification of the electrode. By comparing the FTIR absorption spectra of pristine and SWCNT-COOH, SWCNT oxidized by a mixture of H_2SO_4 and HNO_3 were successfully added with the carboxylic groups (-COOH) to the wall of SWCNT, improving the properties of carbon nanotubes.

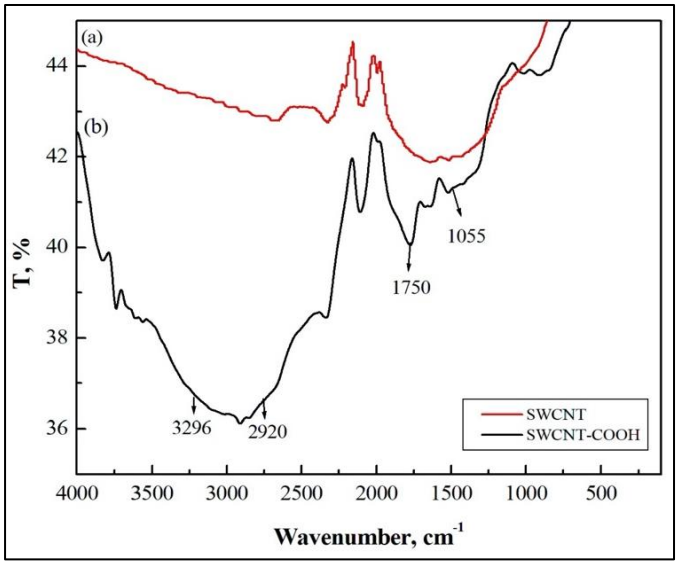

Figure 3. FTIR spectra of (a) pristine single-walled carbon nanotube, (b) functionalized single-walled carbon nanotube

Electrochemical characterization

Cyclic voltammetry (CV) was conducted at 0.50 V to characterize the electrochemical behavior of bare SPCE and modified SPCE. In this study, CV was performed on three different types of electrodes in 0.05 M ferrocyanide $(Fe(CN)_6)^{3-/4-}$ a solution containing 100 mM KCl as shown in Figure 4 (a) bare SPCE, (b) SWCNT-COOH/SPCE, and (c) Tyro-SWCNT-COOH/SPCE. When the surface of the electrode was modified, the ΔIp_a was increased from 34.86 µA at bare SPCE to 97.40 µA and 109.32 µA at SWCNT-COOH/SPCE and Tyro-SWCNT-COOH/SPCE, respectively. The increase in the peak current proves the electrode was successfully developed, which could be described by the transmission of electrons between the electrode and redox probe. The number of electrons transferred can be determined using the peak separation as a criterion for Nernstian behavior. The Randles-Sevcik equation was used to calculate the active surface area of SPCE.

$$I_{pa} = (2.69 \times 10^5)\, n^{3/2} ACD^{1/2} \nu^{1/2} . \quad (1)$$

Based on Equation (1), the real active surface area of the electrode was calculated by substituting the value of n (number of electrons) = 1 $[Fe(CN)^{3-/4-}$ system], A (electrode area) = (22/7) $(0.25\ cm)^2$ = 0.196 cm^2, C (concentration) = 0.05 mol L^{-1}, D (diffusion coefficient) = 7.6×10^{-6} $cm^2\ s^{-1}$ and ν (scan rate) = 0.05 Vs^{-1}. From the calculation, the value of the geometrical surface area of the electrode is 0.126 $cm^{2,}$ and the electrochemical surface area of the real electrode is much larger, as expected. As tabulated in Table 1, the active surface area of bare SPCE was calculated as 4.2091 cm^2 while it was 11.7604 and 13.1997 cm^2 after modification with SWCNT and enzyme tyro, respectively. Thus, higher electron transfer happened at a larger value of active surface area on the modified electrode [26]. This also proved that the modification was successfully improved at each layer of the electrode.

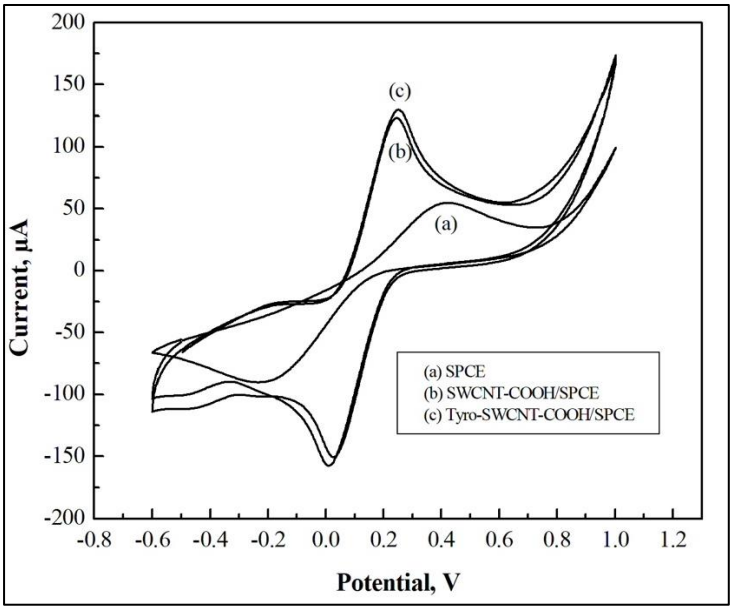

Figure 4. (a) CVs of (a) SPCE, (b) SWCNT-COOH/SPCE, (c) and Tyro-SWCNT-COOH/SPCE (0.05 M $(Fe(CN)_6)^{3-/4-}$ solution containing 100 mM KCl at 50 mVs^{-1})

Table 1: Electrochemical parameters obtained from voltammograms in Figure 4

Electrode	E_{Pc} (V)	E_{Pa} (V)	Ip_c (µA)	Ip_a(µA)	A (cm^2)	Current density (µA/cm^2)
SPCE	0.40	-0.19	-36.67	34.86	4.20	8.28
SWCNT-COOH/SPCE	0.23	0.03	-94.22	97.40	11.76	8.28
Tyro-SWCNT-COOH/SPCE	0.24	0.02	-99.03	109.32	13.19	8.28

Figure 5(a) compares the background current before (solid line) and after modification (dashes-line). The voltammogram of modified SWCNT-COOH/SPCE displayed an increase in peak current as compared to the bare electrode, which can be attributed to the redox behavior of SWCNT-COOH on the electrode surface. Similar voltammogram patterns for carboxyl functionalized on carbon nanotubes (CNT-COOH) were previously reported at different electrode surfaces [30].

The presence of SWCNT-COOH was also verified by CVs measurements in 0.05 M PBS solution containing 100 mM KCl between -0.2 and 1.0 V at a different scan rate of 10, 25, 50, 75, 100, 250, 300, 400 and 500 mVs^{-1}, as shown in Figure 5(b). From the observation, the same pattern is retained from 10 to 100 mVs^{-1} with the appearance of the oxidation peak at 0.1 V, while at a higher scan rate above 250 mVs^{-1}, the redox peak is less visible. According to Venton et al., the rate of diffusion-controlled of the Faradaic currents that occur at the surface of the electrode is proportional to the square root of scan rate resulting in, an increase of background current at a faster rate compared to the Faradaic currents [31]. Thus, the scan rate to be used in this study was at 50 mVs^{-1}.

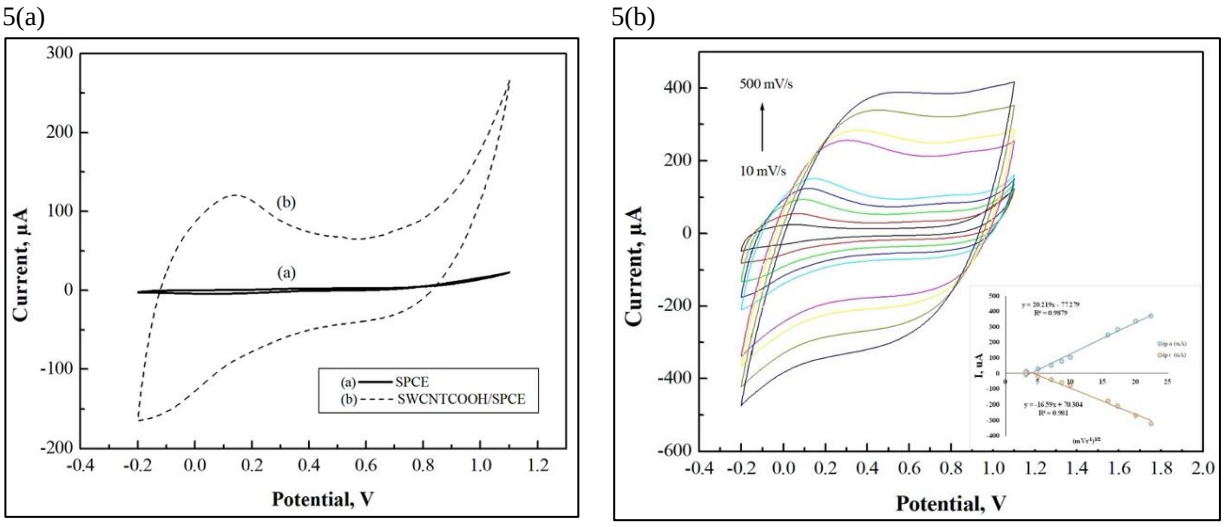

Figure 5: (a) CVs of bare SPCE and SWCNT-COOH/SPCE (50 mM PB buffer solution pH 8.0 containing 100 mM KCl) and (b) CVs of SWCNT-COOH/SPCE (0.05 M PBS solution containing 100 mM KCl) inset: plots of peak current vs square root of scan rate and recorded at 10, 25, 50, 75, 100, 250, 300, 400 and 500 mVs^{-1} inset: plots of peak current vs square root of scan rate.

Optimization of modified electrode composition for determination of tyramine

In this study, the effect of pH was analyzed in a wide range, starting from pH 3.0 to 11.0. Figure 6(a) shows the influence of pH in the detection of tyramine (TYR) at pH 7.0 to 10.0. However, no peak was observed at pH less than 6 and above pH 11 due to the deactivation of tyro under strong acid and alkaline conditions. It can be seen that the activity of tyrosinase (tyro) increased first up to pH 8 and then decreased until pH 10.0. The decreased response of the biosensor might be due to the absence of the biocatalytic activity resulting in enzyme denaturation [32]. Therefore, pH 8.0 was chosen as the optimum pH in all experiments in the electrochemical determination of TYR.

Figure 6(b) shows the effect of the SWCNT-COOH concentration on the modified electrode. This study is important to identify a suitable concentration of SWCNT-COOH on the modified electrode in which increasing performance is correlated with the small size of SWCNT-COOH, which enhanced the large surface area of the electrode. When the enzyme is added in the following stage, the electrode's high specific area allows for the immobilization of higher concentrations of bioreceptor units relative to the biosensor surface [33]. The graph shows an increased pattern starting at 0.2 mg/ml, and a higher reading was observed at 0.5 mg/ml. However, further increasing the concentration of SWCNT-COOH caused a decrease in biosensor response. This can be attributed to the thickness of the nanocomposites that will block the electric conductivity on the surface of the electrode [34]. Thus, 0.5 mg/ml of SWCNT-COOH was selected as the optimum concentration for biosensor fabrication of the SWCNT-COOH layer on SPCE.

Figure 6(c) depicts the effect of increasing the enzyme amount from 2, 4, 6 and 8 L. However, at 10 µL of tyro, a slight decrease in the biosensor response was observed, which can be attributed to the protein loading on the electrode surface rising due to mass transfer diffusion limitation through the electrode surface. Thus, the amount of enzyme at 8 µL was chosen as the optimum parameter in the modification of the biosensor.

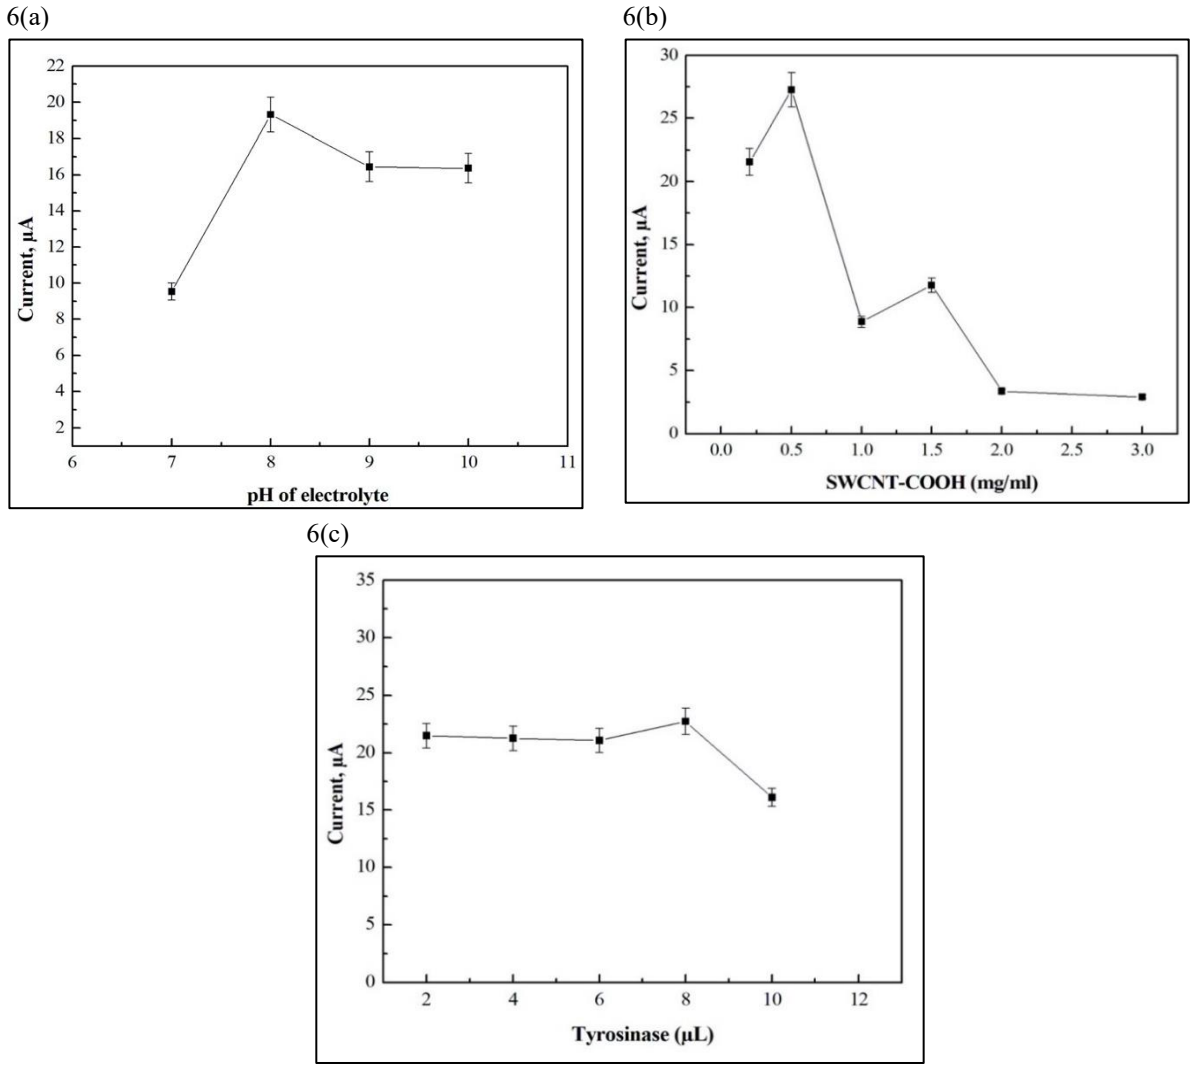

Figure 6. (a) The influence of pH value, (b) concentration of SWCNT-COOH, and (c) amount of tyrosinase on the response of Tyro-SWCNT-COOH/SPCE in 50 mM PB solution containing 0.05 M tyramine at +0.05 V

Figure 7(a) shows the CVs of three-electrode modifications in the presence of 0.05 M tyramine (TYR): bare SPCE (curve a), Tyro-SWCNT-COOH/SPCE (curve b), and SWCNT-COOH/SPCE (curve c) in 0.05 M PB solution pH 8.0, analyzed by CVs from -0.6 to 1.0 V at a scan rate of 100 mVs^{-1}. The peak potential of TYR at modified SWCNT-COOH/SPCE was observed at 0.67 V. While for bare SPCE, no oxidation peak was detected, showing that the modification of electrode SPCE using SWCNT-COOH and enzyme tyro was successfully fabricated. A similar peak potential for TYR oxidation was also reported previously [35].

The standard addition method was investigated to confirm the peak potential of TYR at Tyro-SWCNT-COH/SPCE using differential pulse voltammetry (DPV). Figure 7(b) showed the continuous successive additions of TYR in PBS (0.05 M, pH 8.0) ranging from 0.05 mM to 0.15 mM. The oxidation peak appeared at 0.67 V, and the peak current gradually increased with TYR concentration. From the calibration plot, the correlation coefficient (R^2) was found to be 0.9749 with

a low limit of detection (LOD) value of 0.02 mM. It can be concluded that the Tyro-SWCNT-COOH/SPCE is a sensitive biosensor for TYR detection, which offers lower detection limits.

Conclusion

In this work, a novel biosensor based on Tyro-SWCNT-COOH/SPCE was successfully fabricated, characterized, and optimized for tyramine (TYR) detection. Single-walled carbon nanotubes carboxyl functionalized (SWCNT-COOH) were successfully synthesized and used as a biocompatible matrix for tyrosinase (tyro) immobilization. The SWCNT functionalized -COOH contributed to a suitable microenvironment for immobilization of enzyme, thus retaining the bioactivity of a tyro. The optimum parameters used for this research for the Tyro-SWCNT-COOH/SPCE biosensor exhibit good performance at a scan rate of 50 mVs^{-1}, pH 8.0 of phosphate buffer solution (PBS), 8 µl enzyme tyrosinase and 0.5 mg/ml of SWCNTs. The developed biosensor showed a good lower correlation coefficient (R^2) 0.9749 and detection limits (LOD) of 0.02 mM. All these satisfactory results show that SWCNT-COOH and tyro have good properties as electroactive nanomaterials for biosensor surface modification in the determination of TYR. The biosensor developed could be used to determine TYR in real food sample analysis in the future.

Abstract

We described here an electrochemical immunosensor strip based on a screen-printed carbon electrode (SPCE) for early detection of rice bacterial leaf blight (BLB) disease. The causal agent for this destructive disease has been identified as *Xanthomonas oryzae* pv. *oryzae* (*Xoo*). In order to circumvent the disease outbreak, an early detection system is required. Polyclonal antibody against *Xoo* was employed and immobilized on the SPCE strips modified with polypyrrole (PPy) and functionalized multi-walled carbon nanotube (fMWCNT) network. The anti-*Xoo* antibody is conjugated with horseradish peroxidase (HRP) as an enzyme label and used as the detection agent in the sensor development. Electrochemical detection was carried out via the chronoamperometry technique at a set potential of -200 mV. A fixed anti-*Xoo* antibody concentration at 0.03 mg/mL on the working electrode of the strip surface produced a standard linear curve for *Xoo* detection (R^2 = 0.9746). Two extraction methods for rice leaves (scissors-cutting and grinding) were compared for real samples application analysis. The scissors-cutting method had less matrix interference effect and gave a higher recovery rate than the grinding method. The optimal immunosensor configuration was then compared with the PCR technique for *Xoo* detection in inoculated leaves in a controlled environment. A good correlation of 92.7% was achieved between the two methods. The immunosensor strips were then tested on an Android-based portable biosensor device for on-site detection of BLB in hotspot areas at Bagan Terap, Selangor Northwest and Sg. Burong, Tanjung Karang. On-field detection has indicated that the immunosensor strips can detect BLB disease as early as 15 days after transplant (DAT) before symptoms appear.

Keywords: bacterial leaf blight, early detection, immunosensor, rice disease, *Xanthomonas oryzae* pv.*oryzae*

Abstrak

Satu strip imunosensor elektrokimia berasaskan elektrod karbon bercetak skrin (SPCE) untuk pengesanan awal penyakit hawar daun bakteria (BLB) pada pokok padi dilaporkan dalam kajian ini. Agen penyakit padi ini telah dikenalpasti disebabkan oleh bakteria *Xanthomonas oryzae* pv. *oryzea* (*Xoo*). Bagi mengekang penyebaran penyakit padi ini, satu sistem pengesanan awal penyakit padi adalah diperlukan. Antibodi poliklonal terhadap *Xoo* digunakan dalam kajian ini dan dipegunkan ke atas permukaan strip yang telah diubah suai dengan jaringan polipirol (PPy) dan nanotiub karbon berbilang dinding berfungsi (fMWCNT). Antibodi anti-*Xoo* dikonjugasikan dengan *horseradish peroxidase* (HRP) sebagai label enzim; dan digunakan sebagai agen pengesanan dalam pembangunan sensor. Pengesanan elektrokimia dilakukan dengan menggunakan teknik kronoamperometri pada set potensi -200 mV. Pada kepekatan antibodi 0.03 mg/mLyang dipegunkan pada permukaan elektrod bekerja strip, satu graf piawai linear untuk pengesanan *Xoo* berjaya dibangunkan (R^2 = 0.9746). Bagi aplikasi sampel sebenar, dua kaedah pengekstrakan daun padi (menggunting daun dan pengisaran daun) telah dibandingkan. Kaedah menggunting daun didapati memberikan kesan matriks yang lebih rendah dan kadar pulangan yang lebih tinggi berbanding kaedah pengisaran daun. Kaedah sensor ini kemudian dibandingkan dengan teknik PCR bagi analisis sampel daun teraruh dengan bakteria *Xoo* dalam persekitaran yang terkawal. Korelasi yang baik dengan nilai 92.7% telah dicapai bagi kedua-dua kaedah tersebut. Strip imunosensor ini kemudiannya diuji pada satu peranti biosensor mudah alih berasaskan Android untuk pengesanan BLB di lapangan di kawasan titik panas Bagan Terap, Barat Laut Selangor dan Sg. Burong, Tanjung Karang. Kajian lapangan menunjukkan bahawa strip pengesanan imunosensor ini berupaya mengesan penyakit BLB seawal hari ke-15 selepas transplan (HLT) sebelum kemunculan simptom penyakit.

Introduction

Rice (*Oryza sativa* L.) is an important staple food in Malaysia and the Asia region. However, rice production has always been hampered by the recurrent attack of several rice diseases, causing massive yield and economic loss to the farmers and agricultural industry. In Malaysia itself, rice diseases in a susceptible variety's crop may cause yield reduction up to 70% [1] depending on the stage and duration of water deficit [2]. Bacterial leaf blight (BLB) disease is one of the major rice diseases in Malaysia. This destructive rice disease is caused by *Xanthomonas oryzae* pv.*oryzae (Xoo)*, a gram-negative bacterium. *Xoo* cells invade the rice plants through the wound opening on the leaves. At the initial stage, BLB symptoms appear as tannish-grey to white-yellowish lesions along the leaf's veins, and this alone causes yield losses up to 50% [3]. At advanced stages, however, BLB is difficult to distinguish from the bacterial leaf streak (BLS) disease, and although direct observation of the bacteria is preferred, the indication is not scientifically proven or confirmed.

Chemical control still remains the main method to reduce the infection of bacterial diseases incidence. However, in good plant disease management, the use of pesticides should be minimized. To prevent or control the spread of the disease, it is therefore crucial for farmers or extension agencies to detect the causal pathogens accurately at an early stage. Common practice for rice disease detection relies on the symptom's recognition by experienced plant pathologists or farmers. This technique, however is not scientifically validated. Other laboratory-based methods such as agar plate culture, polymerase chain reaction (PCR), and enzyme-linked immunosorbent assay (ELISA), albeit specific, still require skilled and trained operators to operate them [4]. Furthermore, these techniques are generally not suitable for on-site analysis.

Under this circumstance, there is a considerable need to develop a biosensor system for early and accurate pathogen detection for rice disease management. With this regard, biosensor technology lends itself well due to its attractive features such as rapid detection sensitivity, reliability, inexpensive, simple performance, and most importantly, its ability to provide real-time and on-field analysis [5, 6]. Antibody-based biosensor or immunosensor application for agricultural plant pathogens detection is reported to hold great potential as it allows detection in various sample matrices such as water and seeds [7]. In this study, an antibody-based electrochemical biosensor strip is developed for the early detection of BLB disease. Electrochemical immunosensor has gained much attention in recent

decades owing to their versatility with wide sensing range and high sensitivity [8, 9].

The electrochemical immunosensor works on the principle that the specific binding interaction between antibody and antigen on an electrode strip is sensed and the signal generated is measured and amplified. Surface functionalization on an electrode surface is generally performed using conducting electroactive polymers (CEPs) and/or nanomaterials to provide antibody binding sites and enhance the signal generated. Here, we employ polypyrrole as the CEPs with functionalized multi-walled carbon nanotubes (fMWCNTs) to serve those purposes. MWCNTs-modified biosensor has been widely used due to their superior performance [10], sensitivity, and, most importantly, suitability for biomolecules exposure. When performing an immunochemical reaction, the binding interaction between the biomolecules and their targeted analytes can be performed either by direct or indirect assay format. Herein, a sandwich assay enzyme-linked immunosorbent assay (ELISA) format was adapted and employed in the sensor development.

Following the successful development and performance of the biosensor strips as indicated in the inoculated samples study, the strips were then tested on an Android-based portable electrochemical device for on-site BLB detection in rice fields located at Selangor Northwest. This device is integrated with the Internet-of-Things (IoT) application that allows the analysed data to be stored on a cloud server and accessed by supervisors at different locations instantaneously. The biosensor strips application with a handheld Android device offers flexibility and portability in the IoT-biosensor system [11]. Ultimately, integrating IoT with the biosensor system will greatly change the way plant disease management control, particularly for the early warning system for rice disease detection. Hence the objective of this study is first to develop an immuno-based strip for early detection of BLB disease in rice plants, and secondly, to demonstrate the strips' viability when attached to a custom-made portable biosensor device for on-site application. To the best of our knowledge, the latter has not been reported and ventured by any researchers in rice/plant disease management though several reports on plant disease biosensors have been published [3, 7, 12, 13, 14].

Materials and Methods

Production of polyclonal antibody against *Xoo*

Polyclonal antibody against *Xoo* was raised and developed in-house at Biotechnology and Nanotechnology Research Centre, MARDI Serdang using local isolated cultures from Paddy and Rice Research Center, MARDI Seberang Perai (P0.0, P1.0, and P7.3 strains). The procedure for polyclonal antibody production has been granted with MARDI Animal Ethics Committee Approval (20171103/R/MAEC27). Antibody purification was conducted using the Akta-Prime protein purifier system (GE Healthcare).

Chemicals and reagents

Ethanolamine, phosphate buffer saline (PBS) tablets, pyrrole, sodium bicarbonate ($NaHCO_3$), sodium carbonate (Na_2CO_3), and *3,3',5,5'*-tetramethylbenzidine (TMB) substrate solution were purchased from Sigma-Aldrich, USA. *N*-(3-Dimethylaminopropyl) - *N*'-ethylcarbodiimide hydrochloride (EDC) and *N*-hydroxysuccinimide (NHS) were from Sigma-Aldrich, Japan. Functionalized multi-walled carbon nanotubes (MWCNT-COOH) were supplied from Dropsens, Spain. Plastic-based screen-printed carbon electrodes (SPCEs) were from BioGenes Technologies Sdn. Bhd., Malaysia. EZ-Link™ Plus Activated Peroxidase Kit was from Thermo-Scientific, USA. Phosphate buffered saline (PBS) solution was prepared by dissolving one PBS tablet in 200 mL deionized (DI) water yielding 0.01 M phosphate buffer. All solutions were prepared using DI water from a Milli-Q Ultrapure water system with a resistivity of 18.2 MΩcm.

Surface modification for antibody immobilization

Electrodeposition of polypyrrole and functionalized-MWCNT on the SPCE strip surface was achieved by a one-step electropolymerization of 0.075 M pyrrole in the presence of 0.1 mg/mL MWCNT-COOH via chronoamperometry technique. The mixtures were electrodeposited for 900 s in PBS at a fixed potential of 1.0 V. The strip was then rinsed with DI water and air-dried under nitrogen (N_2) flow. The carboxylic acid group of MWCNT-COOH was activated in a 10 µL

mixture of 0.4 M EDC and 0.1M NHS (1:1) for 15 mins. The excess was washed out using PBS, rinsed with distilled water, and N_2 dried. Next, 5 µL of anti-*Xoo* antibody was dropped on the electrode surface for 1 hour and washed with PBS. The remaining active sites on the SPCE surface were deactivated for 30 mins using 0.1% ethanolamine. *Xoo* cells or samples were placed on the SPCE's working electrode (WE) and incubated for 1 hour. The unbound antigen was washed away with PBS, and 5 µL of purified anti-*Xoo* antibody conjugated with HRP was dropped onto the working electrode and incubated for 30 mins, washed again with PBS. All modification steps were performed at room temperature.

Electrochemical set-up and measurements

Sensor characterization and analysis for the SPCEs were performed on an Autolab PGSTAT 20 potentiostat (Eco Chemie, Netherlands). Unmodified and modified SPCEs were characterized and compared using the cyclic voltammetry (CV) technique in a redox solution of 1 mM FCA in PBS 0.01 M, pH 7.4 (scan rates of 500 mV/s, potential window -0.1 to +0.6 V). Electrochemical measurements for the modified SPCEs with bounded antibody and *Xoo* cells were carried out by placing 50 µL of TMB solution onto SPCEs covering all three-electrode and measured using chronoamperometry at the optimized potential for 300 s.

The developed SPCEs are attached to a handheld Android-based biosensor device for on-site analysis. This portable device with internet-of-things (IoT) integration has been fabricated and developed with BioGenes Technologies Sdn. Bhd., Malaysia. Besides 4G connection with the built-in mobile application, it also has Global Positioning System (GPS) function to pinpoint the location of sampling. This portable electrochemical device consists of two connected hardware units enclosed in a plastic casing. The first unit is a touch-screen Android-based device with developed electrochemical software. The second unit is an electrochemical transducer that converts the signal from chemical reactions into readable and analysable data. The data collected are saved in a central cloud server and can be accessed through the website **https://provenpac.solutions/MARDI/padi** by authorized users. The detection of BLB disease in the rice fields was conducted with a simple extraction method.

Surface morphological study

The microscopic analysis was performed using field emission scanning electron microscopy (FESEM, JOEL JSM-7600F). Samples for FESEM were mounted on the stub, followed by coating with gold. The samples were visualized at 20 kV accelerating voltage with 20,000-60,000x magnification.

Polymerase chain reaction (PCR)

PCR reaction was carried out in a Bio-Rad thermocycler following the conditions: denaturation at 95°C for 5 min followed by 30 cycles of 95°C for 30 s, 58°C for 30 s, and 72°C for 30 s, and final elongation at 72°C for 1 min. The primer used in this study is described in Table 1 below.

Table 1. Primer for BLB disease detection using PCR method

Results and Discussion

Sensor surface modification and characterization

A sandwich enzyme-linked immunosorbent assay (ELISA) format was adapted and employed in the sensor development. Polyclonal antibody against *Xoo* is first immobilized on the modified sensor strip surface, capturing the antigen (i.e.,*Xoo* bacteria) (Fig. 1). Then, a secondary antibody with horseradish peroxidase (HRP) enzyme label, which is associated with the other site of the antigen, is added. Electrochemical detection

was carried out using *3, 3', 5, 5'*-tetramethylbenzidine dihydrochloride (TMB)/H_2O_2 as the enzyme mediator/substrate system and conducted using chronoamperometry at an optimized set potential of -200mV. The enzyme's reaction and its substrate will produce a signal current whereby the intensity of the signal generated is directly proportional to the amount of analyte present in the sample.

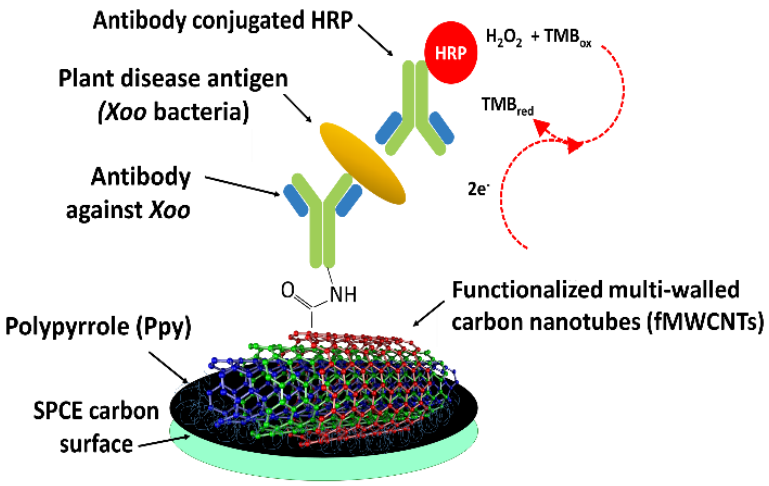

Figure 1. Schematic diagram of electrochemical immunosensor platform employing a sandwich immunoassay format for *Xoo* detection for bacterial leaf blight (BLB) disease

As can be seen from Figure 1, polypyrrole (PPy) and functionalized-multiwall carbon nanotube (MWCNT-COOH) were introduced to the sensor surface. By deliberately attaching or treating certain chemicals or nanomaterials on an electrode surface, the surface would take on the chemical properties of the attached compounds. As carbon material on the SPCE surface is inert, such modification will increase the sensor performance by enhancing the electrochemical properties on the electrode's surface [15]. The challenge of these modified electrodes, though is that they have to be durable and able to retain the activity of the biological receptors so that they do not denature easily and impair the chemical reaction activity. PPy was used in sensor platform modification due to its intrinsic chemical and electrical properties [16]. This type of conducting electroactive polymeris formed under mildly oxidative conditions from aqueous media. The mild conditions used for polymerizations are thus ideal for the immobilization of most of the biological elements in biosensor construction. PPy was incorporated with MWCNT-COOH to improve the sensitivity and selectivity of the biosensor besides providing a high surface area for antibody attachment owing to the carboxylic groups. Several unique properties of MWCNT, such as excellent mechanical strength, superior electrical conductivity, and electrochemically stable in aqueous and nonaqueous solutions, have received much attention in selecting the nanomaterial in sensor surface modification [17]. The EDC-NHS (1:1) was used to cross-link the COOH groups in the fMWCNT with the amine group of antibodies. Amine and carboxyl coupling are commonly achieved via carbodiimide chemistry that utilizes EDC with NHS esters; such has been reported to produce robust amide bond formation [18].

The performance of the modified electrode was characterized by cyclic voltammetry (CV). Figure 2 shows cyclic voltammograms of a bare (unmodified) and modified SPCE in the presence of 1mM ferrocenecarboxylic acid (FCA) in 0.01M PBS pH 7.4. After surface modification with electrodeposited PPy/MWCNT-COOH, peak current was found to increase due to the presence of PPy significantly. The modified electrode's oxidation and reduction peak currents increased two-fold more than the unmodified

electrode (Table 2). This indicates that active surface area has been successfully generated by incorporating the PPy/MWCNT-COOH. Such provides large binding sites and allows more antibody immobilization on the modified electrode surface. PPy has excellent conductivity, increasing the oxidation and reduction current [16] and improving electrochemical performance. On the other hand, MWCNTs incorporated with PPy have effective surface areas that act as supporting matrix for high density antibody attachment and provide a higher selectivity and sensitivity to the analyte of interest [19].

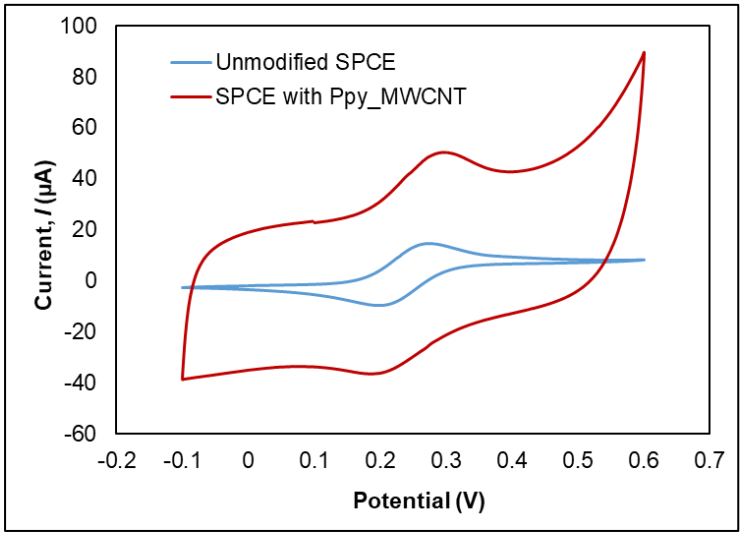

Figure 2. Cyclic voltammograms for an unmodified SPCE (blue line) and modified SPCE with electrodeposited PPy/MWCNT-COOH (red line)

Table 2. Electrochemical properties of unmodified and modified SPCE

	Peak Separation, ΔE(mV)	**Maximum i_{pa} (µA)**	**Maximum i_{pc} (µA)**	**Current Ratio (i_{pa}/i_{pc})**
Unmodified SPCE	63	19.0	-13.3	|0.98|
Modified SPCE	107	50.6	-38.5	|1.03|

Visual characterization of carbon surface prior to and after PPy/MWCNT electrodeposition was analyzed by FESEM. A scanning electron microscopic (SEM) image of the unmodified SPCE surface at 50,000x magnification showed a rough surface structure with the presence of a non-homogenous shape of carbon aggregate (Figure 3a). Following surface modification, typical cauliflower-like structures associated with successful PPy formation are observed (Figure 3b) [20]. Meanwhile, *Xoo* bacteria has rod-shaped cells with flagellum, where each cell has a width in the range of 300-400 nm.

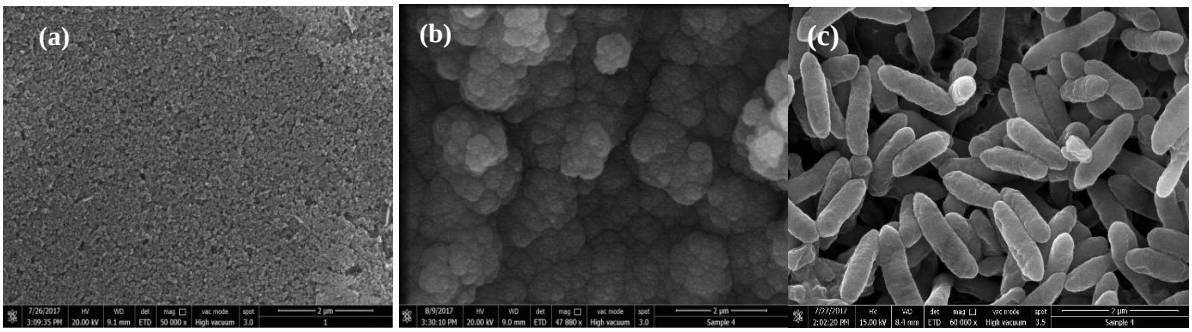

Figure 3. FESEM image of (a) unmodified working electrode (WE) on SPCE, (b) electrodeposited PPy on WE (Magnification of 50 000x); and (c) *Xoo* bacteria cells (Magnification 60,000x)

Development of electrochemical immunosensor

In order to obtain the best detection performance for biosensor development, the set potential was first optimized. Electrooxidative intermediate, produced by the enzyme-substrate interaction, is either oxidized or reduced by the potential applied to the biosensor. Set potential optimization was performed by scanning the potential from -0.6 V to +0.6 V for electrode coated with different concentrations of *Xoo* (i.e. 10^0, 10^2, 10^4, 10^6, 10^8 and 10^9 CFU/mL). The signal current to background current (S/B) ratio was measured. From Figure 4, we can see that the electrochemical current signal was optimum at -0.2 V with a significant S/B current ratio. Hence, -0.2 V was selected as set potential for further study.

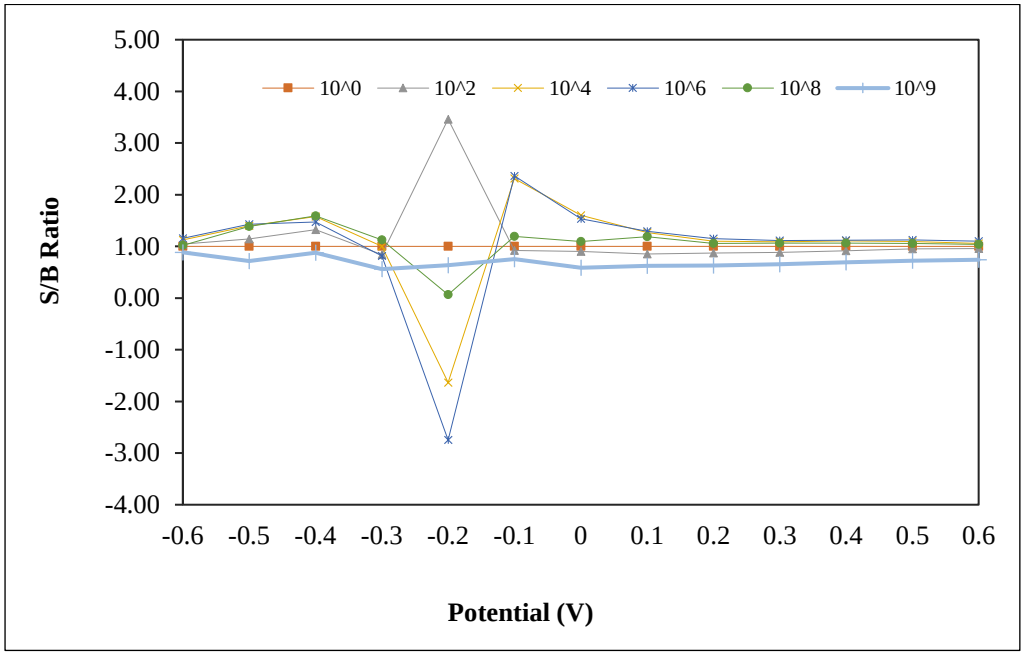

Figure 4. Set potential optimization by scanning the potential window from -0.6 V to +0.6 V

A standard graph was developed at optimized parameters using a mixed culture of *Xoo* (P0.0, P1.0, and P7.3) in carbonate-bicarbonate buffer, pH9.6. The current signal for each concentration of *Xoo* (0 - 10^9 CFU/mL) was recorded via chronoamperometry (CA) analysis at a set potential of -200mV for 300s.

Carbonate-bicarbonate buffer pH9.6 was used as blank control, accounted for 0 CFU/mL standard. An optimal *Xoo* antibody concentration of 0.3 mg/mL is immobilized on the SPCE as previously optimized [21]. The calibration plot of current generated against five concentrations of *Xoo* shows a linear current signal with a correlation coefficient of 0.926 for a linear regression graph (Fig. 5a). The immunosensor developed shows sensitivity with a limit of detection (LOD) at 10^2 CFU/mL. Several parameters have been optimized in order to reduce the non-specific binding in the sensor development, as reported before [22]. These include the dilution for *Xoo* cell cultures in 0.1 M carbonate-bicarbonate buffer, pH 9.6, and the utilization of 0.1% ethanolamine as a blocking buffer as opposed to 0.5% BSA [23].

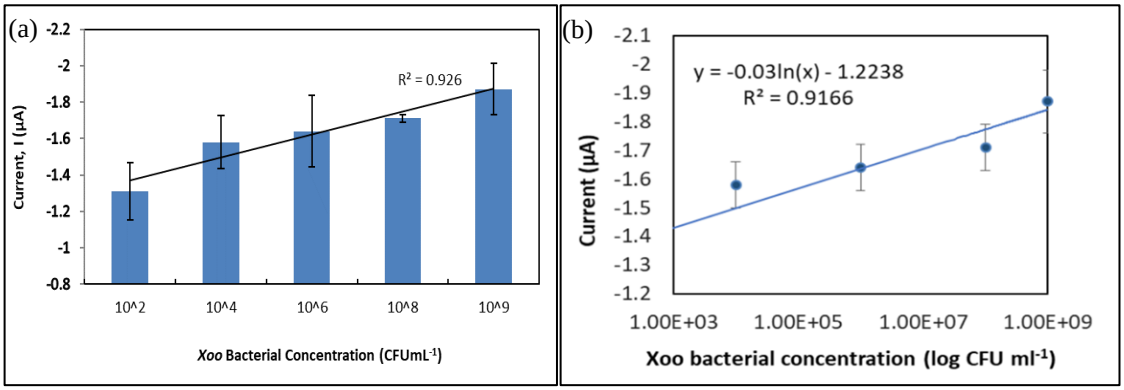

Figure 5. Calibration plot (a) linear regression graph and (b) logarithmic graph of *Xanthomonas oryzae* pv. *oryzae*(*Xoo*) using *Xoo* mixed culture of P0.0, P1.0, and P7.3

The matrix effect study was then performed to investigate the leaves effect in the electrochemical background current. *Xoo* with a concentration between 10^0 to 10^9 CFU/mL were studied in three different matrices, i.e pure culture, ground rice leaves, and cut (with scissors) rice leaves. Standard graph developed in the rice leaves cut using scissors showed excellent current increment response in accordance with the increasing concentration of *Xoo* up to 10^8 CFU/mL. Meanwhile, the standard plot in the grinded rice leaves matrix recorded the lowest current values compared to the other two matrices (Figure 6). Standard curve developed in cut rice leaves also showed good recovery besides exhibiting lower background current at 10^0 CFU/mL (i.e. blank control). Hence, cutting rice leaves with the scissors technique is selected for sample preparation and standard calibration plot development for the next biosensor studies with the real sample application.

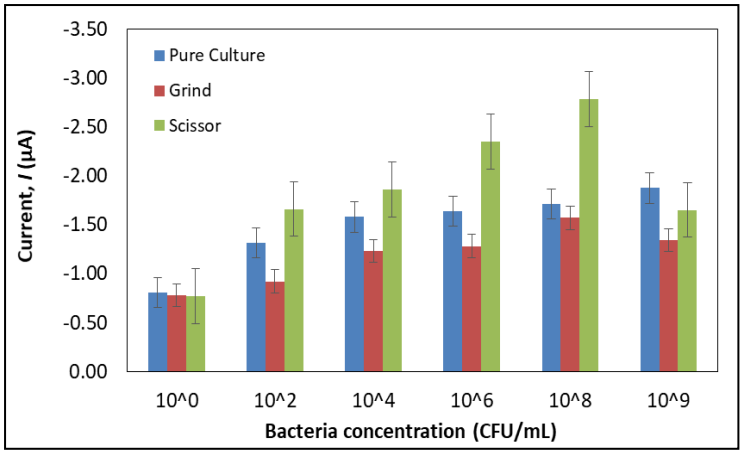

Figure 6. Matrix effect study and comparison of standard plot in different matrix

Performance of BLB disease immunosensor strips in a controlled environment

The performance of the developed electrochemical immunosensor was investigated by testing the strips on artificially infected rice leaves (MR 263 variety) with *Xoo* bacteria. Infection samples were prepared by inoculating *Xoo* in healthy rice leaves in a controlled environment. A total seven bacterial inoculation treatments (*n*=3) with two different inoculation techniques i.e.(i) brushing technique and (ii) scissors-cutting technique at a concentration of *Xoo* 0 CFU/mL (control study with sterile distilled water), 10^2, $10^{4,}$ and 10^8 CFU/mL were carried out. As presented in Table 3, only results from a second replicate (R2) are presented here. The results were determined from the standard calibration curve against the log concentration of *Xoo* cells (CFU/mL). T1R2 and T4R2 are the control study (blank) for brushing and scissors-cutting techniques. While T2R2 and T3R2 were inoculated with 10^4 and 10^8 CFU/mL of *Xoo* respectively by brushing techniques, and T5R2, T6R2, and T7R2 with 10^2, $10^{4,}$ and 10^8 CFU/mL respectively by scissors-cutting techniques.

The developed immunosensor was validated by PCR as a standard method. Table 3 shows the comparison between detection by electrochemical immunosensor strips and PCR for BLB disease detection in 41 inoculated samples. The immunosensor was able to detect the BLB disease as early as the third day of infection with disease agent for T5R2 (inoculation of 10^2 CFU/mL by scissors-cutting techniques) samples. For T3R2 and T7R2 samples, the immunosensor was able to detect the pathogens after 14 days. The results correlate with the PCR method for all the inoculated samples with a 92.7% correlation. This proves that the electrochemical immunosensor system developed has the potential as a bioanalysis tool for the early detection of bacterial leaf blight (BLB) disease and can be used in rice field areas.

Application of immunosensor strips on an IoT-biosensor portable device

A portable biosensor device with internet-of-things integration (IoT-biosensor) was employed for on-site detection of BLB disease using simple sample preparation (Figure 7). The modified strips with antibodies against *Xoo* are attached to the portable reader for sample analysis. Two hotspots for BLB disease are selected for this study, namely rice fields in Sg. Burong, Tanjung Karang and Bagan Terap, Selangor Northwest. The objectives of this study are to investigate the viability of the strips with the handheld device and to simulate a real sample application scenario in the field for future reference. The developed IoT-biosensor device prototype could provide fast data acquisition besides holds potential as a smart biosensor device that can reduce the dependency on bulky instrumentation for detection purposes.

Figure 7. Simple sample preparation on rice field for BLB detection using the fabricated IoT-biosensor handheld device

Table 4 shows the result of on-site analysis on 11 plots of BLB hotspots in Sg. Burong, Tanjung Karang. Samples were collected and tested on the field days after transplant (DAT) of DAT-15 and DAT-25. The results were obtained within 200 s by using the IoT-biosensor device. Results are displayed on the screen and can be stored on a cloud server. The analyzed data and further configurations can be accessed through a dedicated web page https://provenpac.solutions/MARDI/padi. All results were validated by the ELISA method, which used antibody-based detection similar to the immunosensor system developed. The immunosensor strips integrated with the IoT-biosensor device can detect BLB disease at early stage (DAT-15) before the symptoms appear. However, the ELISA method could not detect *Xoo* cells in all DAT-15 samples. All rice plants in the plots were confirmed to have BLB disease at DAT-25, as indicated by both ELISA and IoT-biosensor.

Table 4. Comparison of BLB detection analysis in Sg. Burong, Tanjung Karang hotspot

*DAT	Detection Method	A4	A5	A6	A7	A8	A9	A10	A11	A12	A14	A15
DAT-15	ELISA	-ve										
	IoT-BIOSENSOR	-ve	-ve	-ve	-ve	-ve	+ve	+ve	+ve	+ve	+ve	+ve
DAT-25	ELISA	+ve										
	IoT-BIOSENSOR	+ve										

**DAT=days after transplant*

A second on-field analysis was also conducted in two rice plots in Bagan Terap, Selangor Northwest, late before harvest (i.e. HLT 90-100). As validated by ELISA, Table 5 showed a 100% correlation between IoT-Biosensor with ELISA technique for Plot 1 and 80 % correlation for Plot 2. IoT-Biosensor reader was able to detect the *Xoo* presence even at a very low concentration (sample 2E) when the ELISA technique was unable to detect *Xoo*. The results prove that the IoT-biosensor developed has successfully detected the presence of BLB disease agent below ELISA's detection limit. As reported by Awaludin et al. [14], ELISA methods have limitations where their detection limits are merely in the range of 10^4-10^5 CFU/mL where as our immunosensor strip can detect as low as possible 10^2 CFU/mL.

Table 5. Comparison of BLB detection analysis in Bagan Terap, Selangor Northwest hotspot

BLB Hotspot	IoT-Biosensor	ELISA
1A	+ve	+ve
1B	+ve	+ve
1C	+ve	+ve
1D	+ve	+ve
1E	+ve	+ve
2A	+ve	+ve
2B	+ve	+ve
2C	+ve	+ve
2D	+ve	+ve
2E	+ve	-ve

Compared to other findings on BLB detection using an immunological approach, a Western Blot method using polyclonal antibody against *Xoo* has reported detecting *Xoo* cells at 3.5 x 10^3 CFU/mL [24]. Immuno-based assay using monoclonal antibodies developed by Wu et al. [25] have LOD of 1×10^4 CFU/mL for ELISA and 1×10^5 CFU/mL for immunochromatographic. The immunosensor strips described and developed here are superior to those afore mentioned techniques as they have better and lower LOD of 10^2 CFU/mL. Although a fluorescence-based immunoassay for BLB detection employing the same antibody source as ours has a lower LOD of 22 CFU/mL [14], this method still requires a fluorescence spectroscopy to measure the wavelength thus, portability is a major hindrance.

Conclusion

Here, we have demonstrated the development of an electrochemical immunosensor strip for the early detection of *Xoo* bacteria, the causal agent for bacterial leaf blight disease (BLB) in rice. Early detection mechanism in an efficient plant disease management can reduce the damage and losses due to pathogenic infections. A sandwich assay enzyme-linked immunosorbent assay (ELISA) format was adapted and employed in the sensor development. Surface modification with electrodeposited polypyrrole and functionalized multi-walled carbon nanotube (PPy-fMWCNT) network has greatly improved the sensor strip's performance, as indicated by electrochemical characterizations. A standard calibration plot in pure mix culture of *Xoo* (P0.0, P1.0, and P7.3) has been developed with R^2=0.9166. Scissors cutting for rice leaves was chosen for sample preparation and used in the development of a standard calibration plot for a real sample application. The efficiency of the developed electrochemical strips were tested on inoculated rice leaves samples, and show good sensitivity and high correlation with the PCR method. The electrochemical immunosensor strips were then integrated with an Android-based IoT-biosensor device suited for on-site detection purposes. The system was successfully applied

and tested on rice fields in BLB hotspot areas in Selangor. By using the immunostrips, early detection of BLB has been identified on DAT-15 as indicated by later infection stage using both sensor and ELISA techniques. This Android-based portable handheld reader with the developed immunostrips for BLB disease will eventually be an innovative on-site rice disease detection tool prior to the appearance of any visual symptoms so that corrective measures can be taken to prevent the spread of disease.

Acknowledgement

We thank the Malaysian Agriculture Research and Development Institute (MARDI) for the research funding under the development project (RMK-11) and our appreciation to all the members who have been directly or indirectly involved in this project throughout the years.

Abstract

Mycotoxins have been a huge threat in the agriculture and poultry industries. In Malaysia, the presence of mycotoxins, particularly in grain corn, is not only detrimental to health; it may also have a detrimental effect on the economy, as we rely heavily on this source for animal feed. With this regard, a rapid detection method of mycotoxins on-site lends itself well in reducing the negative economic impact and strengthening the food safety aspect. We report here an electrochemical-based biosensor for mycotoxins detection in grain corn employing differential pulse voltammetry technique. Polyclonal antibodies against Aflatoxin B1 and Ochratoxin A were developed in-house and used in the sensor development. Cross-reactivity study with intra and interspecies proved the selectivity of developed antibodies. The antibodies were then immobilized on a screen-printed carbon electrode functionalized with gold nanoparticles and polyaniline. The developed immunosensor system showed significant performance in both phosphate buffer solution (PBS) and grain corn matrix systems. Excellent R^2 and low limit of detection (LOD) values were achieved in a broad working range for both buffer conditions. Aflatoxin B1 displayed R^2 of 0.9935 and LOD of 0.6 ppb in PBS; and R^2 of 0.978 and LOD of 1.81 ppb in grain corn matrix. Ochratoxin A displayed R^2 of 0.9962 and LOD of 0.87 ppb in PBS; and R^2 of 0.971 and LOD of 3.18 ppb in grain corn matrix. The LODs obtained for both detections are lower than the maximum residues limit (MRLs) permitted for grain corn (5 ppb). Both aflatoxin and ochratoxin biosensors exhibited acceptable recoveries in the 90% to 120% recovery range in grain corn matrix. This successful method could be applied and widened to other cereal grains and their processed food products.

Keywords: aflatoxin B1, ochratoxin A, immunosensor, differential pulse voltammetry, grain corn

Abstrak

Mikotoksin merupakan satu ancaman kepada industri pertanian dan ternakan. Di Malaysia, kehadiran mikotoksin terutamanya dalam jagung bijian bukan sahaja merbahaya kepada kesihatan, tetapi juga membawa kesan yang buruk kepada ekonomi berikutan kebergantungan sepenuhnya kepada jagung bijian sebagai sumber makanan haiwan. Dalam hal ini, kaedah pengesanan pantas mikotoksin di lapangan dapat mengurangkan kesan negatif kepada ekonomi di samping memperkasa aspek keselamatan makanan. Kami melaporkan biosensor berdasarkan elektrokimia untuk pengesanan mikotoksin dalam jagung bijian dengan menggunakan teknik voltametri denyut beza. Antibodi poliklonal terhadap Aflatoksin B1 dan Okratoksin A telah dibangunkan secara dalaman dan digunakan dalam pembangunan sensor. Kajian tindakbalas silang intra dan interspesies membuktikan selektiviti antibodi yang dibangunkan. Antibodi kemudian dipegunkan di atas elektrod skrin-bercetak karbon berfungsi dengan nanozarah emas dan

polianilin. Sistem immunosensor yang dibangunkan menunjukkan prestasi yang signifikan dalam kedua-dua sistem larutan penimbal fosfat (PBS) dan matriks jagung. Nilai R^2 dan had pengesanan rendah (LOD) yang baik dapat dicapai dalam julat bekerja yang luas bagi kedua-dua keadaan penimbal. Aflatoksin B1 menunjukkan R^2 0.9935 dan LOD 0.6 ppb dalam PBS; dan R^2 0.978 dan LOD 1.81 ppb dalam matriks jagung bijian. Ochratoxin A menunjukkan R^2 0.9962 dan LOD 0.87 ppb dalam PBS; dan R^2 0.971 dan LOD 3.18 ppb dalam matriks jagung bijian. LOD yang didapati bagi kedua-dua pengesanan adalah lebih rendah daripada had residu maksimum (MRL) yang dibenarkan untuk jagung bijian (5 ppb). Kedua-dua biosensor aflatoksin dan okratoksin menunjukkan perolehan yang boleh diterima dalam julat perolehan 90% to 120% dalam matriks jagung. Kaedah yang terbukti berjaya ini boleh digunakan dan diperluaskan kepada lain-lain bijian dan produk makanan terproses.

Introduction

Potent mycotoxins such as aflatoxins, ochratoxins, fumonisins, zearalenones and trichothecenes are produced by microfungi such as *Aspergillus* species, *Penicillium* species and *Fusarium* species, which are specific to certain mycotoxins [1]. The presence of those fungi on crops does not guarantee the production of harmful mycotoxins. However, poor aeration and high humidity during storage can accelerate mycotoxins production and eventually lead to serious crop contamination [2]. Natural weather or environmental changes in certain countries or regions also contribute to mycotoxins' occurrence. For instance, the natural tropical weather of Malaysia has led to manifestation of *Aspergillus* species and *Fusarium* species in soil, resulting in contamination of aflatoxins and *Fusarium* related mycotoxins in agricultural crops [3]. In addition, initial contamination can also take place during harvesting, followed by a lack of good processing, handling and transport practices [4]. Primary corn processing such as cleaning, dry milling, steeping and wet milling can help to reduce the level of mycotoxins in food samples but do not entirely eliminate them [5, 6]. Therefore, most of the food or products are already severely contaminated before being consumed by animals and humans. Figure 1 shows the distribution of mycotoxins from contaminated crops to animals and humans.

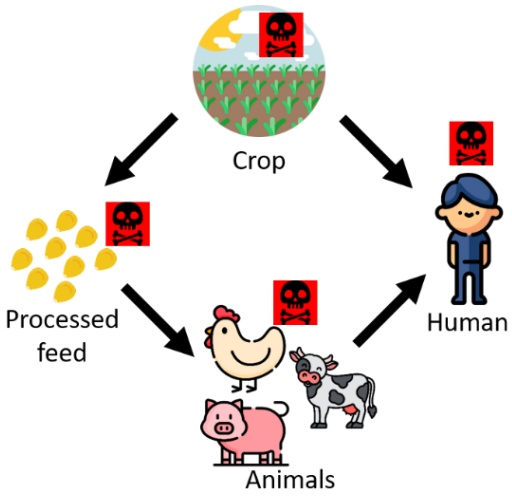

Figure 1. Distribution of mycotoxins from contaminated crops to animals and humans

Mycotoxins are not a minute problem as the occurrence of mycotoxins in food and feed is a global issue and not only subject to certain parts of the world. Even though most places have different natural weather and environment, mycotoxins always have their ways to exist. Ten years of research were conducted by Gruber-Dorninger and team in 2019 [7] to study the occurrence of mycotoxins in 15 regions around the globe. The commodities tested included feed, soybean (grains and meal), corn (silage and grains), wheat, barley and rice.

From the study, deoxynivalenol and fumonisin contaminations were collectively found to be dominating the toxins occurrence in the commodities. The other mycotoxins class also exceeded the maximum limit regulated for each region. Occurrence and contamination of mycotoxins from other studies were also in correspondence with the result obtained [8-12].

The concern for mycotoxins arises due to the alarming consequences of mycotoxin contamination. Crops yield, animal health and productivity, human health, economy and food security are the most affected area, and they are closely related to each other. Low crops productivity due to contamination can cause low income for farmers as no contaminated products are allowed in the market [13]. Consecutively, their well-being can be affected in many ways, such as accessibility to decent food and health care. This situation also applies to animals. Factors such as growth depression, low nutrient absorption, reproductive problems, and low egg production and hatchability result from low mycotoxin consumption of contaminated feed, which is highly associated with declining animal productivity [14]. High ingestion of mycotoxins can lead to acute health problems such as liver, kidney and gastrointestinal damage, haemorrhaging and, in the worst case – death. Since most mycotoxins are carcinogenic, human also shares similar health problems such as oesophageal and liver cancer, alimentary toxic aleukia, kidney disease, cardiac beriberi and death [15]. In terms of economic impact, the final consumer has to pay a high price for the finished products due to the low availability of feed and food in the market, processing and handling cost and regulatory services for monitoring mycotoxins [4]. The United States, Africa and South-East Asia recorded annual losses of around USD 1.68 billion, USD 750 million and USD 1 billion, respectively, as a result of aflatoxins contamination. Eventually, with all these arising problems, food security will be a major concern in the near future.

The most common and conventional mycotoxins detection methods are thin-layer chromatography, gas chromatography, liquid chromatography and real-time polymerase chain reaction [16,17]. Normally, gas and liquid chromatography analysis is often coupled with mass spectrometry to enhance the detection sensitivity [18]. Although these methods can detect multiple analytes in one measurement, the drawbacks (i.e., large sample volume, long sample preparation and analysis, expensive equipment and maintenance, laboratory-based analysis) have urged the development of simpler and easier analytical methods, with similar or better detection. The new approach to the mycotoxin detection method is a biosensor. Biosensor is a device where a reaction between biomolecules is translated into an electrical signal by a transducer, and the data can be recorded and displayed [19]. Biomolecules such as an antibody, aptamer, DNA and molecular imprinted polymer are commonly used as these biorecognition elements are highly sensitive toward their specific target analyte. Electrochemical transducers (potentiometry, voltammetry, amperometry and impedance) are widely used in biosensor development as these techniques offer high sensitivity and a wide working range with a variety of mycotoxins [20]. The combination of biomolecules and electrochemical measurement was proven to detect mycotoxins in the low detection range [21] successfully. Incorporation of nanomaterials (carbon nanotubes, graphene's, gold nanoparticles, quantum dots; to name a few) into the system can enhance the performance of developed biosensors, especially for electrochemical transducers [22, 23]. In addition to simple sample preparation and small sample volume, biosensor carries the potential for in-situ detection that end-users can carry out with moderate training.

Materials and Methods

Materials and instrumentation

Polyclonal antibodies against aflatoxin A (AB1) and ochratoxin A (OA) were produced in-house by the Biotechnology & Nanotechnology Research Centre (Animal Ethics Committee of MARDI approval number 20190215/R/MAEC00045). Phosphate buffer saline (PBS) tablet, dimethyl sulfoxide (DMSO) and OA standard were purchased from Sigma (USA, UK and Israel, respectively). Potassium chloride (KCl), acetonitrile (ACN, HPLC grade), methanol (MeOH, HPLC grade) and glacial acetic acid (GAA) were obtained from Merck (Germany). Potassium hexacyanoferrate (III) (ferricyanide) and potassium hexacyanoferrate (II) trihydrate (ferrocyanide) were

acquired from Sigma-Aldrich (USA and Japan, respectively). Polyaniline emeraldine salt (PANIs) and gold nanoparticle (AuNP) came from Aldrich (USA). AB1 standard, aflatoxin B2 (AB2), aflatoxin G1 (AG1), aflatoxin G2 (AG2), ochratoxin B (OB), fumonisin B1 (FB1), fumonisin B2 (FB2) and fumonisin B3 (FB3) standards were purchased from Romer Labs (Austria). Dry milk powder was obtained from Santa Cruz (USA). All reagents used were of analytical standard or higher, as stated.

Refrigerated centrifuge 5810 R (Eppendorf, Germany) was used during the extraction of corn samples. AUTOLAB Potentiostat (Metrohm, Switzerland) is equipped with Nova 1.10 software for cyclic voltammetry (CV) and differential pulse voltammetry (DPV) measurement. Screen-printed carbon electrode (SPCE) with three electrode system comprising working, counter and reference electrodes made from carbon was purchased from BioGenes Technologies (Malaysia). Chromatographic analysis of mycotoxins was conducted using isocratic high-performance liquid chromatography (HPLC, UVE LCTech, Germany) equipped with a fluorescence detector (Waters 2475 Multi λ Fluorescence Detector). RP C18 column (150 x 4.6 mm, LCTech) with guard column 8 x 4 mm and RP C18 column (125 x 3 mm; 3 µm; 120 A, LCTech) were used for aflatoxin and ochratoxin, respectively. Grain corn sample (GWG888) was obtained from a local source and stored at room temperature.

Modification of SPCE

Bare SPCE was modified with AuNP, PANIs (in DMSO) and a mixture of both to improve the surface performance. A 10 µL of each solution was deposited on a carbon working electrode for 30 minutes. Excess liquid was discarded and left dried at room temperature. A 100 µL 5 mM redox electrolyte (ferricyanide/ferrocyanide in 0.1 M KCl) was added to SPCE and an electrochemical measurement was conducted. The stability of the modified electrode was evaluated by measuring CV for 50 cycles.

Standard curve determination

Mycotoxins standard curve was determined by applying direct assay protocol on modified SPCE. A 10 µL AuNP-PANIs mixture was deposited on the working electrode and left for 30 minutes. After discarding the excess liquid, 10 µL 0.1 mg/mL mycotoxin antibody was immobilised for an hour. The SPCE was washed three times with 50 µL PBS followed by deionised water. A 50 µL blocking buffer (0.05% dry milk in 0.01 M PBS) was added and incubated for 30 minutes. The SPCE has washed again. A 10 µL serial dilutions of five different mycotoxins concentrations were immobilised on the working surface and allowed to incubate for 2 hours. The SPCE has washed again, and 100 µL of 5 mM redox electrolyte was added to the SPCE for the electrochemical measurement. The experiment was carried out at room temperature.

Cross-reactivity

Cross-reactivity of each mycotoxin was conducted by introducing mycotoxins of the same and different groups into the assay. Mycotoxins used were AB2, AG1, AG2, OB, FB2 and FB3. The concentration used was 5 ppb for both AB1 and OA.

Real sample analysis

The sensitivity of the developed electrochemical sensor was evaluated with a real extracted corn sample. The direct assay was conducted on the SPCE to construct a standard mycotoxin curve in a grain corn matrix. Mycotoxins were prepared in grain corn matrix instead of PBS during standard preparation. Then, the procedure was repeated with extracted spiked samples for the recovery study.

HPLC analysis

Prior to HPLC, mycotoxins first were extracted from grain corn samples. For aflatoxin analysis, 100 mL extraction solvent (60% MeOH) was added to 25 g ground corn and blended for 3 minutes or shaken for 60 minutes. 4 mL filtered extract was added to 12 mL PBS. For ochratoxin analysis, the extraction method was the same, except that the extraction solvent used was 80% MeOH.

Aflatoxin and ochratoxin analysis were conducted using isocratic HPLC with fluorescence detection in reverse phase analysis. For aflatoxin analysis, water:MeOH:ACN (60:30:15 v/v) was used as eluent.

Injection of sample volume was 10-100 µL at a flow rate of 1.2 mL/min through RP C18 column at a column temperature of 33 °C. Fluorescence detector; Ex.: 365 nm, Em.: 460 nm. For ochratoxin analysis, water:MeOH:ACN/GAA (40:55:5/1 v/v) was used as eluent. Injection of sample volume was 10-100 µL at a flow rate of 0.6 mL/min through RP C18 column at a column temperature of 40 °C. Fluorescence detector; Ex.: 395 nm, Em.: 440 nm.

Results and Discussion

Modification of SPCE

Figure 2 shows the modification and immobilisation of biomolecules on the electrode surface. Both AuNP and PANIs were used to enhance the electrical and electrochemical properties of the electrode. The immobilisation of the nanoparticles and conducting polymer has improved the conductivity of the carbon surface, and this has been proved by a significant increase in current reading in both voltammetric measurements (Figure 3). Besides, the peak separation of modified electrodes was much closer than bare (unmodified) electrodes, as shown in Figure 3(a), which implied that the redox reaction occurred at a fast pace with a stable rate. The AuNP-PANIs modified SPCE recorded the highest DPV current reading of 466 µA (Figure 3(b)) with low peak separation (100 mV) and a current ratio near 1 (1.04) (Table 1). AuNP played an essential role in enhancing the performance of carbon surfaces. In addition to contributing to the conductivity [24], AuNP also provides binding sites for antibodies. Antibodies can bind with reagents such as thiols and polymers, but they can also directly attach to gold [25,26]. Thus, more binding sites are available, and the developed biosensor's sensitivity will increase accordingly.

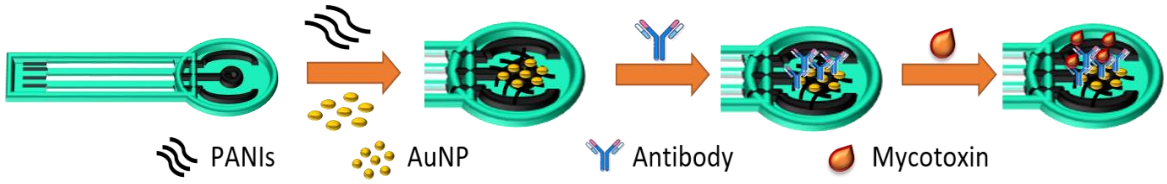

Figure 2. Modification and immobilisation of biomolecules on working SPCE surface

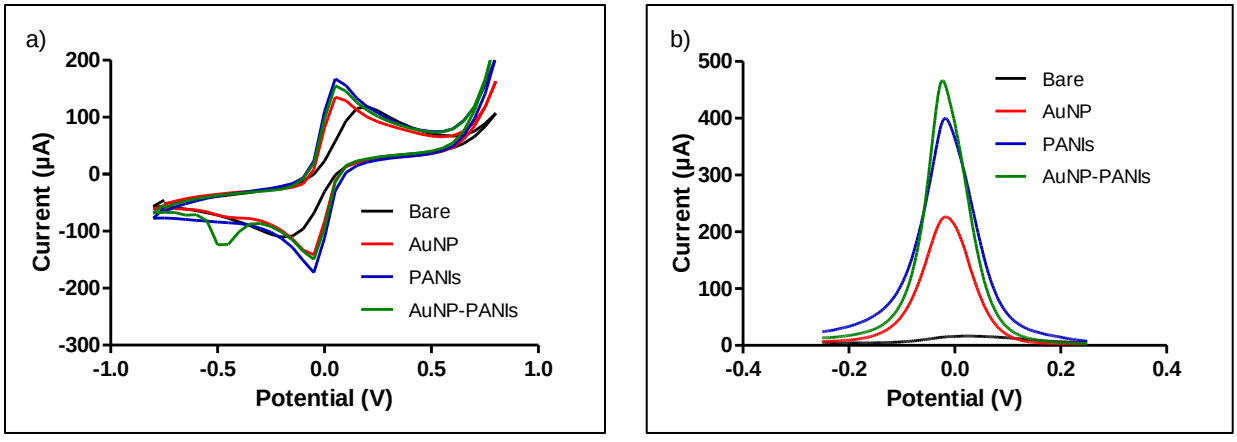

Figure 3. a) CV and b) DPV of bare and modified SPCE in 5 mM ferricyanide/ferrocyanide (in 0.1 M KCl). Scan rate; 50 mV/s (CV) and 2 mV/s (DPV)

Table 1. Electrochemical properties of bare and modified SPCE

	CV		DPV
	Peak Separation (mV)	**Current Ratio (i_a/i_c)**	**Peak Current (µA)**
Bare	400	1.08	16
AuNP	100	0.95	226
PANIs	100	0.97	400
AuNP-PANIs	100	1.04	466

The stability of the AuNP-PANIs-modified electrode has been investigated by allowing the electrode under CV measurement for 50 cycles. Anodic and cathodic peak current values were recorded and presented in Figure 4. A current increase was observed at anodic current starting from cycle 30 onwards. This might suggest that during the measurement, AuNP was fully stabilised by PANIs, resulting in the increased signal current [27]. Overall, the current reading of the modified surface was highly stable throughout the continuous electrochemical cycles, especially the cathodic current. This proved that the immobilised AuNP and PANIs were strongly attached to the carbon surface, and no leaching was detected from the voltammetric measurement.

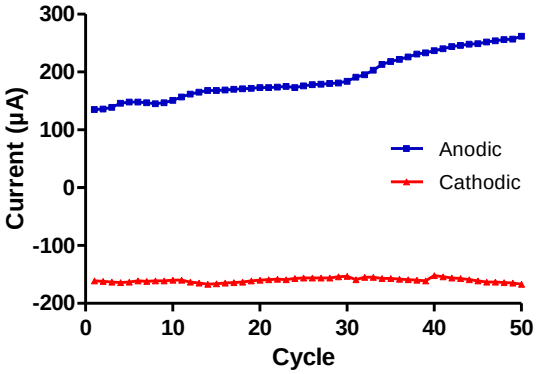

Figure 4. Stability of SPCE modified with 1 mg/mL PANIs and 20 nm AuNP under 50 cycles of CV

Standard curve determination

The sensitivity of developed AB1 and OA sensors were investigated at different concentrations of mycotoxin in PBS. The direct assay was conducted on the modified SPCE (Figure 2), and the sensor's sensitivity was measured using DPV, in terms of the current reading. Both AB1 and OA exhibited good linear correlation (high R^2 values) in a broad working range (Figure 5). Based on the plotted standard curve, the limit of detection (LOD) and limit of quantification (LOQ) were calculated and recorded in Table 2. Both mycotoxins showed lower LOD and LOQ values, which were much lower than the maximum regulation limit (MRL). Aside from contributing to conductivity and large surface area for binding, the combination of AuNP and PANIs also possesses high biocompatibility with antibodies [28]. This allowed more antibodies to be attached to the SPCE surface and maintained the binding stability throughout the assay process. This proved that the developed electrochemical sensor was highly sensitive in detecting the target analytes even in low concentrations.

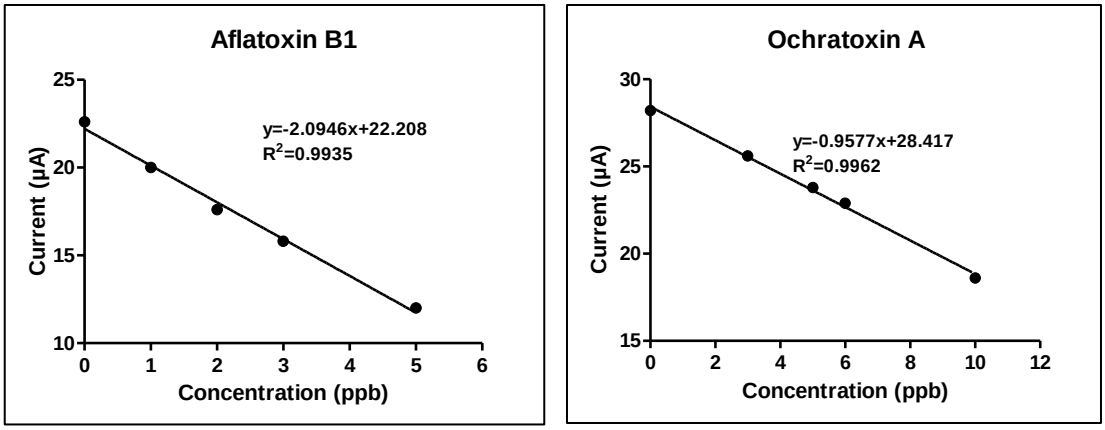

Figure 5. Standard curve of aflatoxin A (AB1) and ochratoxin A (OA) in PBS

Table 2. Calculated LOD and LOQ values for AB1 and OA in PBS

Mycotoxin	LOD (ppb)	LOQ (ppb)	MRL (ppb)
Aflatoxin B1	0.60	1.80	5
Ochratoxin A	0.87	2.63	5

Cross-reactivity

In order to investigate the selectivity of the developed antibody, the assay was tested with other mycotoxins of the same and different groups (Figure 6). AB1 antibody was cross-reacted with AB2, AG1 AG2, OA, OB, FB1, FB2 and FB3, while OA antibody was cross-reacted with OB, AB1, AB2, AG1 AG2, FB1, FB2 and FB3. The results showed that each developed antibody was strongly selective towards its targeted mycotoxin, where no significant electrochemical response was observed when tested against different mycotoxins, even in the same mycotoxin class. This was due to the vast difference in chemical structures between each mycotoxin (Figure 7). AB1 structure depicts stacked oxolane and aromatic rings, while the OA structure exhibits a few aromatic rings containing amine, carboxyl and hydroxyl functional groups. In contrast, the structure of FB1 is a long carbon chain with a number of hydroxyl functional groups, which contributes to its high polarity.

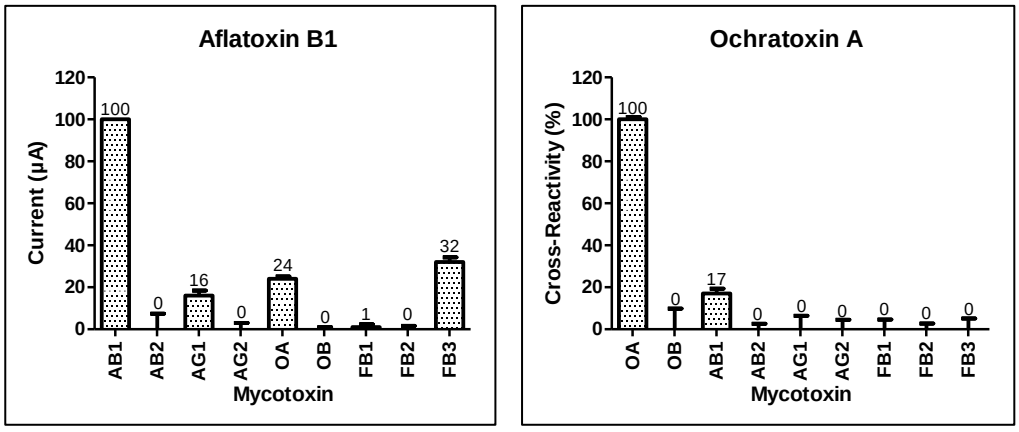

Figure 6. Intra and interspecies cross-reactivity of AB1 and OA

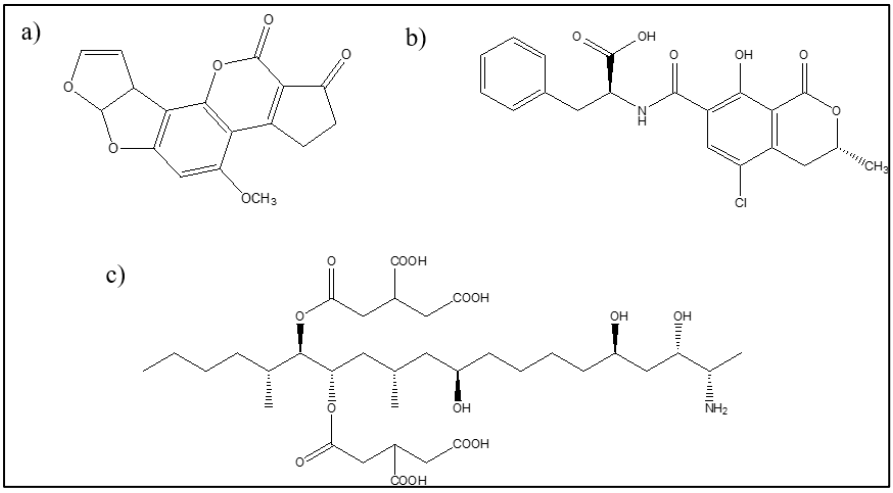

Figure 7. Chemical structure of a) AB1, b) OA, and c) FB1

Real sample analysis

The sensitivity of developed AB1 and OA sensors was also investigated in real grain corn samples. Grain corn is one of the main compositions of animal feed [29], and the inevitable occurrence of mycotoxins in unprocessed and processed grain corn hence gravely affects the animal feed industry. The analysis of samples employed the same direct assay, and the sensor's sensitivity was measured using DPV. Both AB1 and OA exhibited good R^2 values in a wider working range (Figure 8). The calculated LOD and LOQ values were also below the MRL (Table 3). This proved that the developed electrochemical sensor was highly sensitive in detecting the target analytes in the grain corn matrix.

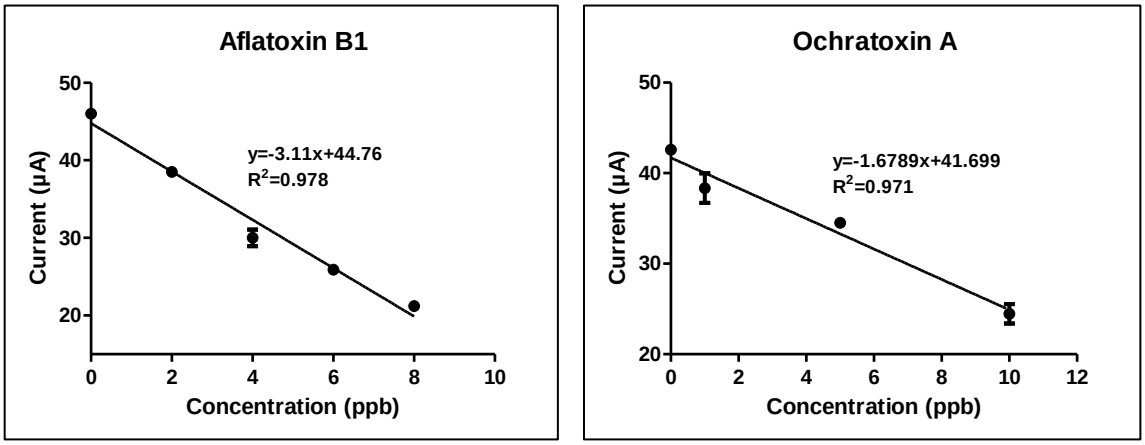

Figure 8. Standard curve of AB1 and OA in grain corn matrix

Table 3. Calculated LOD and LOQ values of AB1 and OA in corn matrix

Mycotoxin	LOD (ppb)	LOQ (ppb)	MRL (ppb)
Aflatoxin B1	1.81	5.48	5
Ochratoxin A	3.18	9.63	5

The recovery study was achieved by spiking several analytes' concentrations into grain corn and electrochemically measuring to detect the presence of mycotoxins in samples (Table 4). Overall, AB1 and OA exhibited good recovery in the range of 90-130%. Polar solvents such as ACN can work with a variety of mycotoxins, thus contributing to the success of mycotoxin extraction in corn samples [30]. The combination of water and the organic solvent was proven to increase polarity and helped in the effective extraction of solid samples [31].

Table 4. Recovery of spiked corn samples with AB1 and OA

Aflatoxin B1			Ochratoxin A		
Spiked (ppb)	**Found (ppb)**	**Recovery (%)**	**Spiked (ppb)**	**Found (ppb)**	**Recovery (%)**
2	1.92	96	5	5.24	105
6	5.52	92	10	12.56	126

Comparison with HPLC analysis

The viability of the developed electrochemical immunosensor for mycotoxins detection in grain corn was compared with chromatographic analysis. Results obtained from both techniques were recorded in Table 5. AB1 was detected lower than the MRL by both methods. AB1 was detected slightly higher from the developed biosensor may be due to the detection date being performed later than HPLC analysis. In contrast, both methods exhibited high OA concentration, which was above the regulated level. The difference in detected concentration between the sensor and HPLC was due to the fact that electrochemical-based detection has a base current limit. For example, the base current for OA was ±15 μA and is able to detect OA concentration in samples up to 15 ppb. The sensor cannot accurately determine the concentration of the target analyte but can determine if the concentration exceeds the MRL. The examined grain corn samples were contaminated by OA and were confirmed by both detection methods.

Table 5. Detected AB1 and OA using HPLC and developed electrochemical sensor

Mycotoxin	Detected Concentration (ppb)		MRL (ppb)
	HPLC	**Sensor**	
Aflatoxin B1	0.34	2.24	5
Ochratoxin A	25.82	15.78	5

Conclusion

The imbuement of AuNP coupled with PANIs onto the carbon working surface has greatly enhanced the properties of the sensor medium in terms of conductivity and as active binding sites. The AuNP-PANIs modified SPCE recorded the highest DPV current reading with low peak separation (100 mV) and a current ratio near 1 (1.04). The performance of the developed antibody-based biosensor has been proven via the sensitivity study in corn matrix and selectivity study with other mycotoxins using the electrochemical technique. Both AB1 and OA displayed high R^2 values in a broad working range with low LOD values. The developed antibodies (AB1 and OA) were exceptionally specific towards their target analyte and showed minimal cross-reactivity toward other mycotoxins. The detection of AB1 and OA in grain corn samples using the developed biosensor was at par with the instrumentation method. When evaluated using both developed electrochemical biosensor and chromatographic techniques, the tested grain corn sample was highly contaminated with OA compared to AB1. In future, AB1 and OA contamination in other food and feeds constituents such as rice, coffee beans, peanut, wheat and barley can be determined using this developed electrochemical biosensor.

Abstract

Tetracycline is one of the antibiotics used therapeutically and as a growth promoter in animals. Tetracycline residues in food products of animal origin have raised concerns among consumers. Due to its adverse effects on human health, it is critical to develop a reliable analytical method for routine monitoring of tetracycline in foods. Biosensors are among the rapid analytical devices that are reliable because of their simple detection methodology, low cost, sensitivity and specificity. For an effective signal transformation of tetracycline residues, it is critical to completely attach the transducer to the biological component, so that a feasible biosensor can be constructed. In this study, the screen-printed carbon electrode (SPCE) was modified with cellulose nanocrystal–gold nanoparticles/chitosan composite (CNC–AuNPs/chitosan). The synthesized CNC–AuNPs composite was characterized using UV–Vis spectroscopy, X-ray diffraction, Fourier-transform infrared spectroscopy and high-resolution transmission electron microscopy. In addition, the electrochemical behavior of the modified SPCE was investigated by cyclic voltammetry, differential pulse voltammetry (DPV) and electrochemical impedance spectroscopy under optimized conditions. DPV showed a linear calibration within the range of 0.01 to1000 µM concentration of tetracycline with the detection limit of 0.07 µM. The developed biosensor also resulted in different peak currents measured after storage for 14 days at room temperature (53.07%) and under 4°C (89.28%). Therefore, with acceptable sensitivity and selectivity, the fabricated biosensor can be suggested as a potential detection method for tetracycline residues.

Abstrak

Tetrasiklin adalah salah satu antibiotik yang digunakan secara terapeutik dan sebagai penyokong pertumbuhan pada haiwan. Sisa tetrasiklin dalam produk makanan yang berasal dari haiwan telah menimbulkan kebimbangan di kalangan pengguna. Oleh kerana kesan buruknya terhadap kesihatan manusia, adalah sangat penting untuk membangunkan kaedah analisis yang boleh dipercayai untuk pemantauan rutin tetrasiklin dalam makanan. Penderia bio adalah antara peranti analisis pantas yang boleh dipercayai kerana kaedah pengesanannya yang mudah, menjimatkan kos, kepekaan dan kekhususannya. Untuk transformasi isyarat yang berkesan dari sisa tetrasiklin, adalah sangat penting untuk melampirkan transduser sepenuhnya ke komponen biologi, supaya penderia bio yang boleh dilaksanakan dapat dibina. Dalam kajian ini, penderia bio dengan pengubahsuaian elektrod skrin bercetak karbon (SPCE) telah melibatkan nanokristal selulosa-partikel nano emas/kitosan (CNC-AuNPs/kitosan). Komposit CNC-AuNPs yang disintesis telah dicirikan dengan menggunakan spektroskopi penglihatan-UV, pembelauan sinaran-X, spektroskopi inframerah transformasi Fourier dan mikroskopi penghantaran elektron. Di samping itu, tingkah laku elektrokimia SPCE yang diubahsuai telah disiasat oleh voltammetri berkitar, voltammetri pembeza denyut (DPV) dan spektrometer electrokimia impedans dibawah keadaan yang optima. DPV menunjukkan kalibrasi linear dalam julat kepekatan tetrasiklin 0.01 hingga 1000 μM dengan had pengesanan 0.07 μM. Penderia bio yang telah dibangunkan juga telah menghasilkan perbezaan dalam arus puncak yang diukur setelah disimpan selama 14 hari pada suhu bilik (53.07%) dan di bawah suhu 4°C (89.28%). Oleh itu, dengan sensitiviti dan selektiviti yang telah diperoleh, penderia bio yang dibangunkan disyorkan berpotensi sebagai kaedah pengesanan sisa tetrasiklin.

Introduction

Antibiotic residues in animal-derived foods, owing mostly to antibiotic abuse in animal husbandry, have become a global concern and a significant health risk for humans and animals [1]. Since the 1940s, tetracycline has played a significant role in veterinary medicine and feed additives because of its broad-spectrum antibacterial properties and economic benefits. In livestock agriculture, tetracycline is frequently used to stimulate growth through increased food intake, weight gain and herd health. This approach may result in the presence of trace levels of these medications in animal-derived products such as milk and eggs, posing substantial health hazards to humans. The presence of tetracycline residues in foods may result in the transmission of antibiotic-resistant pathogenic microorganisms via the food chain. Another effect identified is its potential to trigger allergic reactions in hypersensitive persons [2].

According to Food and Drug Administration summary reports, sales and distribution of antimicrobials authorized for use in food-producing animals totaled roughly 14.8 million kg in 2012, with tetracycline accounting for 40% of total sales [3]. This data demonstrates that tetracycline is widely employed in animal food production, placing it at the top of the list of antibacterial drugs. To assure food safety and protect consumers from exposure to these contaminants, national and international regulatory organizations have established a tolerance level for tetracycline. Maximum residue levels (MRLs) are the maximum permissible concentrations of food residues and/or hazardous metabolites in food and feed products [4]. Food and Agricultural Organization of United Nations/World Health Organization have determined MRLs for tetracycline to be 200 μg kg^{-1} in chicken muscle and 400 μg kg^{-1} in egg samples [5].

Due to the possible detrimental effects of tetracycline in food, it is vital to develop accurate analytical methods that are speedy, precise, cost-effective, time-saving and environmentally friendly for routine tetracycline monitoring in food. Biosensor technology is being implemented in the field of analytical chemistry and is rapidly gaining popularity among researchers. Biosensors are small, portable devices that enable the detection of analytes by converting the chemical reaction to a signal utilizing biological recognition elements adsorbed on the physicochemical transducer [6]. This signal may generate qualitative or quantitative information. Biosensors have become one of the most often used rapid analytical methods, owing to the advantages of being quick, simple and sensitive. As a

result, the integration of biosensors currently has not only enhanced research on food safety involving chemical and microbial contamination but also improved the preservation of food freshness through packaging methods [7].

One of the fundamental principles of the electrochemical biosensor is the correlation between the biological component and the transducer that may affect the specificity of detection. Several previous reports have utilized nanomaterials as a significant advancement in these areas [8–11]. In this study, we propose a novel cellulose nanocrystal–gold nanoparticles/chitosan (CNC–AuNPs/chitosan) as the modifier of the screen-printed carbon electrode (SPCE) to amplify the current signal measured. Using the modification, an electrochemical biosensor was fabricated to determine tetracycline residues. The differential pulse voltammetry (DPV) technique was used in the presence of a redox indicator during detection.

Materials and Methods

Reagents and apparatus

All the chemical reagents used in this study were of analytical grade and used without further purification unless stated otherwise. Dry CNC with 0.94 weight percentage of sulphur (Batch# 2014-FPL-CNC-065) was purchased from the University of Maine (USA). Chitosan, tetracycline hydrochloride and streptomycin sulphate were procured from Nacalai Tesque (Japan). Gold (III) chloride trihydrate ($HAuCl_4.3H_2O$), bovine serum albumin (BSA), trizma hydrochloride (Tris–HCl) and glutaraldehyde (GA) were obtained from Sigma-Aldrich (USA). Potassium chloride (KCl) was obtained from Bendosen Chemical (Malaysia). Potassium ferricyanide ($K_3Fe(CN)_6$) and phosphate buffer saline (PBS) were purchased from R&M Chemicals (Malaysia). Potassium ferrocyanide ($K_4Fe(CN)_6$) was purchased from Millipore (Canada). Synthetic oligonucleotides for amine-terminated ssDNA (tetracycline aptamer, TET-aptamer) were purchased (as lyophilized powder) from Apical Scientific (Malaysia) with the following sequence: 5'-NH_2–CCCC CGGC AGGC CACG GCTT GGGT TGGT CCCA CTGC GCGT-3' (anti-tetracycline). Electrochemical measurements were performed using an Autolab III Eco-Chemie (Netherland) voltammetric analyser with NOVA 1.11 software and an impedance potentiometric module FRA 32M (10 μHz to 32 MHz) (Netherland) with NOVA 2.4 software. The SPCE used for the analysis, which comprises a three-electrode system: a counter electrode, a carbon working electrode and an Ag/AgCl reference electrode, was purchased from Metrohm DropSens (Spain). The characterization was performed using UV–vis spectroscopy (Perkin Elmer), X-ray diffraction (XRD) (Philips), high-resolution transmission electron microscopy (HR-TEM) (JEOL) and Fourier-transform infrared spectroscopy (FTIR) (Shimadzu).

Synthesis and characterization of CNC-AuNPs

CNC–AuNPs were synthesized by mixing 1% sodium citrate solution with 0.2 mM $HAuCl_4$ solution and 0.1% CNC suspension. The volume of the mixture was made up of deionized water and heated at 80°C for an hour. The color changes were observed, and the final solution was then cooled to room temperature and kept in a fridge. The CNC–AuNPs were characterized using UV–vis spectroscopy, XRD, HR-TEM and FTIR.

Fabrication and characterization of modified SPCE

The SPCE was modified based on the layer-by-layer method. First, CNC–AuNPs were sonicated for 5 min. Then, 4 μL of CNC–AuNPs was drop cast on the SPCE (SPCE/CNC–AuNPs) and dried at ambient temperature. Chitosan solution was prepared by adding 0.5 g chitosan to 50 mL acetic acid (2%) and stirred for several hours until completely dissolved. Then, 4 μL chitosan solution was drop cast as the second layer (SPCE/CNC–AuNPs/chitosan) and air-dried. The bare and modified SPCE was characterized after each deposition layer using cyclic voltammetry (CV) at the potential range of –0.4 to 0.7 V for 20 cycles with a scan rate of 0.1 V/s in 1 mM $K_3Fe(CN)_6$ and 50 mM KCl. The electrochemical impedance spectroscopy was conducted at the frequency range of 0.01 to 10 000 Hz with an amplitude of 0.3 V in 5 mM $K_3Fe(CN)_6$, 5 mM $K_4Fe(CN)_6$ and 0.1 mM KCl.

Development of electrochemical biosensor

The modified SPCE was placed in 1% GA and washed. The GA acts as the linker between the DNA probe and

the modified SPCE. Various TET-aptamer concentrations ranging from 0.01 to 1000 nM were drop cast on the SPCE/CNC–AuNPs/chitosan and kept at room temperature at various incubation times ranging from 15 to 90 min. Optimum concentration and incubation time of the TET-aptamer were selected for further analysis. Tris–HCL buffer was used to wash the unbound aptamer on the SPCE/CNC–AuNPs/chitosan/TET-aptamer prior to measurement by DPV. Several concentrations of tetracycline ranging from 10 nM to 1 mM were drop cast on the SPCE/CNC–AuNPs/chitosan/TET-aptamer and incubated for an hour. Tris–HCL buffer was used to wash the unbound tetracycline. Prior to electrochemical measurement, the SPCE/CNC–AuNPs/chitosan/TET-aptamer was immersed in BSA to avoid non-specific binding. DPV was performed at the potential range of –0.6 to 0.7 V and a scan rate of 0.01 V/s in 1 mM $K_3Fe(CN)_6$ and 50 mM KCl.

Results and Discussion

Characterization of CNC-AuNPs

UV–vis spectroscopy was used to confirm the presence of AuNPs in CNC suspension. The CNC–AuNPs nanocomposite, as shown in Figure 1A, exhibited a distinct absorption peak around 525 nm, which can be traced back to the surface plasmon resonance band of AuNPs. The broad peak area is expected from the synthesis of AuNPs using a citrate-reduction method [12]. The cellulose nanocrystal structure of the synthesized CNC–AuNPs was determined using XRD. Figure 1B depicts the XRD patterns of CNC and CNC–AuNPs. The CNC showed a prominent peak at 2 theta at 15.2°, 22.6° and 34.5°, which were derived from the typical reflection planes (110), (200) and (040) of cellulose, respectively [13]. With the addition of those peaks, CNC–AuNPs displayed four new peaks in the vicinity of 39.1°, 44.2°, 64.9° and 77.8°, which were indexed to the (111), (200), (220) and (311) planes of gold lattice, respectively [14]. Consequently, the XRD pattern indicated that the metallic production of AuNPs did not change the crystallographic property of CNC. The FTIR technique was used to determine the chemical composition or structure of the sample. In most cases, the CNC is represented by a broad peak of O–H spanning between 3100 and 3700 cm^{-1} due to the hydrogen connection between the hydroxyl group and the carboxyl group. The presence of a hydrogen bond in the structure aids in the nucleation process that occurs during the synthesis of AuNPs [15]. As illustrated in Figure 1C, the CNC–AuNPs displayed peaks at roughly 2900 cm^{-1} and 1635 cm^{-1}, which were attributed to the C–H stretching and the C=C stretching of the cellulose structure, respectively, in the spectrum.

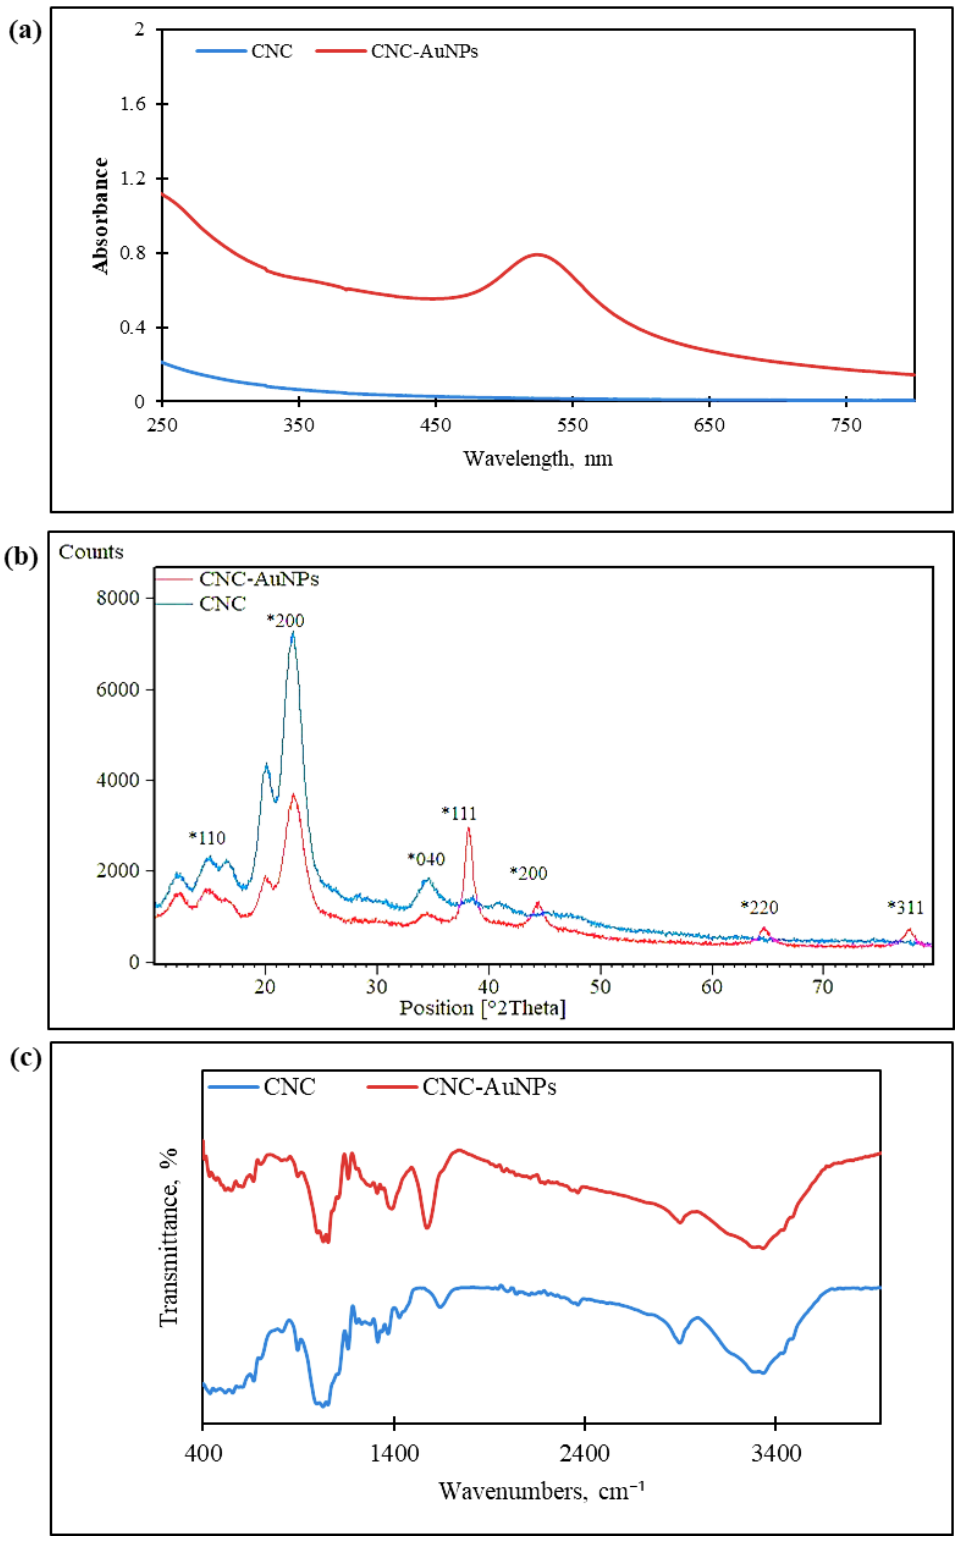

Figure 1. (a) UV-vis spectra, (b) XRD pattern and (c) FTIR spectra of CNC and CNC-AuNPs

The TEM images clearly revealed the production of the gold particles. In Figure 2a, CNC's TEM image revealed rod-like particles of cellulose crystalline with a diameter of less than 10 nm. The distribution showed that most of the cellulose crystals are about 6 to 7 nm. Meanwhile, Figure 2b reveals that there is a small populated zone of AuNPs with a diameter of around 20 nm. The agglomeration and the inconsistency in the particle size of the AuNPs may be due to the inefficient thermal process during the synthesis [16]. In addition, the CNC–AuNPs elemental spectra were obtained using the TEM–EDX. The EDX analysis revealed an abundance of gold particles with a weight percentage of 84.2, indicating that the production of AuNPs in the presence of CNC has occurred.

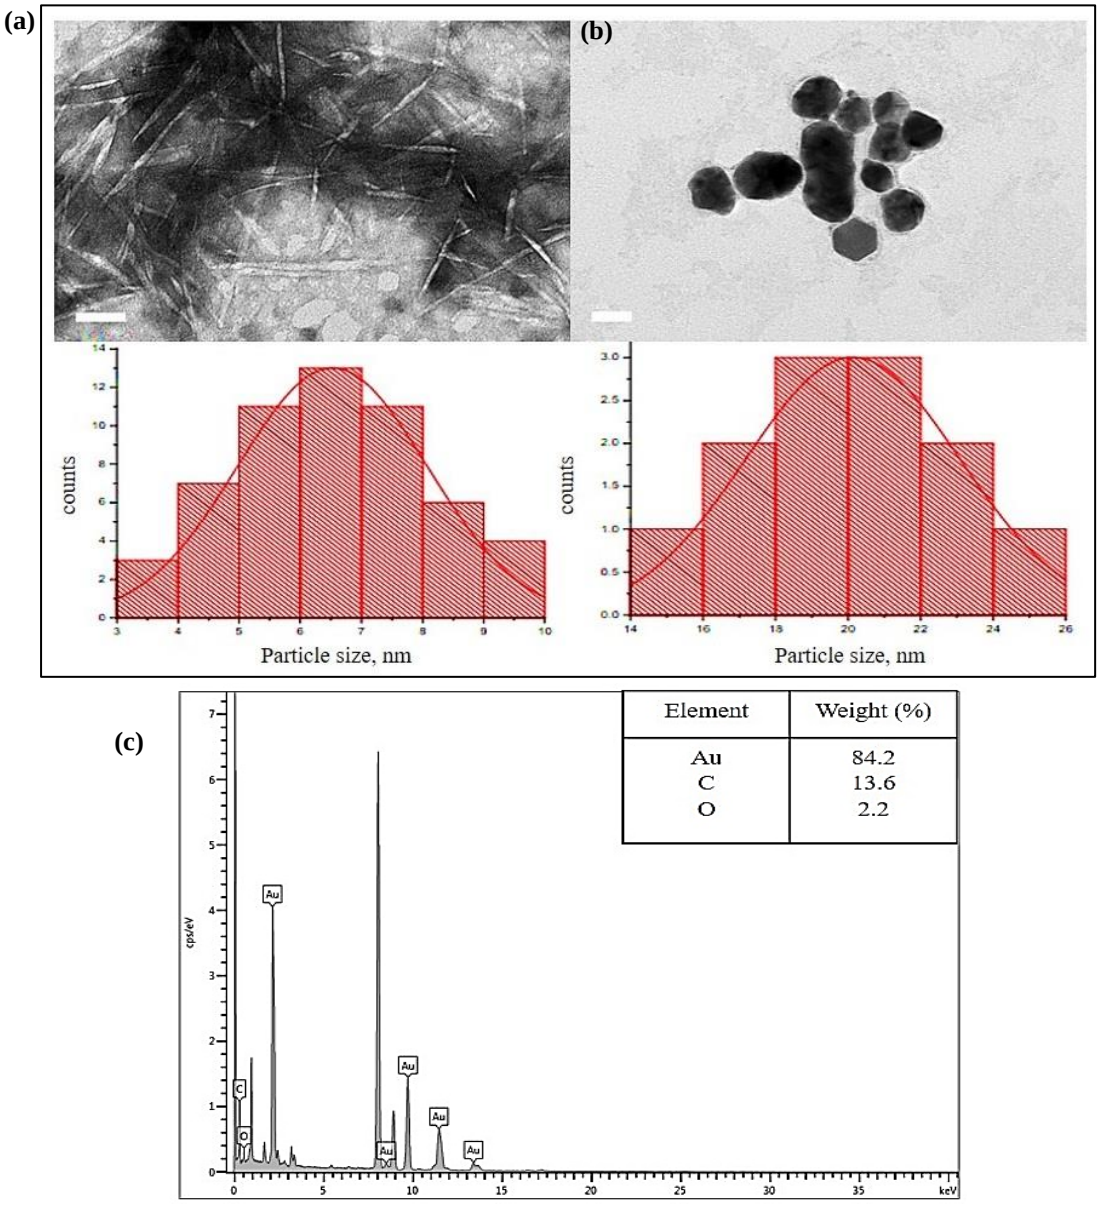

Figure 2. (a) TEM image of CNC, (b) TEM image CNC-AuNPs (50k magnification) and (c) TEM-EDX analysis of CNC-AuNPs (inset; elemental analysis)

Electrochemical properties of the modified electrode

For the modification of the SPCE, chitosan solution was drop cast on the CNC–AuNPs surface. CV was performed to investigate the bare SPCE and CNC–AuNPs/chitosan-modified SPCE, and the signals are shown in Figure 3a. The CNC–AuNPs/chitosan-modified SPCE demonstrated the highest anodic peak, measuring around 74.29 µA when compared with the CNC–AuNPs-modified SPCE. The increment of about sevenfold in the peak current may be due to the chitosan layer that acts as a hydrophobic barrier [17], allowing the CNC–AuNPs to remain intact on the surface of SPCE, thus allowing the amplification of the signal. By calculating the relative standard deviation (RSD), the repeatability and reproducibility of the modified SPCE were determined. The percent RSD for repeatability was 5.1% when five consecutive readings of the modified electrode were taken. Using the same approach on five individual electrodes resulted in a 6.4% RSD for reproducibility. As for the Nyquist plot from Figure 3b, it is proved that the measurement complimented the CV measurements as the resistance decreased for the modified electrode. The R_{ct} values recorded for bare and modified electrodes were 394.08 and 116.27 Ω, respectively. Therefore, it is believed that the modified electrode can improve conductivity while also providing reliable and reproducible measurements for the biosensor.

Optimization of the TET-aptamer

Several variables, including incubation duration and immobilized TET-aptamer concentration, were investigated to obtain the highest possible output from the biosensor. These parameters must be optimized because they have an impact on the binding of the TET-aptamer with the tetracycline as well as the peak current of DPV. To find the optimal concentration of the TET-aptamer, the CNC–AuNPs/chitosan-modified SPCE was pipetted with various concentrations (0.01 to 1000 nM) of the TET-aptamer for 30 min. Based on Figure 4a, the peak current increased as the concentration of the TET-aptamer increased from 0.01 to 1 nM. Nevertheless, the peak current began to decrease as the concentration increased from 10 to 1000 nM. This could be due to the too close proximity on the surface of the CNC–AuNPs/chitosan-modified SPCE that causes electrostatic repulsion. Hence, the optimized concentration of the TET-aptamer was found to be 1 nM. In addition, Figure 4b shows the effect of the incubation time of the TET-aptamer on the DPV peak current. The TET-aptamer (1 nM) was dropped on the CNC–AuNPs/chitosan-modified SPCE for 15 to 90 min. The findings showed that the peak current reached a maximum at 75 min yet decreased at 90 min, which might be due to the instability of the TET-aptamer after being left for a longer period on the electrode surface. Thus, the optimum incubation time of the TET-aptamer was selected at 75 min.

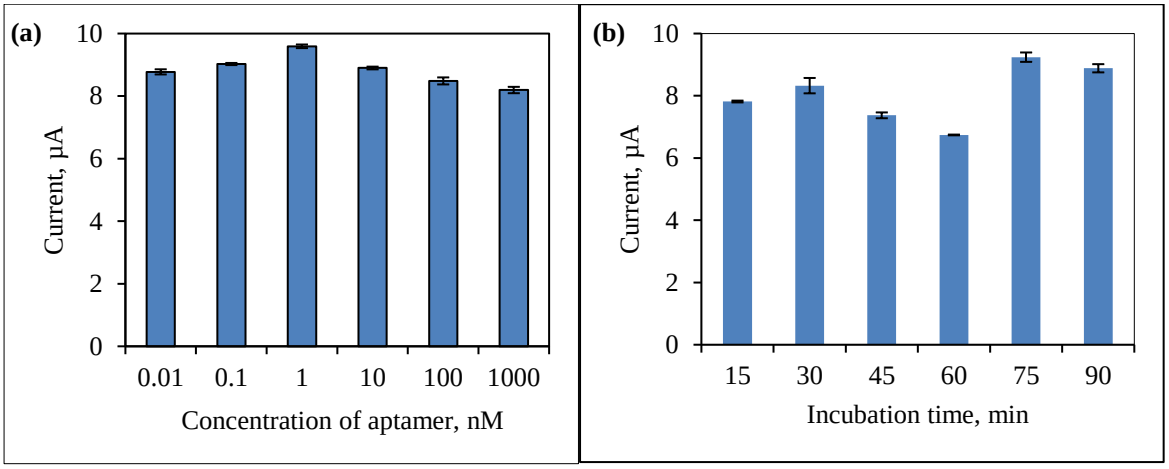

Figure 4. The effect of different **(A)** incubation times and **(B)** concentrations of the TET-aptamer at potential of -0.6 to 0.7 V

Detection of tetracycline

Under the optimal experimental conditions, the DPV response was recorded for the tetracycline detection. To validate the constructed biosensor, tetracycline was incubated on the immobilized TET-aptamer surface at multiple concentrations ranging from 10 nM to 1 mM. It can be observed in Figure 5a that the continuous drop of the DPV peak current was associated with the binding of the tetracycline to the TET-aptamer. These findings also can be compared with those of Zhao et al. [18], Benvidi et al. [19], and Tang et al. [20] who reported a decrease in DPV signals with the presence of tetracycline. In addition, the linear calibration was plotted between the log of different concentrations of tetracycline and the relative change in peak current ($\Delta I/I_0$) (Figure 5b). The biosensor demonstrated a linear regression, which was stated as $y = 0.70x + 4.65$ with a correlation coefficient of $R^2 = 0.9707$. From the linear slope, the limit of detection (LOD) was obtained at 0.07 µM of tetracycline concentration, which was calculated using the $3\sigma/s$ formula, where σ is the standard deviation of the blank and s is the slope of the calibration curve. The reproducibility of the developed biosensor was also evaluated from five individual electrodes and the resulted percent RSD was 4.1%. This proved the consistency of the signal measurements, which relate to the reliability of the fabricated biosensor.

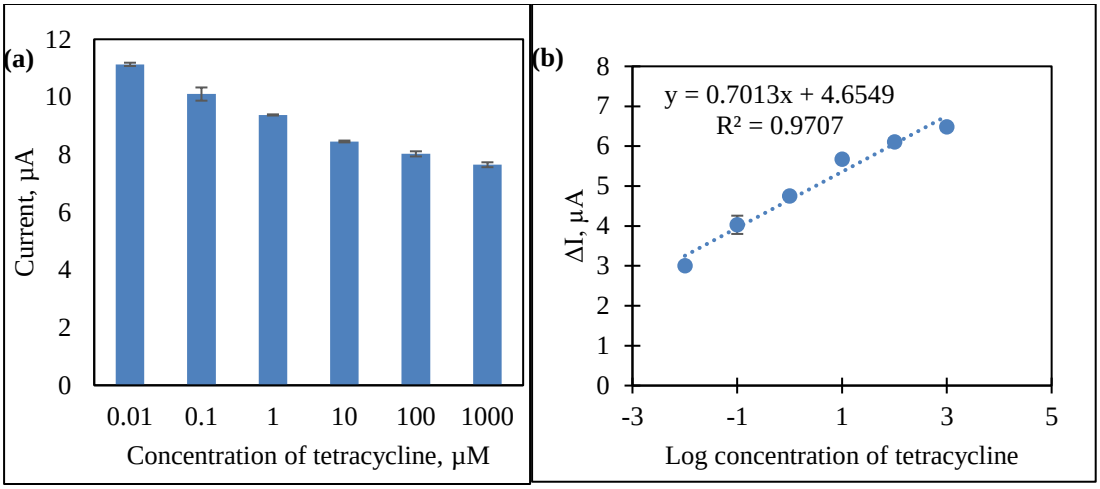

Figure 5. (a) DPV of the biosensor taken at different concentrations of tetracycline and (b) the calibration curve of the biosensor; LOD: 0.07 µM

The selectivity of the biosensor was investigated using several types of antibiotics to assess the specificity of the TET-aptamer binding to the tetracycline. DPV responses to tetracycline, ampicillin, streptomycin and oxytetracycline are demonstrated in Figure 6. The highest peak current (12.32 µA) was observed for ampicillin, owing to the various binding sites of the TET-aptamer that were used to capture it. Compared with the other antibiotics, tetracycline recorded the lowest peak current (10.10 µA). This demonstrates that the TET-aptamer is capable of distinguishing tetracycline from other distinct antibiotic molecules (ampicillin and streptomycin) as well as the structurally related derivative antibiotics (oxytetracycline). The stability of the developed biosensor was also analyzed using 100 µM tetracycline. The biosensor was stored for 14 days at room temperature and under 4 °C. The relative difference in peak current from the initial response for room temperature and under 4 °C was 53.07% and 89.27%, respectively. This indicates that the biosensors cannot be stored more than 2 weeks before use.

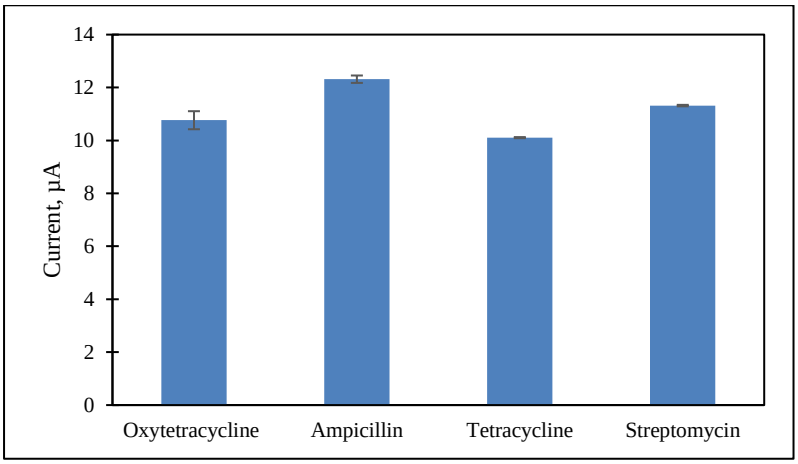

Figure 6. DPV responses of the tetracycline, ampicillin, streptomycin and oxytetracycline

Conclusion

In this study, CNC–AuNPs were synthesized, characterized and employed as the transducer element for the fabrication of a biosensor. After being modified in conjunction with chitosan, the modified SPCE demonstrated a significant current peak increment of sevenfold. With an acceptable percent RSD, the CNC–AuNPs/chitosan-modified SPCE showed a repeatable and reproducible result. With the chosen modified surface, the biosensor was developed for tetracycline detection. DPV recorded a decreasing current with an increasing concentration of tetracycline. From the analysis, it was found that the LOD for the detection was 0.07 μM (RSD = 4.1%). The findings of this study imply that using a combination of approaches to modify disposable SPCEs with CNC–AuNPs and chitosan for prospective use as a biosensor for tetracycline detection may be a potential alternative.

Abstract

Bisphenol A (BPA) is an organic compound in daily plastic products. The compound is primarily transferred from water bottles, food cans liners, and dental fillings into foods and beverages. The BPA is considered an endocrine-disrupting compound related to broad health concerns, such as reproduction problems and the development of various cancers. Consequently, developing a reliable analytical approach to determine BPA levels is urgent. The current study developed an electrochemical sensor from modified screen-printed carbon electrodes (SPCE) with carbon dots-chitosan (CDs-CS) to detect BPA. The CDs-modified SPCE provided a good electrocatalytic application with extraordinary electronic properties and significantly enhanced electrical conductivity. The modified SPCE/CDs-CS sensor was prepared through the drop casting technique. Subsequently, its BPA detection abilities were assessed via differential pulse voltammetry (DPV). In investigating the optimum parameters to elevate the performance of the developed sensors, 1% m/v CS concentration and 1:1 (v/v) CDs to CS ratio were recorded. The obtained CDs-CS/SPCE sensor demonstrated great electrocatalytic features for detecting BPA within the 0.4 and 10 µM concentration range with a sensitivity of 0.46 µA/µM (R^2 = 0.9911) and 0.37 µM limit of detection (LOD).

Keywords: Bisphenol A, carbon dots, chitosan, electrochemical sensor, environmental

Abstrak

Bisfenol A (BPA) adalah sebatian organik yang terdapat dalam produk plastik yang kita gunakan setiap hari. Sebilangan besarnya dipindahkan ke dalam makanan dan minuman termasuk botol air, lapisan tin makanan, dan tampalan gigi. BPA dianggap sebagai sebatian yang mengganggu endokrin yang berkaitan dengan pelbagai jenis masalah kesihatan seperti perkembangan barah dan masalah pembiakan. Oleh itu, pembangunan pendekatan analisis yang boleh dipercayai untuk mengesan BPA adalah isu mendesak. Dalam kajian ini, sensor elektrokimia berasaskan modifikasi elektrod karbon bercetak skrin (SPCE) dengan karbon titik-kitosan (CD-CS) telah diterokai untuk mengesan bisfenol A (BPA). SPCE yang diubahsuai dengan CD memberikan aplikasi elektro-pemangkin yang baik mempunyai sifat elektronik yang luar biasa dan peningkatan besar dalam kekonduksian elektrik. SPCE yang diubahsuai dengan CDs-CS disediakan dengan menggunakan teknik penyalutan titis. Pengesanan BPA pada sensor SPCE / CDs-CS dikaji dengan menggunakan voltammetri denyutan pembezaan (DPV). Parameter optimum pembangunan sensor seperti kepekatan CS 1% (m/v) dan nisbah CD-CS 1/1 (v/v) dikaji untuk meningkatkan prestasi sensor yang dibangunkan. Hasil kajian menunjukkan bahawa SPCE yang dimodifikasi dengan komposit CD-CS mempunyai ciri elektrokatalitik yang hebat untuk

mengesan BPA dalam julat kepekatan dari 0.4 μM hingga 10 μM dengan kepekaan 0.46 μA/μM (R^2 = 0.9911) dan had pengesanan (LOD) 0.37 μM.

Introduction

Bisphenol A (BPA) or 2,2-bis(4-hydroxyphenyl)propane is a compound predominantly employed as monomers in the synthesis of epoxy resins and polycarbonate (PC). A combination of BPA and other materials is utilised in plastic production. Products, such as packaging materials for food, beverages and wastewater samples and engineering plastics, contain BPA [1]. In 2015, the European Food Safety Authority (EFSA) proposed that the minimum amount of temporary tolerable daily intake (t-TDI) of BPA should not exceed 4 $\mu g\ kg^{-1}$ of body weight per day [2]. Minute amounts of BPA might endanger human health and, at worst, lead to prostate, testicular, or breast cancer, reproductive disorders, including low sperm quality, congenital disabilities, and impaired brain development [3]. Consequently, a rapid, simple, sensitive, and selective BPA detection technique is immediately demanded.

Commercialised techniques of BPA detection include high-performance liquid chromatography (HPLC), gas chromatography coupled with mass spectrometry (GC-MS) [4], and liquid chromatography-tandem mass spectrometry (LC-MS-MS) [5]. Although the methods are highly sensitive and offer low detection limits, the techniques involve several operational steps, making them time-consuming, and the procedure for processing the samples is tedious. Furthermore, the instrumentations required are intricate, expensive, and not convenient for on-site detection [6], hence the demand for a novel analytical technique to determine BPA levels.

The BPA is an electroactive species that contain phenolic hydroxyl groups that could be oxidised on electrode surfaces. Nonetheless, the direct determination of BPA with bare electrodes is infrequent due to its weak signal response, and its oxidation involves a relatively high overpotential [7]. Accordingly, to refine the selectivity and sensitivity of BPA detection, various materials have been recommended for the modification of SPCE, such as ionic liquids [8], enzymes, molecularly imprinted polymers [9], carbon materials, including carbon nanotubes [10], single-walled (SWCNT) [11], multiple-walled (MWCNT) [12], and graphene, [13] and metal nanoparticle-based composites, such as gold nanoparticles (AuNPs) [14] and ferroferric oxide nanoparticles (Fe_3O_4NPs) [15].

Carbon dots (CDs) were accidentally discovered during the electrophoretic purification of single-wall carbon nanotubes (SWCNTs) and were derived from its arc-discharge soot [16]. A novel carbon nanomaterial, the CDs has drawn considerable attention in recent years due to its excellent properties, including low toxicity [17], remarkable conductivity [18], large surface area, and high stability [19]. Recently, methods of synthesising CDs, including hydrothermal ultrasonic, laser ablation, and microwave synthesis, have been studied extensively, where the hydrothermal method was reported to be the most simple, environmentally friendly, and inexpensive [20]. The potential applications of CDs were demonstrated in numerous areas, including biosensing [21], chemical sensing [25–27], bioimaging, electrocatalysis, and photocatalysis [25]. Additionally, CDs have been employed in the electrochemical detection of dopamine [26], L-cysteine [27], and curcumin [28], demonstrating the prospects of applying CDs in the electrochemical field.

Chitosan (CS) is a linear polysaccharide composed of randomly distributed β-(1→4)-linked D-glucosamines (deacetylated units) and N-acetyl-D-glucosamines (acetylated units) [29]. The compound is a biocompatible, hydrophilic, cationic, and biodegradable biopolymer [30]. Consequently, CS could be utilised as a dispersant to form a stable film on the surface of electrodes with several kinds of modified materials due to its great film-forming ability, good adhesion, soaring permeability, nontoxicity, cheapness, and susceptibility to chemical modifications [29]. Furthermore, the compound is also applicable as energy storage materials [31], biosensors [29], and cell imaging [32], as it could

be electrodeposited on the broad surfaces of electrodes or conductive substrates to form coatings or patterns with precise spatial and temporal control [34-35]. Some biological materials (such as glucose oxidase and haemoglobin) and nanoparticles (for example, silver nanoparticles and carbon nanotubes) could also be deposited by employing CS [34], where the CS acts as a immobilisation matrix combined with CDs to modified electrodes and utilised as sensors [26].

In the present study, carbon dots-chitosan (CDs-CS) composite deposited on screen-printed carbon electrode (SPCE) for excellent catalytic performance and conductivity for BPA determination was explored. The nanocomposite offered several advantages, including remarkable conductivity, large surface area, good film-forming capabilities, and high stability. Furthermore, the CDs-CS based electrode provided an excellent electrocatalytic activity toward BPA oxidation, representing a new platform for electrochemical sensor development.

Materials and Methods

Reagents and materials

The BPA, potassium chloride (KCl), potassium ferricyanide ($K_3[Fe(CN)_6]$), citric acid, acetic acid, disodium hydrogen phosphate ($Na_2HPO_4.7H_2O$), and potassium dihydrogen phosphate ($NaH_2PO_4.H_2O$) were purchased from R&M Chemicals company (Petaling Jaya, Selangor, Malaysia). The CS was obtained from Sigma-Aldrich (Petaling Jaya, Selangor, Malaysia), while ethylenediamine was bought from Acros Organics (Geel W.Z.2., Geel, Belgium). In the current study, deionised water (18.2 MΩ·cm at 25 ℃, Milli-Q) was employed throughout the experiments.

The screen-printed carbon electrode (3 mm in diameter) consisted of a reference (AgCl), counter (carbon), and working (carbon) electrodes that were purchased from Rapid Labs Sdn. Bhd. (Bangi, Selangor, Malaysia). Each BPA standard solution was diluted with an 80:20 ethanol-to-water ratio in volume per volume (v/v) into a stock solution of 100 µM BPA. Electrochemical measurements were performed with Model Autolab Type III (Eco Chemie B. V., Netherlands). Cyclic voltammetry (CV) and differential pulse voltammetry (DPV) data analyses were conducted via the Nova 1.11 software.

The synthesis of CDs and preparation of CS

The hydrothermal method was employed to synthesise the carbon dots in the present study [35]. First, the citric acid (3.0 g) and ethylenediamine (1.875 mL) were dissolved in deionised distilled water (ddH_2O, 30 mL). The solution was then transferred to a reactor and heated in an oven for five hours at 150℃. Subsequently, the clear brownish solution formed was stored at 4°C and wrapped with aluminium foil to maintain a dark condition. The CS solution (1%, w/v) was then prepared by dissolving 0.5 g CS powder in 1% (w/v) aqueous acetic acid solution (50 mL). The mixture was continuously stirred vigorously overnight.

The preparation of BPA stock solution and supporting electrolyte

A 100 µM BPA was prepared by adding 228 mg of BPA into 80% ethanol and 20% ddH_2O in a 100 mL volumetric flask. The $K_3[Fe(CN)_6]$ (5 mM) and 0.1 M KCl mixture was utilised as a supporting electrolyte, where 0.1646 g $K_3[Fe(CN)_6]$ and 0.7455 g KCl were dissolved in 100 mL of ddH_2O in a 100 mL volumetric flask. Subsequently, a phosphate buffer solution (PBS) was prepared by adding disodium hydrogen phosphate ($Na_2HPO_4.7H_2O$) (2.0 g) and potassium dihydrogen phosphate ($NaH_2PO_4.H_2O$) (0.339 g) into 80 mL of deionised water in a 100 mL conical flask. Hydrochloric acid and sodium hydroxide were employed to adjust the solution to the desired pH.

Modification of SPCE

A mixture (7 µL) of 1:1 (v/v) CDs solution to chitosan (1%, w/v) was spread on the surface of the SPCE before being dried for approximately five hours at room temperature. The modified electrode is then denoted as the CDs-CS/SPCE.

The electrochemical method

The CV analysis was implemented within the −0.4 and 0.65 V potential range at a 100 mV/s scan rate for five cycles to evaluate the performance of the modified SPCE by employing 5 mM $K_3[Fe(CN)_6]$ and 0.1 M KCl. A redox probe consisting of $K_3[Fe(CN)_6]$ was employed to evaluate the electrochemical behaviour of the SPCE

post-modification with CDs-CS [36]. Differential pulse voltammetry (DPV) measurements were recorded within the 0.1 to 0.8 V potential range with PBS (pH 7.4). The assessment parameters were 0.2 V deposition potential, 60 s deposition time, and 10 mV/s scan rate.

Results and Discussion

Electrochemical behaviour of the modified electrodes

The electrochemical behaviours evaluation of the modified electrodes was performed with CV analysis. Figure 1 illustrates cyclic voltammograms of the bare SPCE, CS/SPCE, CDs/SPCE, and CDs-CS/SPCE electrodes. The pair of redox peaks exhibited by the bare SPCE demonstrated its electrochemical characteristics, which provided a rapid location of redox potentials of the electroactive species.

The modified CDs/SPCE recorded enhanced redox peak current at a calculated enhancement factor of 1.85, which might result from the wider active surface area and good electron transfer, as CDs are good conducting material. The electrochemical response of the CS-modified electrode documented a lower redox peak signal than the bare SPCE, indicating that the CS/SPCE was non-electroactive in the selected scanning region [37]. The CDs-CS/SPCE nanocomposites demonstrated synergistic electron transfer, as evidenced by the significant redox peak current signal enhancement at a factor of 4.17 due to the presence of CDs-CSs on the SPCE surface. The CDs were excellent conductors and more stable when CS was employed as a fixative agent on the electrode that opposed the easy dissolution of the CDs from the surfaces of the SPCE into the PBS solution [16]. The oxidation (*Epa*) and reduction (*Epc*) peak potentials were recorded at 0.31 and −0.04 V.

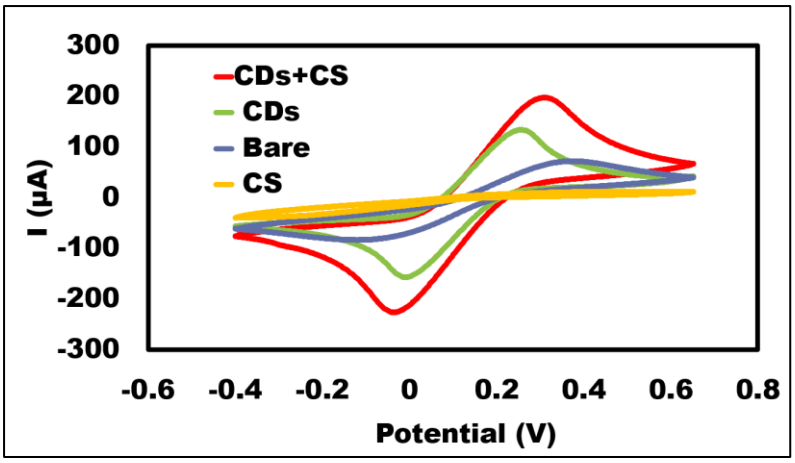

Figure 1. The cyclic voltammograms of the modified electrodes in 5 mM $K_3[Fe(CN)_6]$/0.1M KCl within the −0.4V to 0.65V range potential at 100 mV/s scan rate

Optimisation: The influence of CS concentration (%) and volume and the CDs to CS ratio on the SPCE

The current study determined the optimised parameters for modifying the SPCE surfaces through CV. The optimum percentage of CS mixed with CDs, which could affect the performance of the CDs-CS/SPCE sensor, was investigated. Varying concentrations of CS, 0.1 to 2.0% (w/v), were employed. The current response increased from 0.1 to 1%, and the optimum current response was observed at 1% (w/v) CS. At concentrations exceeding 1%, decreased current response was recorded [see Figure 2(a)]. The observations might be due to the increased resistance at the modified electrode surfaces with higher CS percentages [38]. Consequently, the present study employed 1% (w/v) CS concentration as the ideal percentage for the CDs-CS composite immobilisation onto the sensor.

The amount of CDs-CS composite immobilised on the surface of the SPCE affects the sensitivity of the developed sensor. Accordingly, different CDs-CS volumes (1 to 11 µL) were employed in the present study. The oxidation peak current was observed ascending with an increasing CD-CS volume up to 7 µL before slightly reducing [see Figure 2(b)]. The phenomenon might result from the thicker nanocomposite film formed with larger volumes of CDs-CS, which could obstruct the transfer of electrons and mass on the surface of the SPCE [38]. Consequently, the current study applied 7 µL CDs-CS in the fabrication of the sensor.

In the present study, the ratio of CDs to CS was varied (1:0.1, 1:0.5, 1:1, 1:1.5, and 1:2 v/v) to evaluate the optimum volume ratio of the CDs-CS composite. Figure 2(c) demonstrates that the oxidation current response increased from 1:0.1 to 1:1 before gradually dropping as the ratio rose to 1:2. The results could be due to the high volume of CS, which hindered electron transfer. Accordingly, a 1:1 (v/v) CDs to CS volume ratio was selected to fabricate the sensor developed.

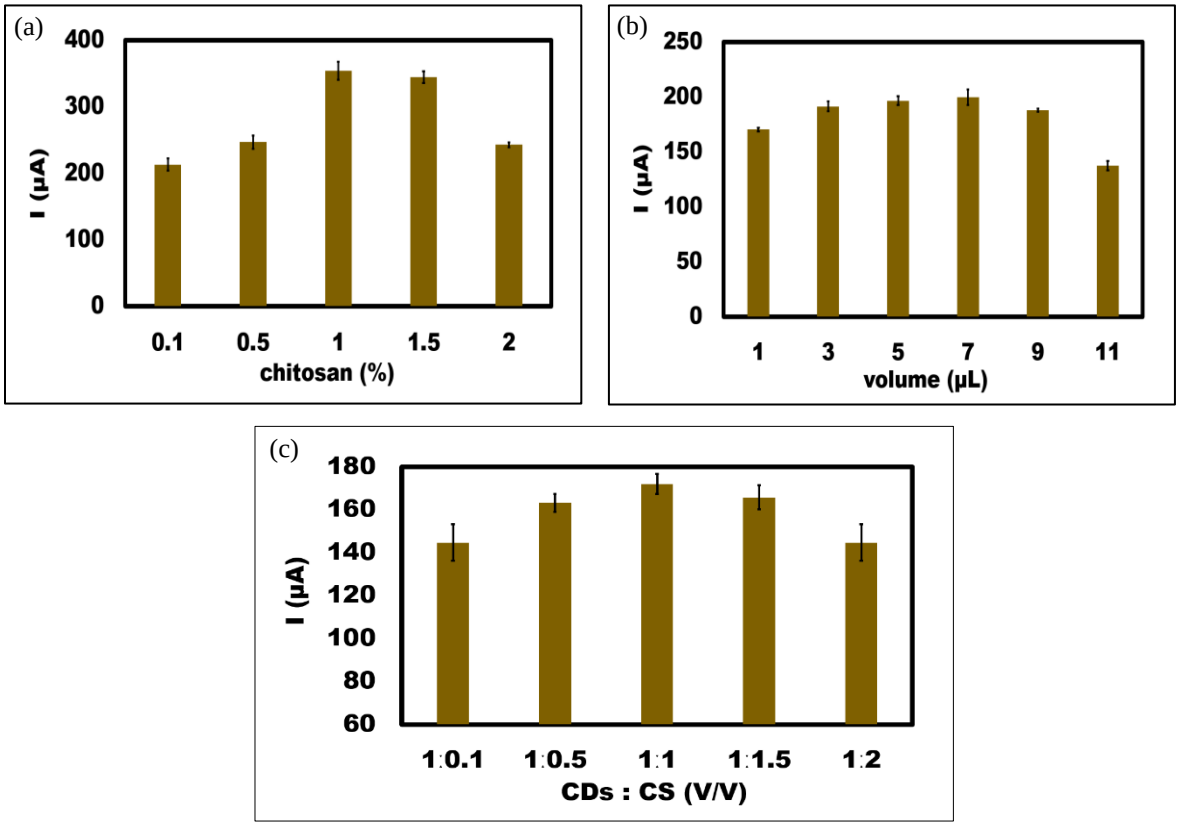

Figure 2. The influence of (a) CS concentration (%, w/v), (b) volume of CDs-CS (µL), and (c) CDs to CS (v/v) ratio mixed drop casted onto the SPCE in 5 mM $K_3[Fe(CN)_6]$/0.1 M KCl at 100 mV/s scan rate

The effects of the supporting electrolyte

Supporting electrolytes play a significant factor in electrochemical studies for detecting analytes. Hydrochloric acid-potassium chloride buffer (HCl-KCl) (pH 3), PBS (pH 7.4), and carbonate-bicarbonate buffer (CBBS) (pH 9) solutions were employed as the supporting electrolyte in the current study (see Figure 3). The buffers were selected due to their different pHs since BPA could be sustained at pHs 3-9 [39]. Nonetheless, numerous reports documented pH 7.4 as the ideal pH to determine BPA levels. The phenomenon might be due to the present form of BPA being affected

by the pH of the supporting electrolyte. In the present study, as 1 µM of BPA was added to PBS (pH 7.4), a 4.0 µA oxidation current was recorded, while HCl-KCl buffer and CBBS documented 2.14 and 2.62 µA, respectively. Consequently, PBS was selected for further analyses.

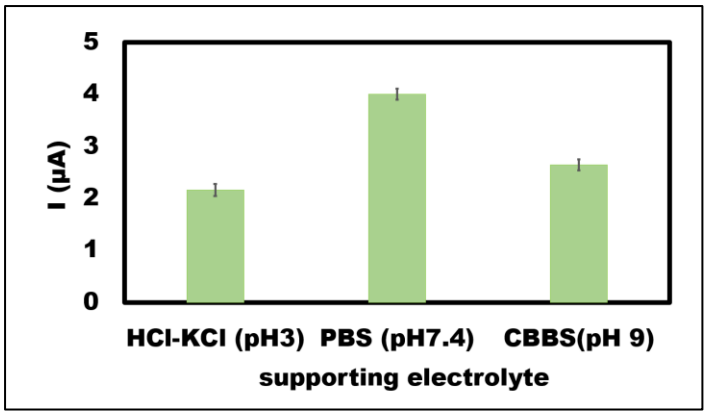

Figure 3. The effects of various supporting electrolytes on the sensor signals in the presence of 1 µM BPA

The effects of pH

Another vital criterion for evaluating the performance of sensors in detecting BPA is pH, and in the current study, the effects were assessed within the 6–8 pH range. The PBS was utilised as the suitable pH to sustain the BPA was reported to be slightly acidic to slightly basic [39]. The anodic peak (E_{pa}) and anodic current (I_{pa}) potentials of 1 µM BPA were examined. The I_{pa} increased from pH 6 to 7 and reached the highest value at pH 7.4. The I_{pa} value then gradually decreased as the pH rose to 8 [see Figure 4(a)]. The CDs could absorb the non-dissociated BPA more easily than the dissociated form in a neutral pH environment with the optimal pH value, which was lower than the pKa of BPA (pKa = 9.73) [35]. Moreover, the results agreed with previous reports that recorded pH 7.4 as the best pH for determining BPA levels [40–41]. Consequently, pH 7.4 was chosen as the optimum pH since it recorded the highest response from the sensor.

Figure 4(b) demonstrates the BPA E_{pa} shifting to a more negative value as the pH was increased due to deprotonation of BPA towards CDs-CS/SPCE [42]. At lower pHs, the H+ ions of the analyte tend to compete with the excess H+ ions originating from the supporting electrolyte. Consequently, a driving force (energy) is required for the BPA to be oxidised, resulting in the peak occurring at higher potentials. The equation Epa (V) = −0.0618 pH + 0.9032, R^2 = 0.9724 illustrates that the E_{pa} and pH possessed a better linearity with a high correlation coefficient. A shift of typically 61.8 mV per pH unit was very close to the Nernst theoretical value, which is 59.10 mV pH^{-1}. The value revealed that the deprotonation of BPA towards CDs-CS/SPCE occurred [42], revealing that equal numbers of proton and electron were present on the electrode that resulted from the electrochemical oxidation of BPA [43]. Accordingly, PBS at pH 7.4 was selected to determine BPA levels in the present study.

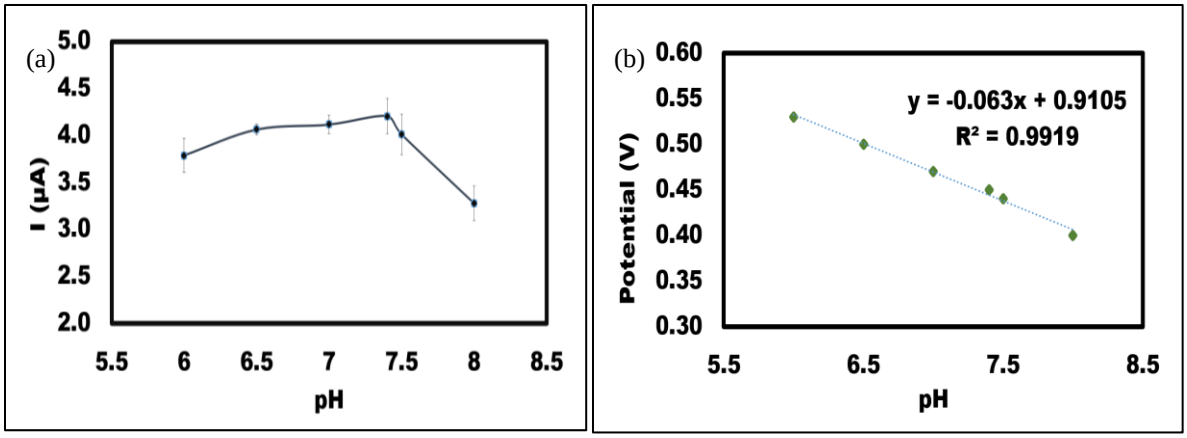

Figure 4. The effects of pH on the (a) oxidation peak current and (b) potential response of 1 µM BPA determined via DPV at 10 mV s^{-1} scan rate

The effects of deposition time and potential

Deposition time is one of the essential factors in improving BPA detection. The data measures the optimum period for the BPA to be deposited onto the surface of the CDs-CS/SPCE sensor. The DPV was employed to evaluate the factor in the presence of 1 µM BPA in PBS (pH 7.4) within a 20-140 s time frame. Figure 5(a) demonstrates the increment of the oxidation peak current at 60 s. At more than 60 s, the oxidation peak current started to descend due to the saturation of the active surface site on the electrode surfaces with BPA, which lessened the electron transfer rate between them. Consequently, 60 s was selected as the best deposition time to develop the sensor in the present study.

Figure 5(b) portrays the relationship between the BPA oxidation peak current signal and deposition potential. As the potential elevated from 0.1 to 0.2 V, the BPA oxidation peak current gradually increased. Conversely, the BPA deposited on the electrode surfaces decreased at deposition potentials exceeding 0.5 V. The phenomenon could be related to saturated adsorption of BPA on the SPCE surfaces. Accordingly, 0.2 V was selected as the optimal deposition potential for the present study.

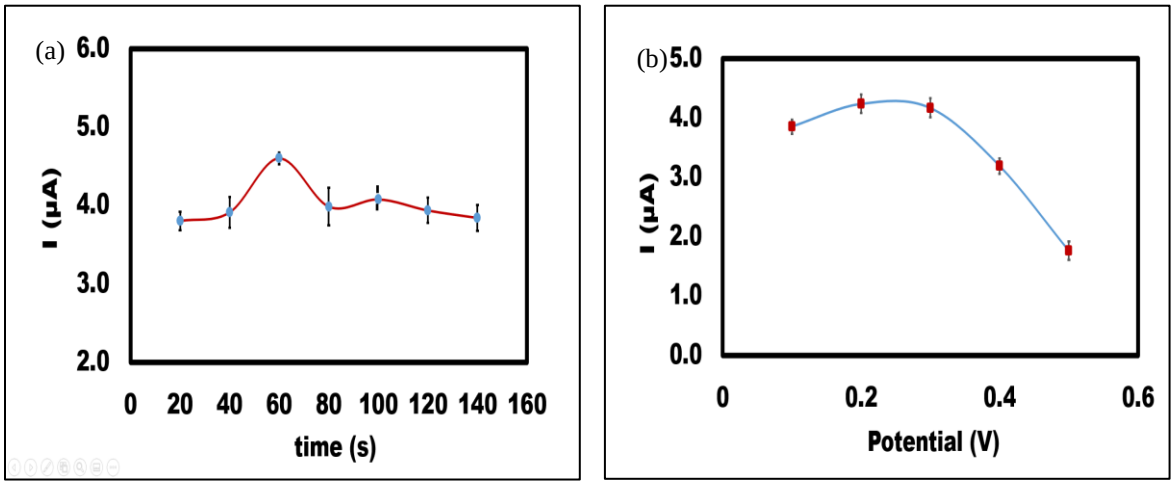

Figure 5. The effects of deposition (a) time and (b) potential on the 1 µM BPA oxidation peak current in PBS (pH 7.4)

Electrochemically active surface area

In the current study, the scan rate employed was within the 10 to 100 mV/s range in $[Fe(CN)_6]^{3-/4-}$ as the probe via the CV technique. By exploring the relationship between the anodic current response and the square root of scan rate, the electroactive surface area of the bare SPCE and the modified CDs-CS/SPCE was determined with the Randles-Sevcik equation (Eq. 1).

$$Ip = (2.69 \times 10^5)\, n^{3/2} A.D^{1/2} V^{1/2} Co \quad (1)$$

where Ip is the maximum current, n is the number of electrons transferred (n = 1), (A) is the electroactive surface area of the electrode (cm^2), D is 7.6×10^{-6} $cm^2 s^{-1}$, which is the diffusion coefficient of $[Fe(CN)_6]^{3-/4-}$ solution, Co is the concentration of $[Fe(CN)_6]^{3-/4-}$, and V is the scan rate (mV/s) [44].

Based on Figure 6(a), the current response constantly increased and shifted towards positive potential at higher scan rates (mV/s). The regression equations, Epa, obtained for the bare SPCE and modified SPCE were slope = 5.778, R^2 = 0.9627 and slope = 21.956, R^2 = 0.9987, respectively. Consequently, the calculated electroactive surface area for the bare SPCE was 0.0016 cm^2, while the CDs-CS/SPCE recorded 0.0049 cm^2, which was approximately 3-fold higher.

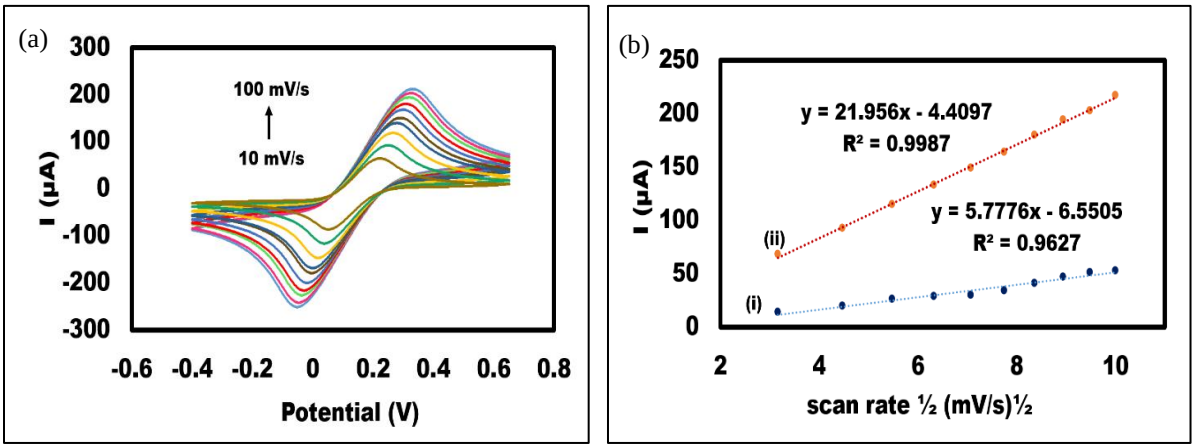

Figure 6. The (a) cyclic voltammograms of the modified electrode for scan rates between 10 and 100mV/s and (b) oxidation current response towards the square root of scan rate for the (i) bare and (ii) CDs-CS/SPCE electrodes

The electrochemical behaviour of BPA

Figure 7(a) illustrates the cyclic voltammograms of the single oxidation peak current of BPA (1 µM) in PBS (0.1 M, pH 7.4). The absence of reduction peak current indicated the irreversible process of BPA determination [45]. Nonetheless, as the cycle increased, the anodic current of BPA significantly decreased. The behaviour could be due to the formation of polymeric products by BPA, which blocked the surfaces of the electrode.

The electrochemical responses of BPA at varying modification conditions of the SPCE were also evaluated through DPV [see Figure 7(b)], consisting of 1 µM BPA in PBS (pH 7.4) and within the +0.2 to +0.7 V potential range. The oxidation peak was observed at the +0.45 V potential for the CDs-CS/SPCE, which was in agreement with previous studies that documented an anodic peak current of 4.23 µA. The BPA electrochemical response for the bare SPCE, CS/SPCE, and CDs/SPCE were observed at 0.48, 0.45, and 0.43 V potentials with anodic peak currents of 0.37, 2.37, and 2.94 µA, respectively.

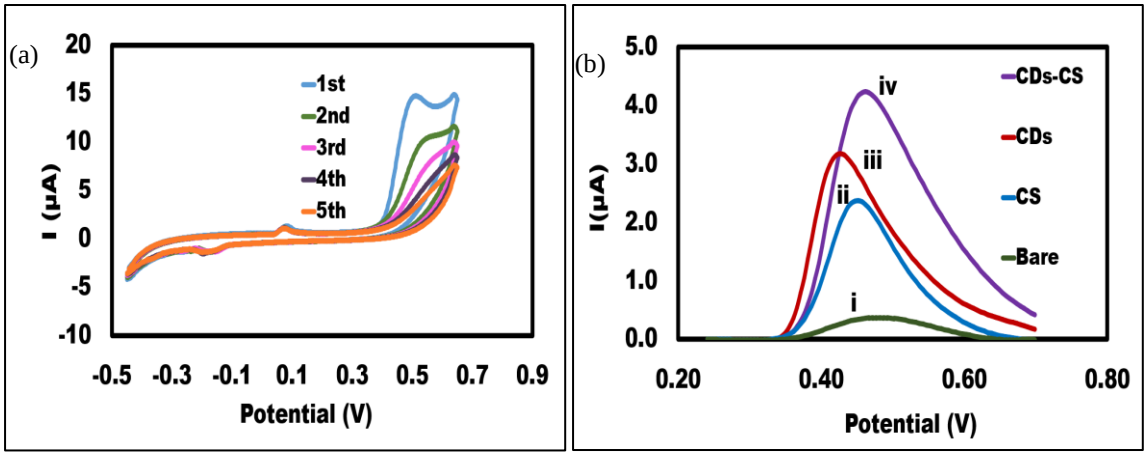

Figure 7. The (a) cyclic voltammograms of different cycles of CDs-CS/SPCE at 100 mV/s scan rate and (b) differential pulse voltammograms of the (i) bare (ii) CS (iii) CDs, and (iv) CDs-CS electrodes in 1 µM BPA with 0.1 M pH 7.4 PBS

The CDs-CS/SPCE sensor recorded an absolute-defined oxidation peak at the +0.45 V potential in DPV. Under optimised conditions, the behaviour of the electrochemical response of the sensor towards BPA in PBS (0.1 M, pH 7.4) as a supporting electrolyte was investigated. Figure 8 illustrates the oxidation peak current observed in varying concentrations of BPA, 0.4 µM to 10 µM, with a sensitivity of 0.4606 µA/µM (R^2 = 0.9911) and a limit of detection (LOD) of 0.37 µM.

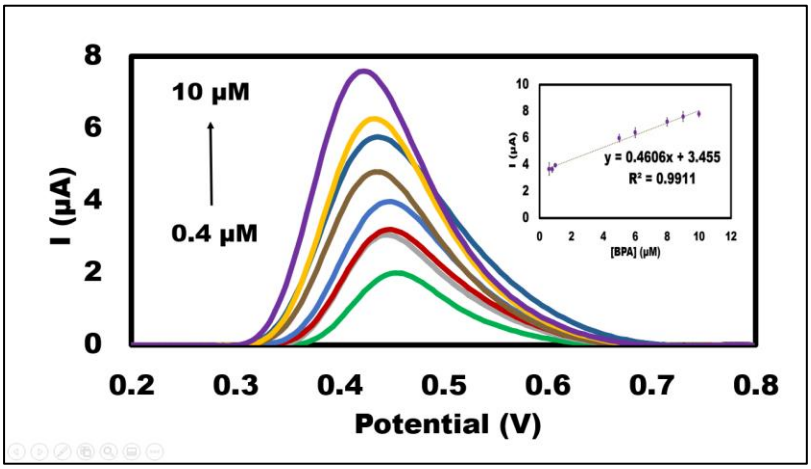

Figure 8. The differential pulse voltammograms of oxidation peak current in varying BPA concentrations (0.4– 10 µM) in PBS (0.1 M, pH 7.4) at 10 mV/s scan rate within 0.2 and 0.8 V potential range versus AgCl. *Note:* The inset diagram denotes the correlation between the current response (µA) and BPA concentration (µM)

Reproducibility, stability, and selectivity of the CDs-CS/SPCE electrodes

The reproducibility of the CDs-CS/SPCE sensor was examined with fabricated sensors prepared independently within similar parameters and evaluated with 1 µM BPA in PBS (pH 7.4). The relative standard deviation (RSD) was 3.66 % (n = 15), indicating good reproducibility. The developed sensor was stored in a

dark box at room temperature for the stability study. The performance of the sensor was evaluated every week in the presence of 1 µM of BPA in PBS (0.1 M, pH 7.4). The sensor retained its performance. Nevertheless, after one, two, and three weeks, the performance decreased to 91.3, 89.5, and 79.5% of its initial response after a month of storage. The selectivity of the developed sensor was also evaluated. Figure 9 demonstrates that the sensor recorded no significant current response towards phenol, 2,4-dinitrophenol, 4-chlorophenol, K^+,Cu^{2+}, Cl^-, and SO_4^{2-}. The compounds were employed at a concentration 10-fold higher (10 µM) than the BPA, proving that the developed sensor was selective towards BPA.

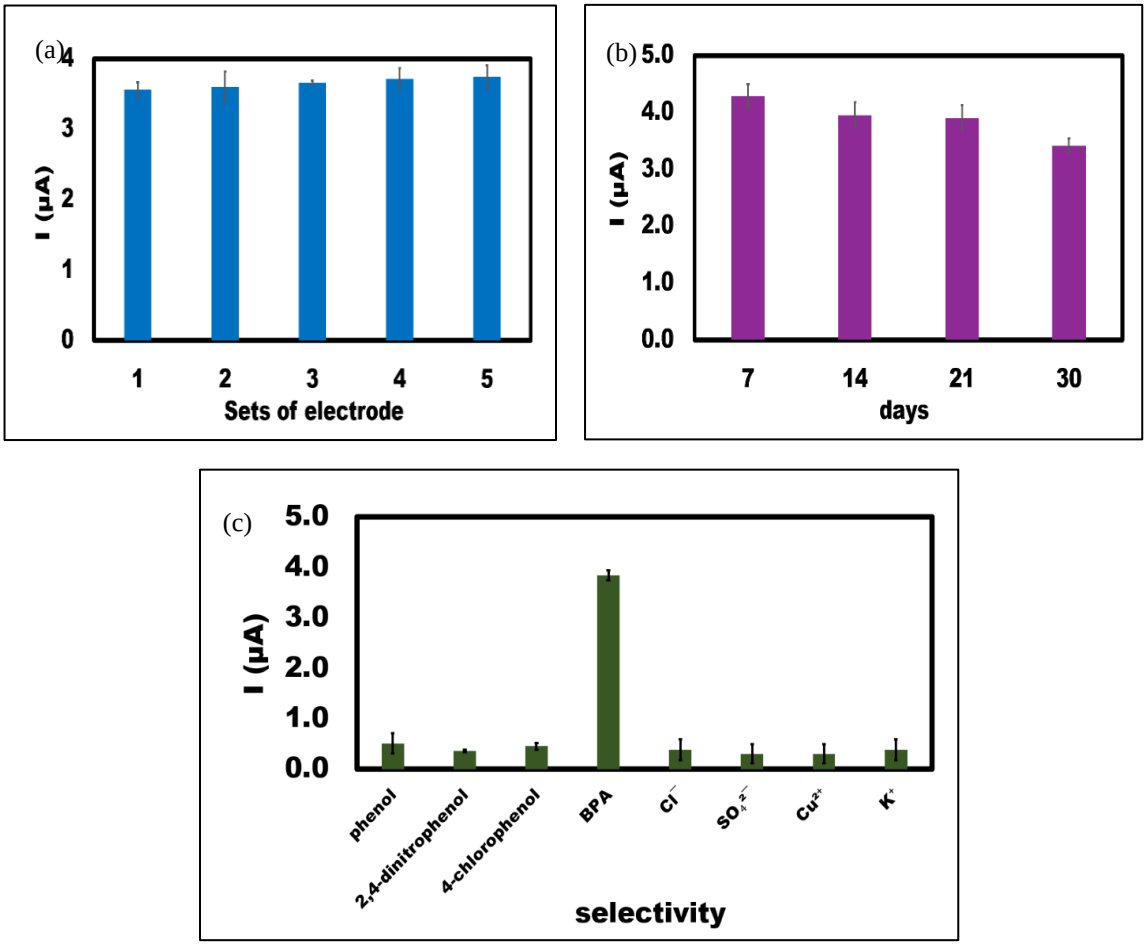

Figure 9. The current responses of (a) different sets of electrodes utilised in the reproducibility study, (b) electrodes analysed on different days in the stability study, and (c) various phenols and ions tested in PBS (pH 7.4) for the selectivity study

Conclusion

The present study successfully fabricated SPCE with CDs-CS to develop electrodes with good electrocatalytic performance to detect BPA. The CDs-CS/SPCE-based sensor exhibited good analytical performance in determining BPA within the 0.4 to 10 µM concentration range, with a sensitivity of 0.46 µA/µM (R^2 = 0.9911) and LOD 0.37 µM. The developed sensor also provided a large surface area for BPA adsorption and good conductivity and selectivity. Furthermore, the sensor demonstrated potential

applications for the sensitive and rapid determinations of BPA levels in aqueous systems.

Abstract

Agarwood oil is highly valued with numerous uses and benefits to the user. However, traditional agarwood grading techniques are subjective, time consuming and labor intensive with poorly reproducible results, in our study, a commercial Fox4000 electronic nose (EN) with AlphaSOFT software was evaluated as a substitute for human nose sniff assessment. Eight pure agarwood oil samples were used: the JBD sample that was selected as the initial high-grade reference sample based on previous research, and seven samples new to the FRIM collection. All samples were subjected to the EN tests and the seven new samples compared with the JBD sample using the non-parametric Wilcoxon's signed-rank test. The REG sample that was closest in aroma profile to JBD was then chosen as the high-grade reference sample for subsequent tests. Varying volumes of REG were blended with gurjun balsam and sandalwood pure oils to produce nineteen blended samples containing increasing percentages of REG. The 19 samples were then used in the EN tests for database establishment. All 19 blended samples were subjected to the EN tests and resulting data transformed using a z-score scale to generate an Agarwood Oil Quality Index (AOQI) that was classified into three levels based on percentage volume of agarwood oil in the oil blend. The EN significant sensor selection process was conducted using Spearman's rho correlation (SRC) and stepwise multi linear regression (SMLR). Finally, the 80:20 k-Nearest Neighbors (kNN) classifier was used to evaluate the AOQI model with the confusion-matrix based performance measure (CMBPM) as the classifier performance evaluator. The results showed SRC with 11 selected sensors outperformed SMLR with 80:20 k-NN test accuracy equal to 89.5%.

Keywords: agarwood oil grading, electronic nose, 80:20 k-NN classifier

Abstrak

Minyak gaharu dikenali mempunyai harga yang tinggi dengan pelbagai kegunaan dan manfaat kepada pengguna. Walau bagaima napun, teknik penggredan gaharu secara tradisional adalah sangat terhad dari segi subjektiviti, kebolehulangan yang rendah, peng gunaan masa, dankos buruh yang mahal. Dalam kajian ini, Hidung Elektronik (EN) Fox4000 komersial dengan perisian AlphaS OFT telah digunakan bagi menggantikan penilaian menghidu menggunakan hidung manusia. Lapan sampel minyak gaharu tulen telah digunakan. Sampel JBD telah dipilih sebagai sampel rujukan bergred tinggi berdasarkan kajian terdahulu . Semua sampel te rtakluk kepada eksperimen EN dan dibandingkan dengan sampel JBD menggunakan ujian peringkat-bertanda Wilcoxon bukan pa rametrik untuk pemilihan sampel rujukan gred tinggi yang baharu. Sampel REG telah dipilih dan dicampur dengan sampel miny ak keruing dan cendana tulen . Kesemua 19 sampel campuran telah melalui ujian EN untuk penubuhan tiga tahap utama Indeks K ualiti Minyak Gaharu (AOQI) menggunakan skala skor-z. Proses pemilihan sensor EN yang signifikan telah dijalankan menggun akan teknik Spearman Rho Correlation (SRC) dan Stepwise Multi Linear Regression (SMLR). Akhirnya, teknik kelasifikasi 80:2 0 k-Nearest Neighbors (k-NN) telah digunakan untuk menilai model AOQI dengan teknik Confusion-Matrix Based Performance Measure (CMBPM) sebagai penilai prestasi pengelasan. Keputusan menunjukkan SRC dengan 11 sensor terpilih mengatasi prest asi SMLR dengan ketepatan ujian 80:20 k-NN bersamaan dengan 89.50%.

Introduction

The wood and essential oils of agarwood (Aquilaria spp.) command very high prices of up to USD90,000/kg for grade AAAAA wood and USD14,000/kg for super grade essential oil on the global market. In Malaysia, grade A agarwood is priced at MYR18,000/kg [1]. Grading methods traditionally used by traders involve assessing the color (shine and resin content estimation), size, shape, fragrance, thickness and density of the raw materials. These grading methods are subjective and can leave the harvesters' product undervalued [2]. To address this problem, better techniques used to grade and classify agarwood woodchips and essential oils have been developed based on wood colour scale template (grades A through C) [3], intended usage (aroma, block, classic, dust, extractable wood and fragrance) [4], wood extractive resin content (A, B, C and D), and electronic nose (EN) grading (high and low grades) for wood [1].

Not as easily accessible are scientific grading or quality assessment techniques offered to the agarwood industry as technical services, such as gas chromatography (GC), gas chromatography–mass spectrometry (GCMS), solid phase micro extraction (SPME) and EN approaches. These methods are typically used separately to identify the selected predefined quality of agarwood oils (pure and in oil blends) and for low and high grade classifications [5-13]. To date, no research has evaluated the use of EN combined with chemistry inputs in quantifying agarwood oil percentages in oil blends for export regulation (taxation or tax exemption) or for use by agarwood traders as an evaluation standard. This study proposes a technique to evaluate the established three levels of the agarwood oil quality index (AOQI) using the 80:20 k-NN classifier with Spearman's rho correlation (SRC) and stepwise multi linear regression (SMLR).

Materials and Methods

The overall research flow outlined in Figure 1 includes agarwood oil sample collection, EN tests, statistical ana lysis for selection of a high-grade reference sample, sam ple blending, EN features extraction, data scaling for A OQI and the 80:20 kNN classifier. The detailed methods for each step are described below.

Agarwood oil collection and high-grade reference sample selection

Eight agarwood oil samples and two common essential oils i.e., gurjun balsam (*Dipterocarpus* sp.) and sandalwood (*Santalum album*) were collected or purchased from local reputable traders of agarwood oil. The Johor Baharu Deluxe (JBD) agarwood sample was selected as the high-grade oil benchmark and reference sample (REFF) as it reportedly contains all significant c hemical compounds found in high-grade agarwood. A n ew high-grade agarwood oil reference (B1) was selecte d based on its EN fingerprint aroma, from seven new sa mples in the Forest Research Institute Malaysia (FRIM) collection (EXQ-OUDO30, HER-OUDO35, MAL1-O UDOI9, MAL2-OUDOI10, MAL3-OUDOI11, MAJ-O UDOI12 and REG-OUDOI13), and using statistical cor

relation of EN data with JBD EN data.

Sample blending processes and EN tests

Pure samples of the three selected reference oils: agarwood (B1), sandalwood (B2) and gurjun balsam (B3) were blended by volume in ratios as given in Table 1. A total of 19 samples (S1–S19) were blended. The blending formula in Table 1 was based on fixed volumes of B2 and B3 while the volume of B1 varied from 0% to 90%. S12 had an equal volume ratio for B1, B2 and B3 (33%:33%:33%). The percentage value of agarwood oil was represented by the percentage value of its volume in the blended oil samples. A commercial FOX4000 EN (Alpha-MOS, Toulouse, France) containing an 18-sensor array of metal oxide semiconductor (MOS) chemical sensors, bundled with AlphaSOFT version 12 data analysis software were used. The EN sensor chambers were divided into three types of high performance (HiP) chambers: chamber A containing doped metal oxide sensors (T30/1, P10/1, P10/2, P40/1, T70/2 and PA2), chamber B containing doped metal oxide sensors (P30/1, P30/2, P40/2, T40/2, T40/1 and TA2) and chamber CL2 containing undoped metal oxide sensors (LY2/AA, LY2/G, LY2/gCT, LY2/gCTl, LY2/Gh and LY2/LG). The carrier gas used was purified air grade (P = 5 psi). For each EN test, the sample was first prepared, heated, then injected via an injection port into the EN sample inlet, which recorded sensor response data into a main database. The EN was used to capture the uniqueness of each sample's scent and transform that information into sensor response data. The headspace generated from each heated sample was injected manually into the injection port using a gas-tight syringe. The system allowed the purified air as the headspace carrier gas to carry the sample headspace through all three chambers in the system and exit at the exhaust port. Simultaneously, the AlphaSOFT software recorded all EN raw data in the database. A total of 135 sample vials were used in the EN tests in developing the database.

Agarwood oil quality index (AOQI) scaling and 80:20 k-nearest neighbors' classifier (kNN)

The AOQI scale is based on the conversion of B1 values (of 0% to 90%) in the sample blends (S1-S19) into a z-score scale using the z-score transformation. The z-score is a standard score method that normalises each score to its standard deviation from the mean score. For the z-score data scaling process in our study, the main EN database data were converted into x-scale values using Equation 1.

$$Z_{\text{score}} = \frac{X - \mu}{\sigma} = \frac{X - mean}{standard\ deviation} \quad (1)$$

Z-score conversion values (Table 2) produced two main threshold values that fell between -0.55 and -0.37 (closest to -0.5) and between 0.34 and 0.70 (closest to 0.5), which corresponded with 20% and 50% B1 volumes in the original data for the blended samples, respectively. Three indices were selected for AOQI with z-score and actual values as illustrated in Figure 2. As a result, three values for AOQI were established as represented in Equation 2.

$$\text{Agarwood oil quality index (AOQI)} = \begin{bmatrix} \text{INDEX 3: HIGH \% VOLUME} \geq 50\% \\ 20\% < \text{INDEX 2: MIDDLE \% VOLUME} < 50\% \\ \text{INDEX 1: LOW \% VOLUME} \leq 20\% \end{bmatrix} \quad (2)$$

Table 2. The Agarwood Oil Quality Index (AOQI) three scales based on z-score conversion values

K nearest neighbor (kNN) is one of the simplest machine learning algorithms with a robust statistical-based supervised machine learning classification technique. The kNN classifier assigns samples that are unclassified to the class that most of its k-nearest neighbors belong to. Furthermore, it is a classifier that uses distance between a point and all its neighbors in an image to find nearest neighbors. The core idea of the kNN algorithm is to select the category of the sample with the most same categories among the K nearest samples in the feature space as the classification of the sample to be tested [14-18].

In our study, the 80:20 kNN was optimized with training and testing datasets constructed from 80% and 20% data partitioned from total EN data, respectively. Three AOQI indices represent three different classes (Figure 2) and the three indices previously defined with the z-score method therefore show 8, 6 and 5 samples falling under Index 1, 2 and 3, respectively.

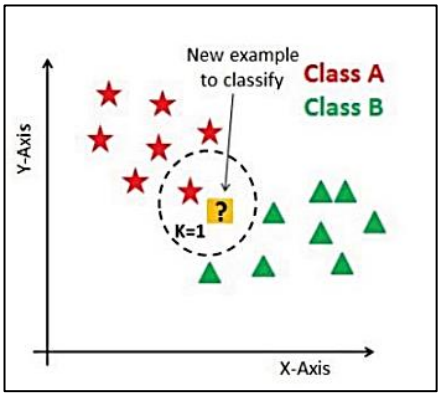

Figure 2. K-nearest neighbor (kNN) classifier illustration [17]

The 80% training dataset consisted of 64 data from Index 1, 48 data from Index 2 and 40 data from Index 3 for a total of 152 data (Table 3). All unique data patterns related to each index group were recorded in the kNN model. The remaining 20% testing data consisted of 16 data from Index 1, 12 data from Index 2 and 10 data from Index 3

for a total of 38 data. After that, the 20% testing data were projected to the kNN classifier training database to find the nearest matching index group. Finally, classifier accuracy was calculated using the confusion-matrix based performance measure (CMBPM; Equation 3) where TP = true positive, TN = true negative, FN = false negative and FP = false positive. The highest classifier accuracy is 100%.

$$80{:}20\ k-NN\ Accuracy\ (\%) = \frac{TP+TN}{TP+TN+FN+FP} \quad (3)$$

Results and Discussion

For the normal data distribution test, all samples were not normally distributed as all p and h values were < 0.05 and 1, respectively (Table 4). Thus, a non-parametric statistical test was selected. For EN data comparison between JBD with seven selected samples using the Wilcoxon rank sum test, REG had the highest p-value = 0.78293 and h = 0 indicating REG had almost the same odor data in continuous distribution as JBD (Table 5). The REG sample was then selected as the reference agarwood oil (B1) mixed with B2 and B3 to produce 19 oil blend samples. All 19 samples were subjected to EN testing and were stored in the main EN database.

Table 4. The results of the sample normality distribution test (Lilliefors test) for the eight agarwood oil samples

	JBD	**MAL2**	**MAL3**	**MAJ**	**REG**	**MAL1**	**EXQ**	**HER**
P-value	0	5.83E-05	0.005966499	6.67E-05	0	0.000617	0	0

h	1	1	0	0*	1	1	0

*Note: P-value > 0.05 & h=0 ---> x1 and x2 are from the same continuous distribution

From Spearman's rho correlation (SRC) test in Table 6, all 11 less correlated sensors with p < 0.05 were selected including T30/1, P10/1, P10/2, P40/1, T70/2, PA/2, P30/1, P30/2, T40/2, T40/1 and TA/2. From MATLAB results in Figure 3, five EN sensors including LY2/LG, LY2/G, LY2/GH, P10/2 and P10/2 were selected by stepwise multi linear regression (SMLR). Both groups of selected sensors were then tested using the kNN 80:20 classifier and the result with the best classification accuracy was chosen.

Figure 3. Electronic nose sensor selection using stepwise multi linear regression (SMLR) in MATLAB

The highest kNN 80:20 classifier training accuracy values for SMLR and SRC were from k = 1 and k = 2, respectively, while the highest kNN 80:20 classifier testing accuracy values for SMLR and SRC were from k = 4 and k = 1 same as k = 2, respectively (Figures 4 and 5). Between the two features extraction techniques, the best k-NN 80:20 classifier training and testing accuracy values were from SRC with values of 100.0% and 89.5%, respectively. While SMLR had a training accuracy of 100.0%, testing accuracy was only 82.5% (Table 7).

Conclusions

The REG sample was selected from among seven new samples in the FRIM collection as the high-grade reference (B1) in our study because it had an aroma profile closest to that of the JBD sample. Varying volumes of B1 were then mixed with B2 and B3 (in fixed, 1:1 ratios) to produce nineteen blended samples containing increasing percentages of B1. The 19 samples were then used in the EN tests for database establishment. The z-score-transformed EN data

successfully indexed the AOQI into three levels. The AOQI with 11 sensors selected by SRC was proven to generate a classification test accuracy that was 7% higher than the SMLR-selected 5 sensors (89.5% vs 82.5% respectively). Lastly, the kNN classifier only needed 11 significant sensors from 18 sensors to produce the best test accuracy. In conclusion, the 80:20 kNN classifier was proven to classify the percentage volume of pure agarwood oil in the oil blend into three groups with Index 1, 2 and 3 denoting AOQI low, medium and high percentage volumes of ≤ 20%, 20% < index < 50% and ≥ 50%, respectively.

Abstract

The interdigitated array of electrodes (IDAE) is a common choice for integration in small electrochemical sensors due to the amplified currents and fast response times. The design and assessment of IDAE performance in microfluidic cells require the use of mathematical models, in which the diffusion equation is widely applied. Analytical solutions for this equation are available for IDAEs in tall cells; however, they are not currently available for shallow cells, as is the case with microfluidic devices. The issue of whether it is possible to model the time response of IDAEs in shallow cells using simple exponential functions is addressed in this work. This is achieved by numerically solving the diffusion equation to obtain the time response of the current and later by applying non-linear regression to obtain exponential models. The current response is generally complex due to the many Fourier harmonics involved. However, the findings reveal that when the elapsed time is greater than some characteristic time, the current response can be approximated by an exponential curve. Furthermore, higher currents can be obtained at the expense of longer response times when the cell is tall, while shorter response times can be obtained at the expense of lower currents when the cell is shallow.

Abstrak

Elektrod susunan interdigital (IDEA) adalah pilihan biasa bagi intergrasi dalam sensor elektrokimia kecil berdasarkan arus teramplikasi dan respons masa yang pantas. Rekabentuk dan penilaian bagi prestasi IDEA di dalam sel mikrobendalir memerlukan pemodelan matematik, di mana persamaan resapan digunakan secara meluas. Penyelesaian analitikal bagi persamaan ini sesuai

bagi IDEA dalam sel tinggi; namun belum ada bagi sel cetek, khusus bagi kes bersama mikrobendalir. Isu terhadap kebarangkalian ia berhasil terhadap model respons masa di dalam sel cetek menggunakan fungsi eksponen mudah telah dikaji. Ia dicapai melalui penyelesaian berangka persamaan resapan untuk mendapatkan respons masa bagi arus dan kemudian digunakan bagi regresi tak linear untuk mendapatkan model eksponen. Respons arus secara umum adalah kompleks disebabkan oleh penglibatan harmonik Fourier. Namun, hasil kajian mendapati apabila masa berlalu lebih kuat berbanding masa pencirian, responsa arus boleh dianggar oleh lengkung eksponen. Selanjutnya, arus yang tinggi boleh diperolehi pada masa respons yang lebih lama apabila susunan sel adalah tinggi, sebaliknya masa respons yang lebih pendek diperolehi pada arus yang rendah di mana kedudukan sel adalah cetek.

Kata kunci: sel elektrokimia cetek, susunan interdigital, simulasi berangka, respons arus

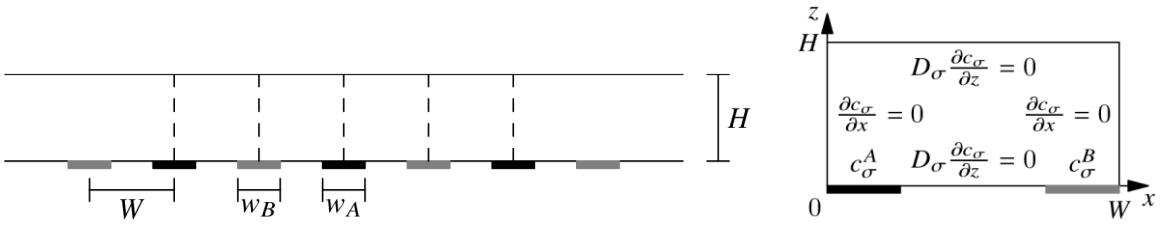
Introduction

Microelectrodes are of interest in electrochemical detection due to their fast response, high current density, and reduced sample volumes [1]. Among these, the interdigitated array of electrodes (IDAE) is a common choice for integration in microfluidic electrochemical sensors due to the amplified currents obtained by redox cycling at multiple electrode bands and the fact that microfluidic devices and microelectrodes share similar fabrication techniques [2, 3].

Obtaining good designs or assessing the performance of IDAE in microfluidic electrochemical cells requires the use of mathematical models. In particular, the diffusion equation is a commonly used model and valid when the effects of convection and migration in the cell are negligible. An analytical solution of the diffusion equation is possible for IDAEs in very tall cells [4]; however, this is not currently available for shallow cells, as in the case of many microfluidic cells. For this reason, numerical simulations of the diffusion equation are commonly performed to obtain the concentration profile and subsequently the current through the cell for the device in question [5, 6].

The issue of whether it is possible to model the time response of the current using simple exponential functions is addressed in this research. This is achieved by numerically solving the diffusion equation for electrochemical cells of different heights containing an IDAE with bands and gaps of equal width. Once this has been done, non-linear regressions are performed on the simulated currents to obtain their fitting parameters, which correspond to the magnitude in steady state and the time constant (reciprocal of the exponential decay constant). The obtained exponential approximations are valid when the elapsed time is greater than some characteristic times. This model for the current shows that there is a trade-off between faster time responses and higher detection currents, depending on the dimensions of the electrochemical cell and IDAE.

Materials and Methods



Model of the IDAE

Consider an IDAE located at the bottom of an electrochemical cell of height H (Figure 1a). The IDAE consists of two band arrays, A (black) and B (gray), where consecutive bands are separated by the distance W between their centers, have widths of w_A and w_B, and share a common length L which is in contact with the electrochemical solution in the channel. The electrochemical cell may also include a counter electrode, external to the IDAE, when each array is potentiostated independently with a bipotentiostat.

The solution comprises a mixture of oxidized (O) and reduced (R) species, in uniform initial concentrations $c_{O,i}$ and $c_{R,i}$, respectively, which are transported only by diffusion (with diffusion coefficient D) and react at the surface of the electrodes by exchanging n_e electrons.

$$O + n_e\, e^- \rightleftharpoons R \qquad (1)$$

For the sake of simplicity, reversible electrode reactions are assumed, and therefore, the Nernst equation is valid even when the current flows through the electrodes [7].

(a) Cross section of the full cell (b) One unit of symmetry (unit cell)

Figure 1. Shallow electrochemical cell with an IDAE. This cell can be regarded as an assembly of several unit cells. Here c_σ is the concentration of species σ (either O or R), and c_σ^A and c_σ^B are the concentrations applied at bands A and B, respectively

If the length L is sufficiently large, the fringing effects at the ends of each band can be neglected, and the electrochemical cell reduced to two dimensions. Moreover, if the number of bands is large enough, the fringing effects at both ends of the IDAE can also be neglected, allowing the IDAE to be represented as an assembly of two-dimensional *unit cells* (Figure 1b) due to its periodic arrangement [4, 8]. In the event of a counter electrode external to the IDAE, this is assumed to be located far away, such that the fringing effects at both ends of the IDAE are further avoided.

Under these conditions, the concentration profile inside a single unit cell is given by the diffusion equation

$$\frac{1}{D}\frac{\partial c_\sigma}{\partial t} = \frac{\partial^2 c_\sigma}{\partial x^2} + \frac{\partial^2 c_\sigma}{\partial z^2} \tag{2}$$

where $c_\sigma(x, z, t)$ is the concentration of species σ (either O or R), which is subject to the initial concentrations present in the electrochemical cell

$$c_\sigma(x, z, 0^-) = c_{\sigma,i} \tag{3}$$

as well as boundary conditions for insulation (top and bottom), symmetry (left and right), and applied concentrations c_σ^A and c_σ^B at the bands, as indicated in Figure 1b.

It should be noted that the concentrations applied at the surface of the bands E (which can be either A or B) are uniform. This is possible due to the validity of the Nernst equation

$$ln\left(\frac{c_O^E}{c_R^E}\right) = \frac{Fn_e}{RT}(V_E - V^{o\prime}) \tag{4}$$

where F is Faraday's constant, R is the universal gas constant, T is the temperature of the system, V_E is the potential applied at bands E, and $V^{o\prime}$ is the formal potential of the redox couple. Furthermore, the sum of concentrations at any point in the unit cell is constant and uniform [4, 8]

$$c_O(x, z, t) + c_R(x, z, t) = c_{O,i} + c_{R,i}$$

Both facts make the concentrations of species O and R at each band E (either A or B) uniform and dependent only on the potential applied at that same band

$$c_O^E = \frac{c_{O,i}+c_{R,i}}{1+e^{\frac{-Fn_e}{RT}(V_E - V^{o\prime})}} \tag{5}$$

$$c_R^E = \frac{c_{R,i}+c_{O,i}}{1+e^{\frac{+Fn_e}{RT}(V_E - V^{o\prime})}} \tag{6}$$

Once the concentration profile is known, the current at an individual band E (either A or B) can be obtained by integrating the current density on that band

$$i_E = \int_E \mp F\, n_e D \frac{\partial c_\sigma}{\partial z}(x, 0, t) L dx \tag{7}$$

where minus or plus signs should be used when the species σ corresponds to O or R, respectively.

Implementation of the simulations

All equations were normalized using the relations $\gamma_\sigma = [c_\sigma - c_\sigma{}^A]/[c_\sigma{}^B - c_\sigma{}^A]$, $\xi = x/W$, $\zeta = z/W$ and $\tau = \pi^2 Dt/W^2$, to make the results available for devices fabricated at different scales. In particular, the diffusion equation, its initial concentration, and the concentrations at the bands were transformed to

$$\pi^2 \frac{\partial \gamma_\sigma}{\partial \tau} = \frac{\partial^2 \gamma_\sigma}{\partial \xi^2} + \frac{\partial^2 \gamma_\sigma}{\partial \zeta^2} \quad (8)$$

$$\gamma_\sigma(\xi, \zeta, 0^-) = \gamma_{\sigma,i} = \frac{c_{\sigma,i} - c_\sigma^A}{c_\sigma^B - c_\sigma^A} \quad (9)$$

$$\gamma_\sigma(\xi, 0, \tau) = 0 \text{ for } \xi \in A \quad (10)$$

$$\gamma_\sigma(\xi, 0, \tau) = 1 \text{ for } \xi \in B \quad (11)$$

while the boundary conditions for insulation and symmetry remained equal to zero, and the normalized current at a single band resulted in

$$\frac{i_E/L}{\pi^2 F n_e D[c_\sigma^B - c_\sigma^A]} = \int_E \frac{\mp 1}{\pi^2} \frac{\partial \gamma_\sigma}{\partial \zeta}(\xi, 0, \tau) d\xi \quad (12)$$

where minus or plus signs should be used when the species σ corresponds to O or R, respectively.

Two cases were considered for initial concentrations: (i) The case $\gamma_{\sigma,i} = 0$, where the initial concentration of one species equals the concentration applied at one of the arrays $c_{\sigma,i} = c_\sigma{}^A$. This is a common setup for IDAEs, especially when $c_{\sigma,i} = 0$ and the concentration $c_\sigma{}^A$ is forced to zero by potentiostating at a fixed extreme potential [4], while the concentration at the other array $c_\sigma{}^B$ is potentiostated at will. This configuration requires a bipotentiostat with a counter electrode external to the IDAE.

(ii) The case $\gamma_{\sigma,i} = 0.5$, where the average concentration applied to the arrays is equal to the initial concentration $(c_\sigma{}^A + c_\sigma{}^B)/2 = c_{\sigma,i}$. This condition, together with bands of equal width ($w_A = w_B$), produces symmetrical concentration profiles, leading to equal currents at the arrays [8, 9]. This last situation corresponds to the case where a conventional potentiostat drives one of the arrays while the other array performs as a counter electrode, thus sparing the need for an external counter electrode.

In particular, IDAEs with bands and gaps of equal width ($w_A = w_B = W/2$) were considered for all simulations, since this is a common design choice, and also because it facilitates the display of results. This choice also simplifies the implementation of the meshes, chosen in this study to be of an exponential kind as shown in Figure 2. Each mesh used in the simulations consists of $n_x \times n_z$ elements, where the size of the smallest element is $\delta_x = \delta_z = \delta_0$, and the remaining elements increase in size according to the growth factor (stretching parameter) $r_x = r_z = r$ [10]. The resolution of the meshes was tested for diffusion in steady state with a unit cell with an aspect ratio $H/W = 1$ (Figure 2) and successively refined until the absolute error of the normalized current between two consecutive iterations was less than 0.0005, corresponding approximately to three decimal places of accuracy. The values obtained for the smallest element and the growth factor were $\delta_0 = 0.00025$ and $r \approx 1.2496$, respectively, and used for all simulations in this study.

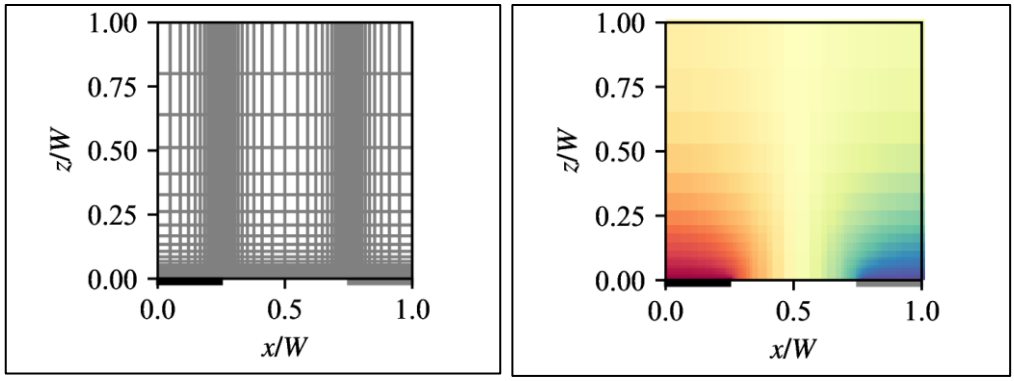


Figure 2. Exponential mesh (left) and normalized concentration in steady state (right) for the case $H/W = 1$. Number of elements is $n_x \times n_z = 100 \times 31$, and size of the smallest element $\delta_x = \delta_z = \delta_0 = 0.00025$ with a growth factor of $r_x = r_z = r \approx 1.2496$.

The simulations considered different aspect ratios $H/W = \{1, 1/2, 1/3, \ldots, 1/10\}$, and were solved numerically by writing the normalized diffusion equation, its boundary conditions, and the corresponding meshes in Python with the aid of the FiPy package [11]. These simulations can be downloaded from [12].

Exponential fits for the current response

The concentration profile in a shallow cell containing an IDAE evolves over time in a complex manner, with the addition of several Fourier harmonics to produce the right result. Each of these harmonics contains an exponential factor

$$exp\left(-\left[n^2 + k^2\frac{W^2}{H^2}\right]\frac{\pi^2}{W^2}Dt\right) \text{ for } \begin{matrix} n = 1,2,\ldots \\ k = 0,1,\ldots \end{matrix} \qquad (13)$$

which dampens the influence of the harmonic over time. Some of these harmonics will decay faster than others. In particular, the harmonic $(n, k) = (1, 0)$ is the slowest to decay and the only one remaining and contributing to the concentration for times $\pi^2 Dt/W^2 > 1$ and aspect ratios $H/W < 1/2$. The exponential factors of all other harmonics ($n \geq 1$ and $k \geq 1$) are less than $\exp(-[1^2 + 1^2 \times 2^2]) = \exp(-5) \approx 0.0067 = 0.67\%$ and therefore disappear quickly. This leads the concentration profile to behave like an exponential under the conditions stated previously [8].

The previous argument also suggests that the current may behave like an exponential after a certain time T

$$i_E = i_f + K\exp(-t/\tau_i) \quad \text{for } t \gtrsim T \qquad (14)$$

where i_f is the current of a single band in steady state, K is a real number, and τ_i is the *time constant* of the current response. However, this time T may not be equal to its counterpart obtained for the concentration.

After obtaining the time response of the current by numerically solving the diffusion equation, we searched for the time T and the parameters i_f, K and τ_i of the exponential curve. This was done in four steps (see Figure 3): (i) Search for the time t_{ss} where the current i_E and its steady state i_f differ by 0.67%. This gives a rough approximation of the time when an exponential decays to 0.67% (which corresponds to $5\tau_i$). (ii) Find the time $t_{ss}/5$. This gives a rough approximation of the time constant of the current τ_i. However, this time may be too soon for the current to behave exponentially. (iii) Find the time $T = 2t_{ss}/5$. This time gives a rough approximation of $2\tau_i$, where it is more likely for the current to start behaving exponentially. We could have also chosen $3t_{ss}/5$; however, $2t_{ss}/5$ gave good results for exponential fit. Times near $4t_{ss}/5$ or beyond are not advisable, since they would be too close to the time where the current reaches steady state, and thus the current would no longer be exponential but nearly constant. (iv) Once $T = 2t_{ss}/5$ is known, fit an exponential curve to the simulation data of the current between times T and t_{ss} to obtain the fitting parameters i_f, K, and τ_i. Since the model for the current is not linear

in its parameters, a non-linear fit needs to be performed. This procedure was also implemented in Python, whose script can be downloaded from [12].

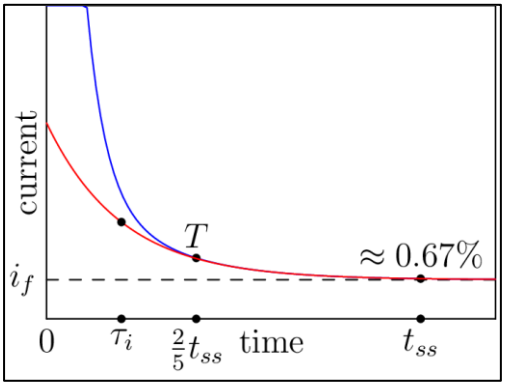

Figure 3. Process to obtain the exponential fit (red) for the time response of the current (blue). (i) Find t_{ss}, which corresponds to the time where the current i_E and i_f differ by 0.67%. (ii) Find $t_{ss}/5$, which gives a rough approximation of τ_i. (iii) Find $T = 2t_{ss}/5$, which gives a rough approximation of the time $2\tau_i$. (iv) Fit an exponential curve to the time response of the current i_E, by taking the simulation data between $T = 2t_{ss}/5$ and t_{ss}

Results and Discussion

The simulations of the currents and their respective exponential fits were performed for the cases involving external and internal counter electrodes, using a bipotentiostat and conventional potentiostat, respectively; the most common configurations to drive an IDAE. For both cases, electrochemical cells of different heights were used while fixing the width of the unit cell. The results are discussed below.

Case of external counter electrode ($c_{\sigma,i} = c_\sigma^A$)

For this case, we considered that the initial concentration of one species equals its concentration applied at one array $c_{\sigma,i} = c_\sigma^A$, achieved by potentiostating array A and forcing c_σ^A to be equal to $c_{\sigma,i}$, while array B is potentiostated at will. In practice, this requires the use of a bipotentiostat with a counter electrode external to the IDAE.

Under these conditions, several simulations were performed using different values of W/H. The simulations produced currents of different magnitude at bands A and B, as shown in Figure 4. This provides clear evidence of the need for a counter electrode, external to the IDAE, to be responsible for collecting the net current $i_{\text{net}} = i_A + i_B \neq 0$ produced in every unit cell, as indicated in Figure 5. However, as the simulations reach steady state, the net current tends to zero, meaning that the currents at both bands must be balanced in steady state $i_A = -i_B$. This is only possible under the assumption of a large number of bands and an external counter electrode far away from the IDAE.

As expected, all currents obtained by simulation (circles) can be approximated by exponentials (lines), as presented in Figures 4 and 5. In fact, in the case of currents at B in Figure 4, the exponential approximations show some deviation from their simulated counterparts for $t > \tau_i$, while improving considerably for $t > T$ (where T is roughly $2\tau_i$), and clearly showing a steady-state response for $t > 5\tau_i$. The parameters i_f, K, and τ_i obtained from all exponential fits are given in Table 1, such that the exponential approximations can be easily reconstructed as required.

In Figure 6, the magnitudes of currents at A and B are equal in steady state and decrease as the cell becomes shallower. This is because there are two main gradients

of concentration when the electrochemical cell is tall: (i) between the IDAE and the bulk concentration near the roof of the cell; and (ii) in between consecutive bands (Figure 2). However, when the cell becomes shallower, the gradient between the IDAE and the roof of the cell tends to disappear, leaving only the gradient of concentration between consecutive bands. The time constants of currents at A and B, as well as the net current, are all equal, decreasing as the cell becomes shallower. This is because the electrochemical species can escape to the region of bulk concentration near the roof of the cell when the cell is tall (Figure 2) and later diffuse to the external counter electrode. However, when the cell becomes shallower, the electrochemical species are forced to diffuse only between consecutive bands due to the low roof of the cell. Therefore, in the case of a shallow cell, the species diffuse through a shorter distance compared to the case of a taller cell.

The previous results show that there is a compromise between sensitivity (current) and response time (time constant) of the sensor. The taller the electrochemical cell, the more sensitive it becomes, but the longer the response time. Conversely, the shallower the electrochemical cell, the less sensitive it becomes, but the shorter the response time.

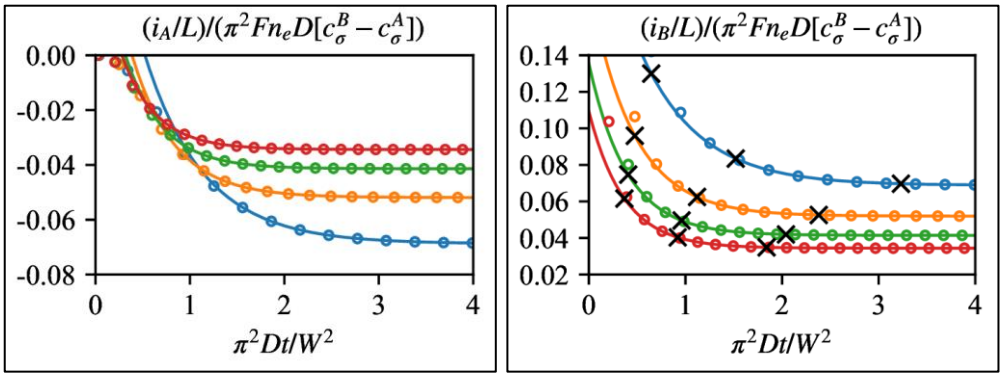

Figure 4. Normalized versions of the current through single bands i_A (left) and i_B (right) for selected aspect ratios W/H = {4, 6, 8, 10} (lines in order from blue to red) and initial concentration $c_{\sigma,i} = c_\sigma{}^A$. Circles correspond to the simulation points, while solid lines correspond to the exponential fit. Crosses on a line correspond to the times τ_i, T and $5\tau_i$ (in order from left to right)

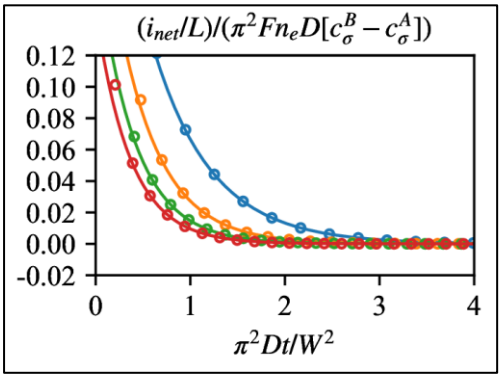

Figure 5. Normalized version of the net current $i_{net} = i_A + i_B$ for selected aspect ratios W/H = {4, 6, 8, 10} (lines in order from blue to red) and initial concentration $c_{\sigma,i} = c_\sigma{}^A$. Circles correspond to the simulation points, while solid lines correspond to the exponential fit

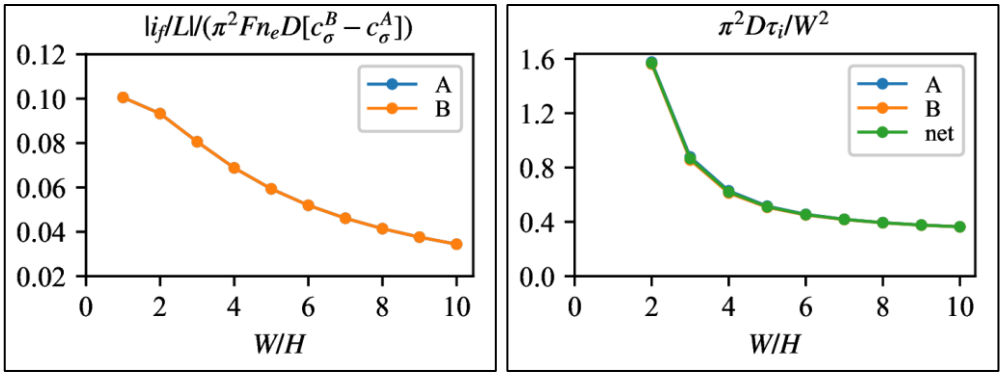

Figure 6. Normalized versions of the absolute value of the steady-state current $|i_f|$ (left) and the time constant of the current τ_i (right) for different aspect ratios W/H and initial concentration $c_{\sigma,i} = c_\sigma{}^A$. The case $W/H = 1$ has been omitted from the normalized time constant plot to maintain good visualization of the lower values

Table 1. Parameters resulting from the exponential fit of normalized currents for different aspect ratios W/H and initial concentration $c_{\sigma,i} = c_\sigma{}^A = 0$. The parameters p_0, p_1, and p_2 correspond to the normalized versions of i_f, K and τ_i, that is, $(i_f/L)/(\pi^2 F n_e D[c_\sigma{}^A - c_\sigma{}^B])$, $(K/L)/(\pi^2 F n_e D[c_\sigma{}^A - c_\sigma{}^B])$, and $\pi^2 D\tau_i/W^2$. The coefficient of determination was $R^2 > 0.9999$ for all cases

Case of internal counter electrode ($c_{\sigma,i} = [c_\sigma{}^A + c_\sigma{}^B]/2$)
In this case, the average concentration applied at the bands equals the initial concentration $(c_\sigma{}^A + c_\sigma{}^B)/2 = c_{\sigma,i}$, corresponding to the case where a conventional potentiostat drives one of the arrays while the other array performs as a counter electrode. Here, the potential (and therefore the concentration) of the counter electrode is regulated automatically by the potentiostat following the previous average condition, which can be rewritten as $[c_\sigma{}^B - c_{\sigma,i}] = -[c_\sigma{}^A - c_{\sigma,i}]$.

Under these conditions, several simulations were performed using different values of W/H. Unlike the case of the external counter electrode, these simulations

produced currents of the same magnitude at bands A and B, but with the opposite sign $i_A = -i_B$, and not only during steady state but for all simulation times (Figure 7). This means that all current generated by bands B is always collected by bands A, thus confirming the use of an internal counter electrode.

As before, all currents obtained by simulation (circles) can be approximated by exponentials (lines), as presented in Figure 7. For example, in the case of currents at bands B, the exponential approximations show some deviation for times $t > \tau_i$, but a considerable improvement for $t > T$ (roughly $2\tau_i$). All current responses reach steady state at times $t > 5\tau_i$. The parameters i_f, K, and τ_i obtained from all exponential fits are given in Table 2, such that the exponential approximations can be easily reconstructed as required.

In Figure 8, the magnitudes of the currents at bands A and B decrease as the cell becomes shallower, in the same way as in the case of the external counter electrode (at least for their normalized versions). In similarity to the case of the external counter electrode, this is due to the vertical gradient of concentration between the IDAE and the roof of the cell (Figure 2), which disappears as the cell becomes shallower. The time constants of the currents at bands A and B are equal, decreasing as the cell becomes shallower. However, the values obtained here are much shorter than those obtained for the external counter electrode (compared with Figure 6). This can be explained by the absence of an external counter electrode, and therefore, the species cannot escape far from the IDAE but diffuse only between consecutive bands, even in the case of a tall electrochemical cell.

Finally, as in the case of the external counter electrode, a compromise exists between the sensitivity (current) and response time (time constant) of the electrochemical sensor. The shallower the electrochemical cell, the less sensitive it becomes, but the shorter the response time. And vice versa in the case of tall cells.

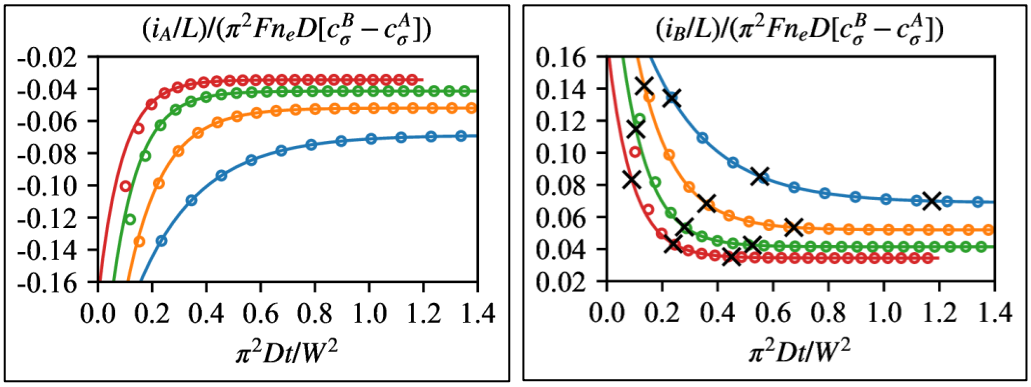

Figure 7. Normalized versions of the current through single bands i_A (left) and i_B (right) for selected aspect ratios W/H = {4, 6, 8, 10} (lines in order from blue to red) and initial concentration $c_{\sigma,i} = (c_\sigma^A + c_\sigma^B)/2$. Circles correspond to the simulation points, while solid lines correspond to the exponential fit. Crosses on a line correspond to the times τ_i, T, and $5\tau_i$ (in order from left to right)

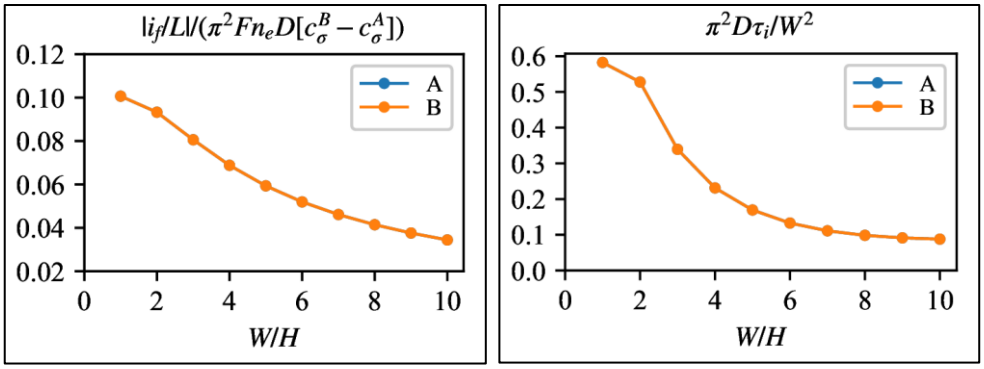

Figure 8. Normalized versions of the absolute value of the steady-state current $|i_f|$ (left) and the time constant of the current τ_i (right) for different aspect ratios W/H and initial concentration $c_{\sigma,i} = (c_\sigma^A + c_\sigma^B)/2$

Table 2. Parameters resulting from the exponential fit of normalized currents for different aspect ratios W/H and initial concentration $c_{\sigma,i} = (c_\sigma^A + c_\sigma^B)/2$. The parameters p_0, p_1, and p_2 correspond to the normalized versions of i_f, K, and τ_i, that is, $(i_f/L)/(\pi^2 F n_e D[c_\sigma^A - c_\sigma^B])$, $(K/L)/(\pi^2 F n_e D[c_\sigma^A - c_\sigma^B])$, and $\pi^2 D\tau_i/W^2$. The coefficient of determination was $R^2 > 0.9985$ for all cases

Conclusion

In this work, the main issue of whether the current response of an IDAE in a shallow electrochemical cell can be modeled by an exponential function has been addressed. The results show that a simple exponential function can approximate the time response of the current for elapsed times greater than approximately two-time constants, reaching steady state after approximately five-time constants. Normalized steady-state currents and time constants were tabulated for different aspect ratios (separation between bands with respect to height of the cell), such that they can be used for cells of different scales or dimensions.

When driving the IDAE with a bipotentiostat (both arrays perform as working electrodes), the net current at the arrays is non-zero during the transient state (approaching zero in steady state) and must be collected

by an external counter electrode. On the other hand, when driving the IDAE with a conventional potentiostat (one array performs as a working electrode, while the other performs as an internal counter electrode), the currents at the arrays are always of equal magnitude and opposite signs (during the transient and steady states).

In the cases of external and internal counter electrodes, the steady-state magnitude and time constant of the current decrease as the electrochemical cell becomes shallower. This shows a trade-off or compromise between sensitivity (in terms of current magnitude) and response time (in terms of time constant) for IDAEs in shallow cells. Higher currents can be obtained at the expense of longer response times when the cell is tall (compared to the separation between consecutive bands of the IDAE) and shorter response times at the expense of lower currents when the cell is shallow.

Abstract

L-glutamate is widely used as a flavour enhancer in various foodstuffs and seasoning in the form of monosodium glutamate (MSG). MSG has been linked to neurotoxic effects, metabolic disorders, headache, numbness and palpitation. In this work, an amperometric L-glutamate biosensor based on photocurable poly(2-hydroxylethyl methacrylate)-containing ferrocene film for the determination of L-glutamate in food samples is described. The sensor is fabricated based on simultaneous immobilization of both L-glutamate oxidase and ferrocene as a mediator during the deposition of poly(2-hydroxylethyl methacrylate) film via photocuring. Ferrocene was used to shuttle the electrons directly between the reduced enzyme and the electrode. From electrochemical studies, a linear response towards L-glutamate in the concentration range of 10-30 mM was obtained at applied potential of +0.25 V with the detection limit of 7.7 mM. The storage stability of the biosensor is up to 4 months under storage condition of 4 ^{o}C in refrigerator. The performance of the biosensor was applied to the determination of L-glutamate in food stocks from local supermarkets. Results from amperometric L-glutamate biosensor were further validated with HPLC method.

Keywords: photocurable, methacrylate polymers, ferrocene, L-glutamate biosensor

Abstrak

L-glutamat digunakan secara meluas dalam pelbagai bahan makanan dan perasa dalam bentuk mononatrium glutamat (MSG). MSG telah dikaitkan dengan kesan neurotoksik, gangguan metabolik, sakit kepala, rasa kebas dan berdebar-debar. Biosensor amperomerik L-glutamat berasaskan fotosalutan poli(2-hidroksiletil matakrilat)-mengandungi filem ferosena dihuraikan untuk

penentuan L-glutamat di dalam sampel makanan. Sensor ini direka berasaskan pemegunan secara serentak bagi L-glutamat oksida dan ferosena sebagai perantara semasa pemendapan filem poli(2-hidroksiletil metakrilat) menerusi fotosalutan. Ferosena digunakan sebagai perantara ulang-alik elektron secara langsung antara penurunan enzim dengan elektrod. Berdasarkan kajian elektrokimia, rangsangan linear terhadap L-glutamat diperoleh dalam julat kepekatan 10-30 mM pada keupayaan +0.25 V dengan had pengesanan 7.7 mM. Jangka hayat kestabilan biosensor penyimpanan dalam peti sejuk adalah mencapai sehingga 4 bulan pada suhu 4^{o}C. Prestasi biosensor diaplikasikan untuk penentuan L-glutamat dalam stok makanan daripada pasar raya tempatan. Keputusan daripada biosensor L-glutamat seterusnya disahkan dengan kaedah HPLC.

Kata kunci: fotosalutan, polimer metakrilat, ferosena, biosensor L-glutamat

Introduction

Glutamic acid is an important neurotransmitter of the central nervous system [1]. It is widely used as an additive to enhance the flavour in variety of foods prepared at home, restaurants, and by food processor in a form of monosodium glutamate (MSG). Glutamic acid exists both as free glutamate and bound with other amino acids in a protein. Only the free form of L-glutamate can enhance the food's flavour. The use of MSG in foods became controversial in the late 1960s when it was claimed to be the cause of a range of adverse reactions in people who had eaten foods containing the additive. Symptoms of MSG-sensitivity (called "Chinese restaurant syndrome") consist of numbness at the back of the neck and arms, weakness and palpitation. There is growing evidence linking the abnormalities of endogenous glutamate metabolism with certain diseases, such as Alzheimer's, Huntington's disease and Amyotrophic lateral sclerosis [2]. In Malaysia, the use of MSG must be in the form of 99.9% L-glutamate but there is no regulation on the limit of MSG that can be added into the food [3]. However, based on European Food Safety Authority (EFSA) panel after re-evaluating the safety of glutamate additives in 2017, the acceptable daily intake for glutamate additive has been set to 30 mg/kg bw/day [4].

There are several methods to determine the L-glutamate. Typically, separation techniques, in particular high-performance liquid chromatography [5, 6, 7], high-performance thin layer chromatography [8], thin layer chromatography and liquid chromatography-mass spectrometry [9] and capillary electrophoresis [10] are commonly used but require pre-concentration and sample derivatization. These techniques are also time consuming and need to be performed by highly trained operators. In contrast, simple and cost-effective spectrophotometric [11, 12, 13] and potentiometric [14] methods with chemical derivatization have been considered by some authors as an alternative for determination of L-glutamate in food. However, poor selectivity and interference from complex matrices in food may give inaccurate determination of L-glutamate. Therefore, enzymatic biosensors are gaining considerable attention due to their advantages of high selectivity and sensitivity towards L-glutamate**.** L-glutamate dehydrogenase [15, 16] and L-glutamate oxidase [17-23] had been widely used as a biological recognition to construct enzymatic sensors. Many enzymic methods have been used in conjunction with spectrophotometry [16, 19], potentiometry [20, 21] and amperometry [15, 17, 18, 22, 23] for the analysis of L-glutamate.

Enzyme electrodes have been proven to be the most widely applicable since it served to concentrate the enzyme activity in the vicinity of the sensor surface. A mixture of glutaraldehyde and bovine serum albumin (BSA) were usually used as a cross-linking reagent to immobilize the enzyme onto the electrode. A photo-cross linkable polymer polyvinyl alcohol bearing styrylpyridinium (PVA-SbQ) mixed with BSA and glutaraldehyde exposure has been reported for fabrication of an enzyme L-glutamate oxidase on a planar palladium electrode [18]. Hydrogen peroxide produced from the catalytic reaction by the L-glutamate oxidase which is proportional to the concentration of MSG was recorded at a potential of +400 mV versus Ag/AgCl reference electrode. The measurement range of L-glutamate was obtained between 50 nM - 100 µM. However, this method required a long procedure where glutaraldehyde in vaporized form was used instead of mixing directly to prevent enzyme deactivation during chemical attachment. Another approached was the

development of amperometric biosensor of L-glutamate based on the co-immobilization of L-glutamate dehydrogenase (GLDH) and salicylate hydroxylase (SHL) entrapped in a poly(carbamoyl) sulfonate (PCS) hydrogel and sandwiched between a dialysis membrane and a Teflon membrane on a Clark-type oxygen electrode [15]. Enzyme solution of GLDH and SHL was mixed with PCS and polymerization then achieved by adjusting the pH of the enzyme matrix through the addition of polyethylenimine (PEI). The mixture of the enzyme-PCS gel was spread over a Teflon membrane, followed by drying and storing at 4°C overnight. Simple immobilization technique through entrapment of the L-glutamate oxidase in chitosan film also required a few hours to complete the immobilization process [17].

In this work, the enzyme L-glutamate oxidase (Glox) was used as a biological recognition element to detect L-glutamate. The enzyme reactions with L-glutamate are illustrated in Equation 1. L-glutamate reacted with Glox producing H_2O_2, α-ketoglutarate, NH_3 and a reduced form of Glox. The product H_2O_2 is an electroactive species, which can be oxidized to yield current flow. However, due to the high oxidation potential of H_2O_2 which gives poor selectivity and interferences to the biosensor signal, therefore H_2O_2 was not used in the transduction process. Instead, ferrocene (Fc) was used as a mediator to shuttle electrons directly between the reduced enzyme and the electrode (Equation 2). The Fc diffused to the working electrode, oxidized or reduced at a fixed potential until it reached equilibrium (Equation 3). In this way, the current generated was directly proportional to the concentration of L-glutamate. The similar concept had been reported to construct glucose biosensor [24].

$$\mathrm{L-glutamate} + \mathrm{Glox_{oxidized}} \rightarrow \mathrm{Glox_{reduced}} + \alpha\mathrm{-ketoglutarate} + \mathrm{NH_3} + \mathrm{H_2O_2} \quad (1)$$

$$\mathrm{Glox_{reduced}} + 2\,\mathrm{Fc^+} \rightarrow \mathrm{Glox_{oxidized}} + 2\,\mathrm{Fc} \quad (2)$$

$$\text{At the working electrode: } \mathrm{Fc} \leftrightarrows \mathrm{Fc^+} + \mathrm{e^-} \quad (3)$$

A one-step procedure for fabrication of a L-glutamate biosensor film is using a photocuring technique. Briefly, both Fc mediator and Glox are immobilized in a polymer which is formed from photopolymerization of 2-hydroxylethyl methacrylate (HEMA). This is a simple and rapid technique for preparation of a biosensor, as compared with those described elsewhere [22, 23].

Materials and Methods

Materials and reagent

All chemicals used were of analytical grade and deionized water was used throughout for all solutions preparation. Ferrocene was obtained from Fluka (98% purity), 2-hydroxylethyl methacrylate (HEMA, 98%) purity) and L-glutamate oxidase (Glox) (≥ 5.0 unit/mg) were obtained from Sigma. Initiator 2,2-dimethoxy-2-phenylacetophenone (DMPP, 99% purity) was supplied by Aldrich and monosodium glutamate monohydrate was supplied by Acros Organic (99% purity). Phosphate buffer (0.1 M, pH 7.0) used as electrolyte in electrochemical measurements was prepared in 0.1 M NaCl.

Preparation of biosensors

Carbon-paste screen-printed electrodes (SPE) (Scrint Print Technology, Malaysia) were used as working electrodes with electrode surface 4 mm in diameter. Initially, a stock homogeneous solution of HEMA containing DMPP and Fc was prepared by mixing 1 mL of HEMA solution, 1.6 % DMPP (w/w) and 1 % Fc (w/w) in a dark bottle. The stock solution was stored at 4°C when not in used. The formulation was changed accordingly when certain experimental parameters were investigated. Then, appropriate amount of stock HEMA solution was mixed with Glox and a volume of 5 µL mixture solution of Fc/HEMA/Glox was deposited on the working electrode area and then exposed to UV radiation (λ = 365 nm, 15 W) under nitrogen gas in 8 minutes to form a solid thin layer membrane.

Electrochemical measurements

The electrochemical measurements were performed with an Autolab PGSTAT 12 Potentiostat/Galvanostat. A one compartment cell with a working volume of 4 mL 0.1 M phosphate/NaCl buffer was used. The working

electrode is a SPE coated with polymer-containing Fc film whereas silver/silver chloride (Ag/AgCl) and a glassy carbon electrode were used as reference electrode and auxiliary electrode respectively. The characterization of the potential-dependent behaviour of Fc with cyclic voltammetric (CV) was carried out by scanning between -0.5 - 0.7 V (versus Ag/AgCl) at a scan rate 5 mV/s in an unstirred 0.1 M phosphate/NaCl buffer pH 7. The effect of the detection potential on the electrode sensitivity was examined amperometrically for applied potentials varying between +0.1 - +0.4 V under a stirred solution of 4 mL 0.1 M phosphate/NaCl buffer pH 7.0, 30 mM L-glutamate.

The biosensor was optimized with regards to several parameters, namely, effect of pH, Fc and enzyme loading over the amperometric response of the electrode at an optimum applied potential of +0.25 V versus Ag/AgCl. For the determination of the effect of pH value on the biosensor response, 30 mM L-glutamate solution was prepared by adding 60 µL of 2 M L-glutamate with 4 ml of buffer with different pH (5 - 9). The stock pH 5 - 9 buffer solution was obtained by mixing 0.1 M phosphate solution with NaCl and pH was adjusted with NaOH or HCl. The effect of the Fc concentration used as a mediator on the biosensor response was tested by varying the concentration of Fc at 0.5%, 1% and 2% (w/w) and for enzyme loading, the amount of Glox was varied in the range of 20 - 160 U/g Fc/HEMA at the fixed amount of Fc and pH.

The stability of the biosensor for reusability (repetitive usage) was tested by preparing six different biosensors which three of them were used once a day and another three were used once in every two weeks. The performance for each biosensor was measured by using 20 mM standard L-glutamate. The biosensor performance of the first day was used as a reference and the percentage of the relative response was determined. After each usage the biosensors was stored in a closed container under dry storage at 4ºC. The reusability was carried out until the percentage relative response reached below 50% [25]. For the storage stability, another three biosensors were prepared and they were stored dry at 4ºC. The biosensors were tested periodically once a month for six months using 20 mM L-glutamate solution.

The calibration measurements were performed by placing the working electrode in 4 mL of a stirred 0.1 M phosphate/NaCl buffer (pH 7.0) at an applied potential of +0.25 V versus Ag/AgCl. When the background current reaching the steady value, an appropriate amount of L-glutamate solution was added into an electrochemical cell. After the addition, the current increased to a new steady value. The L-glutamate concentrations were added then plotted against the difference in current between before and after glutamate addition.

Biosensor at the optimum condition was applied to determine the concentration of the L-glutamate in food samples. The interference effect of the matrix in the samples was tested first by measuring any possible amperometric response after adding three possible interference species such as ascorbic acid, L-aspartate and D-glutamic acid into the samples. The interference study was also carried out by doing recovery study. For recovery studies, the biosensors were employed for the determination of L-glutamate in four different food samples such as fried rice seasoning, fish sauce, sour curry paste and concentrated chicken stock. Two set of food samples were prepared which one without spiked standard L-glutamate and the other one with spiked standard L-glutamate. Percent recovery was calculated by the formula below:

$$\% \text{ recovery} = (x-y)/z \times 100$$

x = average [L-glutamate] in spiked sample
y = average [L-glutamate] in non-spiked sample
z = average [L-glutamte] that was spiked in the sample

Food stocks were obtained from local supermarkets. Solid samples and pastes were dissolved in boiling water according to the manufacturer's instructions and treated as liquid samples. Samples were filtered using filter paper type Whatman Ashless before the determination. The liquid sample produced well-defined amperometric responses similar to those of L-glutamate standard.

HPLC method for L-glutamate determination

For HPLC method, the sample was centrifuged at 3000 rpm for 15 minutes and filtered using 0.4 µm membrane filter. L-glutamate levels were determined by isocratic liquid chromatographic using fluorescence detection after pre-column derivatization with o-phthaldialdehyde (OPA) [26]. OPA (108 mg) was dissolved in 1 mL of 99.5% ethanol. Borate buffer (0.4 M, pH 10.4) was added and followed by 20 µL of 2-mercaptoethanol and 20 µL of L-glutamate/sample made up to 10 mL. The derivatized L-glutamate solution was injected into the HPLC column within one minute after preparation. The HPLC analysis was carried out using a Jasco PV-1580 instrument with a ThermoHypersil-Keystone Hypersil ODS column (250 × 4.6 mm, 5 µm) at room temperature. The excitation and emission wavelengths of the Jasco FD-1520-Intelligent Fluorescence detector were set at 330 nm and 455 nm respectively to detect the derivatized L-glutamate. The volume of the derivatized sample injected was 20 µL. The analysis was carried out isocratically using a mobile phase of methanol-phosphate buffer (35:65, v/v) at pH 5.8.

Results and Discussion

The cyclic voltammetry study of immobilized ferrocene mediator in the biosensor

As shown in Figure 1, as the potential becomes more positive and the reduced form of the Fc is converted into the oxidized ferricenium species, hence there is appearance of the anodic peak in the range of +0.2 - +0.5 V. As the potential is reversed, a cathodic peak is detected in the range of +0.1 - +0.3 V attributed to the electrochemical activity of the ferricenium generated during the forward scan. The similar pattern was also observed in an earlier study using the similar polymer films with Fc as a mediator [24]. It can be shown that the immobilised Fc mediator demonstrated electrochemical reversible behaviour. Therefore, effect of applied potential on the biosensor response against L-glutamate was tested in the range of +0.1 – +0.5 V and the results are shown in Figure 2.

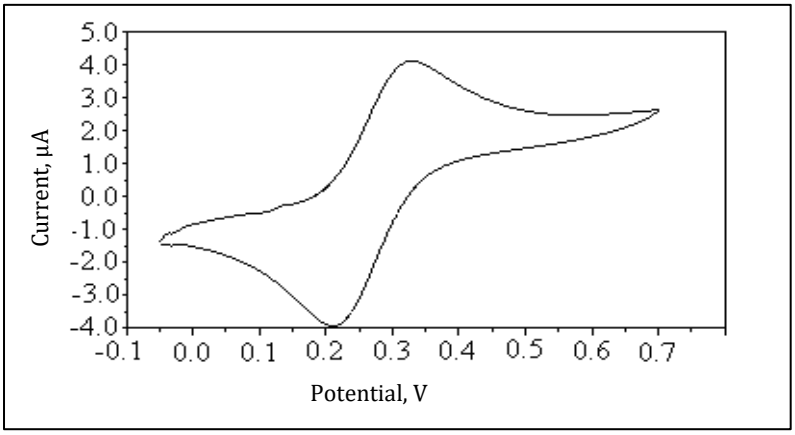

Figure 1. Cyclic voltammograms of Fc/HEMA/Glox biosensor versus Ag/AgCl electrode from -0.5 – +0.7 V with a scan rate of 5 mV/s in an unstirred 0.1 M phosphate buffer/NaCl pH 7

The biosensor response showed rapidly increasing with the applied potential until it reached at optimum potential of +0.25 V. At the potential higher than +0.25 V, the current was observed to decrease. The obtained potential was relatively low compared to reported potential by Liu et. al. [23] that was +0.6 V. The low applied potential was beneficial to avoid any interference from other electroactive species such as

ascorbic acid. Therefore, an applied potential of +0.25 V versus Ag/AgCl was carried out for all subsequent studies.

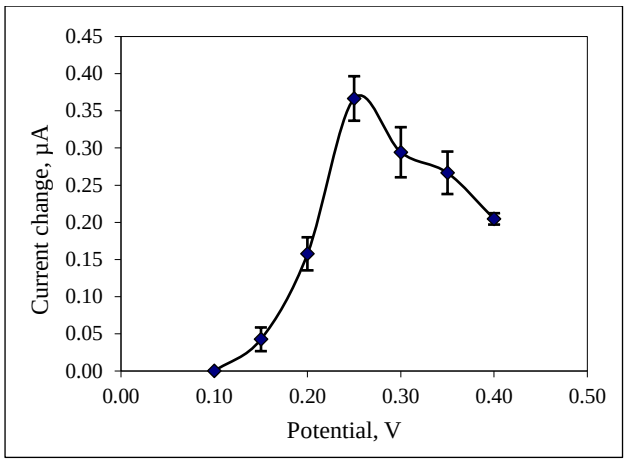

Figure 2. Effect of applied potential on the biosensor response studied for amperometric measurements for 25 mM L-glutamate in 0.1 M phosphate/NaCl buffer pH 7.0 versus Ag/AgCl electrode

Effect of pH

The influence of the buffer pH is very essential to the sensitivity of the biosensors because the pH does not only affect the electrochemical behavior of Fc but also the bioactivity of Glox. The bioactivity of the immobilized enzyme with Fc/HEMA/Glox that deposited on the electrode was influenced by the pH of the buffer used as shown in Figure 3. All buffers were solutions of 0.1 M phosphate buffer/NaCl. A plot of the current response to a fixed amount of L-glutamate as a function of pH change indicated that the response reached maximum value at pH 7.0. The behavior of the enzyme Glox was reported to be more stable in pH between 7.0 - 7.4 [27]. Therefore, further studies of the biosensor response with L-glutamate will be carried out at pH 7.0.

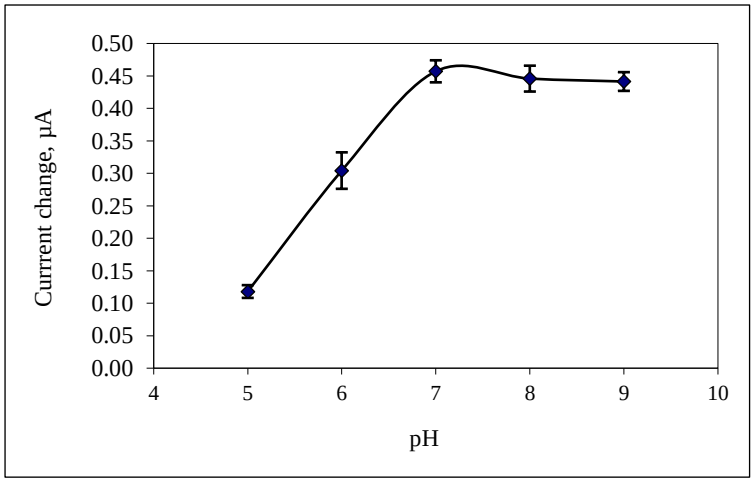

Figure 3. Effect of pH on the maximum response of the glutamate biosensor in 30 mM of L-glutamate at +0.25 V in 0.1 M phosphate/NaCl buffer pH 7.0 versus Ag/AgCl electrode

Effect of ferrocene concentration

Ferrocene as a mediator was used in this constructed biosensor. Ferrocene was immobilized together with Glox/HEMA deposited on the working electrode. In the absence of mediator, the biosensor did not demonstrate any response to the present of L-glutamate. This may be attributed to the non-existence of redox reaction of the H_2O_2 at the surface of the working electrode. In the presence of the Fc mediator, the one-electron oxidation of Fc to the stable ferricenium cation was a simple electron transfer reaction, where complications arising from adsorption or associated chemical reaction which were not expected [28]. Ferrocene has been used as the mediator for the determination of glucose using glucose oxidase as a biological sensing material [24]. Glucose oxidase and Glox belong to the same oxidase family with the same cofactor (FAD) with almost the same enzyme conformation [29].

The effect of varying concentration of immobilized mediator Fc on the biosensor response can be seen in Figure 4. The optimum concentration of Fc to give the best biosensor response to L-glutamate is at 1% of Fc by weighting of the biosensor film. The Fc concentration above 1% did not increase the biosensor response but instead resulting a decrease of response signal. This was probably due to the blockage of the access to the active site of the enzyme by excessive Fc molecules in the biosensor membrane. Ferrocene concentration of 0.5% was not enough to oxidize back the reduced enzyme and interact with L-glutamate substrate. These scenarios were agreeable with Wang et al. [30], when the mediator concentration was low, the biosensor response was limited by the enzyme-mediator kinetic whereas as the concentration was higher, the biosensor response was limited by the enzyme-substrate kinetics.

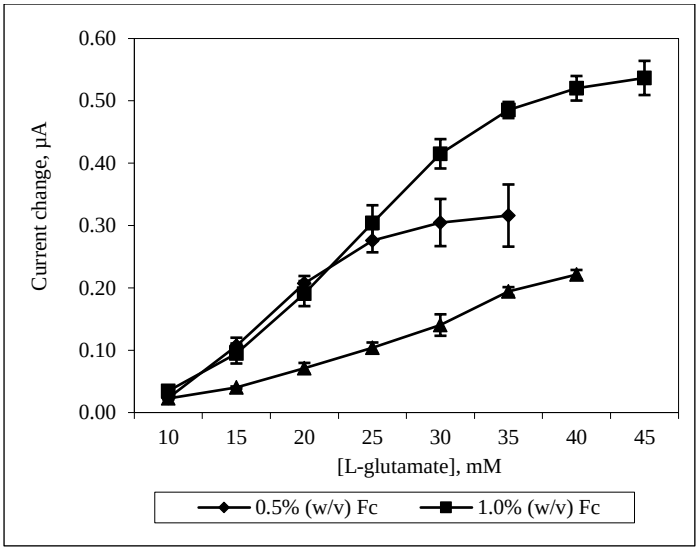

Figure 4. Effect of Fc concentration on the biosensor response at +0.25 V for a series of L-glutamate concentration in 0.1 M phosphate buffer/NaCl pH 7.0 versus Ag/AgCl electrode

Effect of enzyme loading

Enzyme loading also affected the performance of the biosensor. The Glox enzyme was used as a biological reagent for the detection of L-glutamate substrates in Fc/HEMA membranes. From the study of Glox enzyme loading (20 - 160 U/g Fc/HEMA), 120 U/g was enough to give the best performance for the biosensor (Figure 5). The insert graph was the plot enzyme loading versus current change in 40 mM L-glutamate. Reaction rates increased linearly with the increasing concentration of enzyme if the concentration of the substrate was in excess when compared with the amount of enzyme [31]. The sensitivity and the linear dynamic range of the biosensor increased with the increase amount of immobilized enzyme [32]. However, large immobilized enzyme loads were also considered unsuitable because

the limited space in the polymer caused the enzyme active site to be shielded and cannot be fully exposed to glutamate oxidation and reduction reactions [33]. Therefore, an enzyme load of 120 U/g HEMA was selected in this study for the preparation of all biosensors for further amperometry studies.

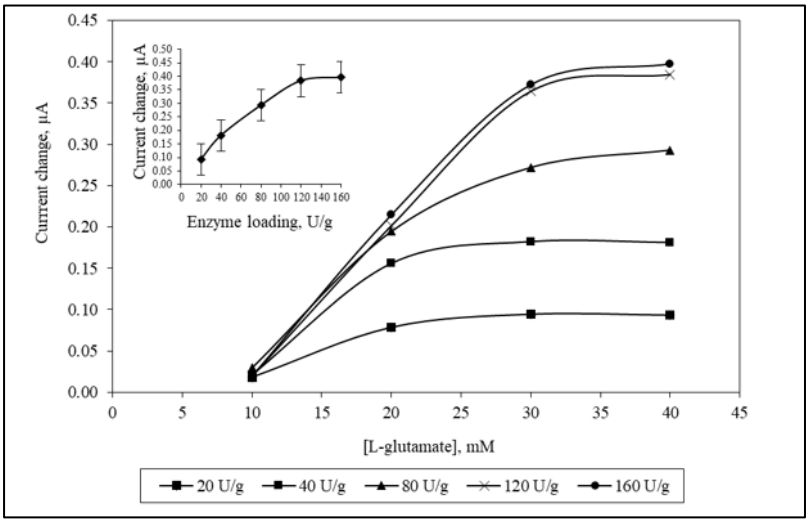

Figure 5. Effect of enzyme loading on the biosensor response at +0.25 V for a series of L-glutamate concentration in 0.1 M phosphate buffer/NaCl pH 7.0 versus Ag/AgCl electrode. The insert graph was the plot enzyme loading versus current change in 40 mM L-glutamate

The stability of L-glutamate biosensor

Stability characteristics related to reusability (repetitive usage) and shelf life are the important factors need to investigate. The stability of a biosensor was influenced by factors such as the method of enzyme immobilization and biosensor storage conditions. From the study of the stability by using the same biosensor for repeated measurement (Figure 6), the percent relative response showed an increasing trend from day 1 – 4 due to conditioning steps until its stabilized. This is associated with decreasing diffusional barriers of the analyte and membrane [25]. The percent relative response was very stable upon repeated injection from day 4 - 9, demonstrating that the membrane did not undergo fouling by the oxidation products. However, the percent relative response started to decrease from day 10 and reached below 50% at day 17. The decreasing trend of the biosensor may be due to hydrophilic property of the HEMA and its swell after it immersed in aqueous L-glutamate solution. The swelling process caused more L-glutamate substrate to penetrate the membrane. This condition would cause the enzyme activity to decrease due to the overexposure to the glutamate solution. Lim and Ang [31] also reported that the enzyme activity was decreased when exposing to high substrate concentrations. The swelling process of polymer membranes affected diffusion, surface properties, mechanical properties and surface movement [34].

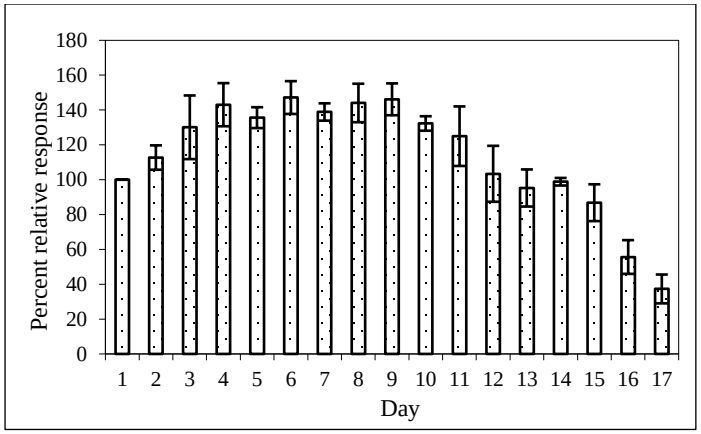

Figure 6. The stability of glutamate biosensor by using the same biosensor for reusability by taking the measurement once a day and kept dry at 4ºC while not in use

The stability of the biosensor was also tested by measuring the percent relative response in 2 weeks' time (Figure 7). The measurement on the first day was used as a reference and considered 100% performance. After measuring, the biosensor was stored dry at 4 ºC. The usage on the 75th day showed that the percent relative response decreased significantly by 41%. The finding showed that, if the biosensor did not use in everyday but only once in two weeks' time, the stability of the biosensor can be extended.

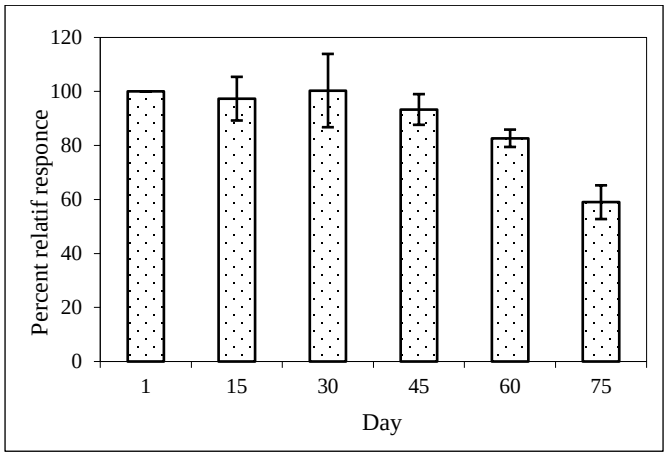

Figure 7. The stability of glutamate biosensor by using the same biosensor for reusability by taking the measurement once in two week's time and kept dry at 4ºC while not in use

Figure 8 showed the performance of a biosensor prepared in a similar preparation, stored at a temperature of 4ºC in a close container and dry state. According to Chang et al. [18], the storage stability of biosensors can be improved if the working electrode containing the immobilized enzyme is stored in a dry state (not dipped in a buffer solution). The first day measurement was used as a reference for the subsequence measurement. Biosensor using different Fc/HEMA/Glox membrane was measured only once at 1-month intervals and it showed a good performance up to 4 months of storage. A decrease in the performance of the biosensor after 4 months of storage, may be because of drying process of the membrane, even though it was not in used. Since the

biosensors were kept in drying state, continuous drying of the Fc/HEMA/Glox membrane in turn causing it to be unable to maintain enzyme activity. Water molecules was trapped in the Fc/HEMA/Glox membrane and were considered important in maintaining the enzyme activity.

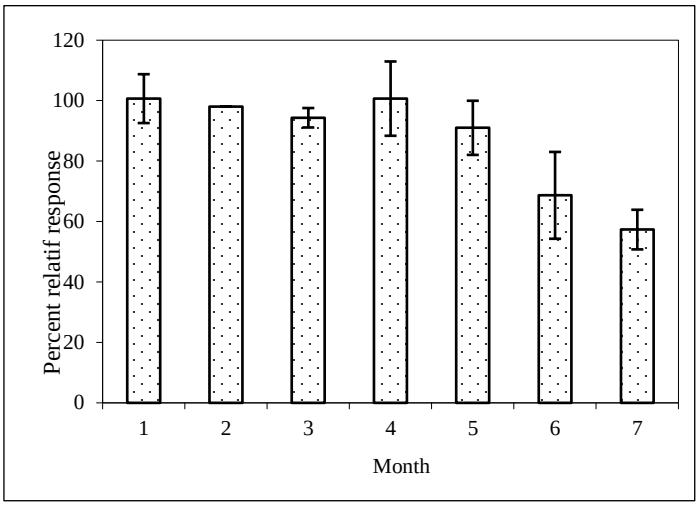

Figure 8. The storage stability of biosensor by taking the measurements once a month of different biosensor in 20 mM L-glutamate

The analytical performance of the L-glutamate biosensor

The electrochemical response of the biosensor to increasing concentration of L-glutamate is shown in Figure 9. A linear response to L-glutamate from 10 – 30 mM was demonstrated, with a sensitivity slope of 0.0173 μAmM^{-1} (R^2 = 0.984). The corresponding detection limit calculated from the L-glutamate concentration that producing an amperometric signal equals to the signal of the baseline plus three times of the standard deviation value [35] was 7.7 mM. The reproducibility of each data point had a relative standard deviation (RSD) value between 2.6% - 11.2% (n = 3) and this indicated that the biosensor showed reproducible responses.

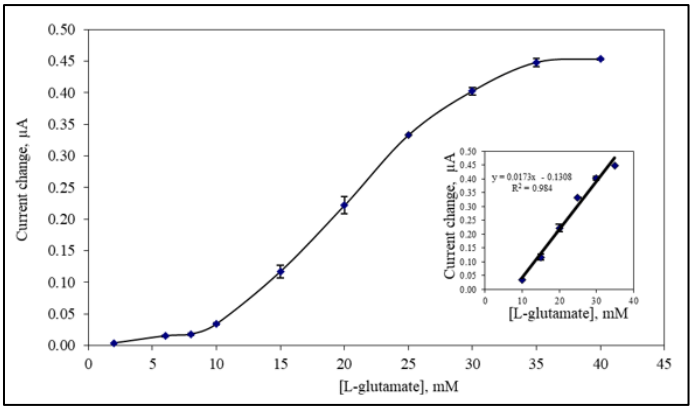

Figure 9. Response of the L-glutamate biosensor with changes in the concentrations of L-glutamate determined at applied potential +0.25 V versus Ag/AgCl electrode in stirred solution of 0.1 M phosphate/NaCl buffer pH 7. The linear range is also shown by the inset

The proposed glutamate biosensor was compared with the reported glutamate biosensor in literature. Performance of the proposed biosensor (Table 1) resulted the limit of detection which slightly higher than those of biosensors reported in literature. However, the proposed biosensor in terms of the fabrication is simple and faster. Moreover, the amount of L-glutamate in food sample was relatively high; in the range of 6.7 – 658 mg/100 g in fresh food to 0.05 – 6830 mg/100 g in processed food [36] and in food seasoning 4.8 – 21.3% [37]. Therefore, the proposed biosensor was practical to be used as a tool to detect the presence of L-glutamate in food.

Table 1. Characteristics of some glutamate biosensors reported in the literature

Type of Enzyme	Biosensor Configuration (Operational Mode)	Detection Mode	Linearity (mM)	LOD (mM)	Reference
Glox	Photocurable poly(2-hydroxylethyl methacrylate)/ferrocene	+0.25 V vs Ag/AgCl	10 – 30	7.7	Proposed
Glox	Absorption chitosan	+0.4 V vs Ag/AgCl	5×10^{-4} – 2×10^{-1}	1.0×10^{-4}	[17]
Glucose oxdase	Cross-linking glutaraldehyde/BSA/Nafion/ metal viologen	-0.65 V vs. SCE	Until 0.75	2×10^{-2}	[29]
Glox	Cross-linking glutraldehyde/BSA	+0.7 V vs Ag/AgCl	Until 0.8	3×10^{-3}	[38]
Glox	Nafion/Prussion blue	+0.0 V vs Ag/AgCl	1×10^{-4} – 1×10^{-1}	1×10^{-4}	[39]

The specificity of the biosensor to L-glutamate was evaluated by measuring a standard solution of possible interferents such as ascorbic acid, L-aspartate and D-glutamic acid under the same conditions. Ascorbic acid was chosen to represent any interference from carboxylic acid group species, L-aspartate for amino acid group and D-glutamate is a chiral to L-glutamate. No response was observed demonstrating that these substances did not interfere with the detection of L-glutamate.

Recoveries ranging from 98 –105% were obtained to the determination of L-glutamate using the L-glutamate biosensor in four different types of food matrices; this indicated that the complicated matrices of these food samples did not interfere with the performance of the glutamate biosensor.

The results of a comparative study for L-glutamate determination in some food samples using both the biosensor and standard HPLC procedure are shown in Table 2. When compared with the HPLC method, the content of L-glutamate determined in the selected food items which was analyzed by the biosensor and demonstrated a very close result. A statistical analysis (*t*-test) at 95% confidence level comparing the means of measurements obtained from the two methods of glutamate sensor and HPLC also showed no significant difference, indicating that the method developed was in good agreement with the established method.

Table 2. Comparison of L-glutamate level in food stocks obtained from local supermarkets by using the L-glutamate biosensor and HPLC method (n=3)

Type of Food	L-Glutamate Level (%)		
	Biosensor	HPLC	t-test
Anchovies stock cube	17.70 ± 0.27	17.73 ± 0.29	0.1
Fried rice mix-chicken seasoning	21.24 ± 0.46	21.38 ± 0.48	0.4
Vegetable soup seasoning	5.75 ± 0.09	5.66 ± 0.15	0.9
Fried vermicelli paste	5.47 ± 0.17	5.57 ± 0.06	1.0

Conclusion

The use of Fc mediator together with photocurable membrane technology in the fabrication of L-glutamate biosensor has successfully produced an amperometric L-glutamate biosensor (applied potential of +0.25 V versus Ag/AgCl, pH electrolyte 7.0, 1% ferrocene concentration, 120 U/g enzyme loading and with up to 4 months shelf life) that can be used to detect L-glutamate in food items. The photocurable technique in this work was simple and faster compared to covalent bonding or absorption technique reported in the literature. The biosensor exhibited a reproducible characteristic with acceptable RSD values. The biosensor had developed a linear dynamic range of 10 – 30 mM L-glutamate with LOD 7.7 mM. L-glutamate level in food samples determined from the biosensor was comparable to conventional HPLC method.

Abstract

Solar energy has gained increasing popularity in the last decade, resulting in the development of photovoltaic/thermal (PV/T) systems to improve photovoltaic cell efficiency. Working fluid is one of the most important components in a heat transfer system. In this study, Fe_3O_4@Sylgard 309 nanoparticles were synthesized for nanofluid preparation. The stability and particle size of the nanofluid were analyzed using the dynamic light scattering method. Water-based nanofluid at pH 7 had the highest zeta potential compared to the same water-based nanofluid at different pHs ranging from 5.2 to 9.4. The nanofluid synthesized using cetyltrimethylammonium ammonium bromide and sodium dodecyl sulfate as the surfactant achieved better stability than the nanofluid synthesized without the addition of the surfactant. Ethylene glycol (EG)-based nanofluid had the highest zeta potential value of -2.54 mV compared to the water-based and polyethylene glycol (PEG)-based nanofluids. Nanoparticles in the PEG-based nanofluid remained suspended for two days and were better than the water-based and EG-based nanofluids. The improvement of the thermal conductivity of the metal oxide nanofluid compared to the conventional base fluid in previous studies was reviewed. The results showed that the thermal conductivity of nanofluid was higher than the base fluid up to 49.4%, indicating the potential for nanofluid applications in PV/T systems if the stability of the nanofluid can be improved.

Keywords: Ferum(III) oxide, magnetic nanoparticle, nanofluid, thermal conductivity, thermophysical property

Abstrak

Popularitи tenaga suria semakin meningkat sejak sedekad yang lalu dan menghasilkan pembangunan sistem fotovolta/terma (PV/T) untuk meningkatkan kecekapan sel fotovolta. Bendalir kerja adalah salah satu komponen terpenting dalam sistem pemindahan haba. Dalam kajian ini, nanozarah Fe_3O_4@Sylgard 309 telah disintesis untuk menyediakan cecair nano. Kestabilan dan saiz zarah cecair nano dianalisis menggunakan kaedah penyerakan cahaya dinamik. Bendalir nano berasaskan air pada pH 7 mempunyai potensi zeta yang paling tinggi berbanding dengan cecair nano berasaskan air yang sama pada pH berbeza antara 5.2 hingga 9.4. Kestabilan cecair nano yang disintesis menggunakan setiltrimetilammonium bromida dan natrium dodesil sulfat sebagai surfaktan adalah lebih baik iaitu -2.54 mV daripada cecair nano yang disintesis tanpa penambahan surfaktan. Bendalir nano berasaskan etilena glikol (EG) mempunyai nilai potensi zeta yang paling tinggi berbanding dengan cecair nano berasaskan air dan polietilena glikol (PEG). Nanozarah dalam cecair nano berasaskan PEG kekal terampai selama dua hari dan lebih baik daripada cecair nano berasaskan air dan EG. Peningkatan kekonduksian terma bagi cecair nano oksida logam berbanding dengan cecair asas konvensional dalam kajian terdahulu telah dikaji semula. Keputusan menunjukkan bahawa kekonduksian terma cecair nano adalah lebih tinggi daripada cecair asas sehingga 49.4% dan mempunyai potensi aplikasi cecair nano dalam sistem PV/T sekiranya kestabilan cecair nano dapat dipertingkatkan.

Introduction

As global warming worsens due to the emission of greenhouse gases, the demand for energy consumption is expected to increase, particularly in the industrial sector. According to the data obtained from the International Energy Agency, the growth of energy demand between 2017 and 2018 was 4% in 2018, which was equivalent to 900 TWh. The demand is expected to increase continuously as climate change increases the demand for air conditioning and consumption in the industrial sector [1-3].

Although solar energy can be converted into electrical energy using photovoltaic (PV) cells, long-term exposure will increase the temperature of the cells. Proton transfer rate is hindered in a commercial solar panel [4]. Meanwhile, 30% of the industrial process and heating, ventilation, and air conditioning (HVAC) systems require temperatures below 100 ℃, which can be achieved using commercial solar thermal collectors [3]. Working fluids (e.g., thermal oil, water, and glycols) have been implemented in HVAC systems but with poor efficiency.

Based on previous studies, PV electrical efficiency could be enhanced by integration with a heat collection system. The PV electrical efficiency of a photovoltaic/thermal (PV/T) system using silicon carbide (SiC) nanofluid under different solar irradiance levels (400–600 W) was enhanced significantly in the range of 13.3%-13.9% compared to the PV electrical efficiency of the reference PV module without a heat collection system in the range of 5.2%-10.52%. Another study on a PV/T system using SiC nanofluid reported an increase in the electrical efficiency up to 24.1% compared to the PV system alone [7]. A study on a PV/T system showed that the overall energy efficiency increased by 76.6% and achieved an overall energy efficiency of 16.9% using titanium dioxide (TiO_2) nanofluid compared to water [8]. These findings highlight the potential application of nanofluid in the PV/T system.

Magnetic nanoparticles possess magnetic properties that ease recycling and adsorption in the heat transfer process. Magnetic nanoparticles consist of iron oxides, iron alloys, and ferrite-based nanoparticles [9,10]. Nanofluid is the colloidal suspension of nanoparticles in the base fluid. Several types of nanofluid have been synthesized using carbon nanotube, metal oxide, and silica nanoparticles [11-25]. Surfactants such as cetyltrimethylammonium bromide (CTAB), sodium dodecyl sulfate (SDS), sodium dodecylbenzene sulfonate (SDBS), and acetic acid have been used to reduce agglomeration and improve the stability of nanofluids. The dispersion stability of the nanoparticles in the liquid will affect the commercialization of the nanofluid as the sedimented particles might cause scaling in the pump [26].

Ghadiri et al. synthesized Fe_3O_4 nanofluid with a nanoparticle concentration up to 3 wt. %. Acetic acid

was added to the nanofluid and ultrasonicated for 30 min to stabilize the nanofluid. The nanoparticle size was 45 nm and the nanofluid was stable for a month. The electrical and thermal efficiency of the PV/T system using 3 wt. % Fe_3O_4 nanofluid recorded an improvement of 4.8% and 35%, respectively, compared to the PV/T system using distilled water [27].

In the author's previous research, metal oxide nanofluid known as adsorbent MNP-Sylgard 309 was synthesized for the extraction of pollutants from environmental samples [11]. The excellent results allowed the metal oxide nanofluid to be applied in a new research field, which is the application for improving thermal conductivity. This is because the behavior of the synthesized metal oxide nanofluid has the tendency to increase the heat transfer rate in a heat exchanger without increasing its size. This is due to the higher thermal conductivity of the nanofluid. This improvement will lead to a lower temperature requirement in the thermal conductivity of a solar collector.

In this study, Fe_3O_4 nanoparticles were synthesized using the chemical co-precipitation method. Iron oxide nanoparticles were modified using 3-(triethoxysilyl)propylamine (APTES) and surfactant Sylgard 309. Fe_3O_4@Sylgard 309 nanoparticles were dispersed in the base fluid using ultrasonication to stabilize the nanofluid. Later, Fe_3O_4@Sylgard 309 nanoparticles were synthesized at different pHs using different base fluids. The nanoparticles and nanofluid synthesized were characterized using the dynamic light scattering (DLS) method. The stability of Fe_3O_4@Sylgard 309 nanoparticles in the water at different pHs was analyzed and compared. Furthermore, the stability of Fe_3O_4@Sylgard 309 nanoparticles in different base fluids (polyethylene glycol (PEG), ethylene glycol (EG), and water) at similar pH with the addition of different surfactants was compared. A review of previous studies regarding the thermal conductivity of metal oxide nanofluid in solar collectors was performed and summarized. Fe_3O_4@Sylgard 309 nanoparticles are feasible to be explored as the metal oxide nanofluid to be added to the solar collector for improving thermal conductivity.

Materials and Methods

Materials and reagents

Methanol (99.7%), ammonia hydroxide (25%), APTES, acetic acid, CTAB, polyethylene glycol (PEG 1500), EG, and SDS were purchased from Merck (Darmstadt, Germany). Iron(III) chloride hexahydrate ($FeCl_3 \cdot 6H_2O$) and iron chloride tetrahydrate ($FeCl_2 \cdot 4H_2O$) were supplied by R&M Chemicals (Essex, UK). Deionized water (18.2 MΩ cm^{-1}) used in the nanoparticles and nanofluid preparation was produced by a Sartorius Milli-Q system.

Synthesis of Fe_3O_4 nanoparticles

First, 3.1736 g of $FeCl_2 \cdot 4H_2O$ and 7.5709 g of $FeCl_3 \cdot 6H_2O$ were dissolved in 320 mL of deionized water and stirred under inert conditions for 1 h at 80 °C. Then, 40 mL of aqueous ammonia was added to the mixture and stirred for 1 h under inert conditions before being cooled to room temperature. The synthesized blackish liquid containing magnetic nanoparticles was decanted using a permanent magnet and washed using hot water five times to obtain Fe_3O_4 nanoparticles.

Surface modification of Fe_3O_4 nanoparticles using APTES and Sylgard 309

Next, the Fe_3O_4 nanoparticle surface was modified using APTES. A total amount of 4.2252 g of Fe_3O_4 was dissolved in 150 mL ethanol (50%) and sonicated for 30 min. Then, 17 mL of APTES was added to the mixture and stirred under inert conditions for 2 h at 40 °C before being cooled to room temperature. The modified nanoparticles were decanted and washed using ethanol and deionized water a few times prior to drying for 24 h at 70 °C under vacuum conditions. Finally, 0.2 g of the modified nanoparticles was dispersed in 8 mL of Sylgard 309 and stirred under inert conditions for 24 h at 60 °C before being cooled to room temperature. The final product was decanted and washed with deionized water and ethanol before being dried under vacuum conditions for 24 h at 70 °C. The synthesized nanoparticles were characterized using a Malvern Nano-ZS particle size analyzer to determine their hydrodynamic size and zeta potential. The synthesis of the Fe_3O_4@Sylgard 309 nanoparticle is shown in Figure 1.

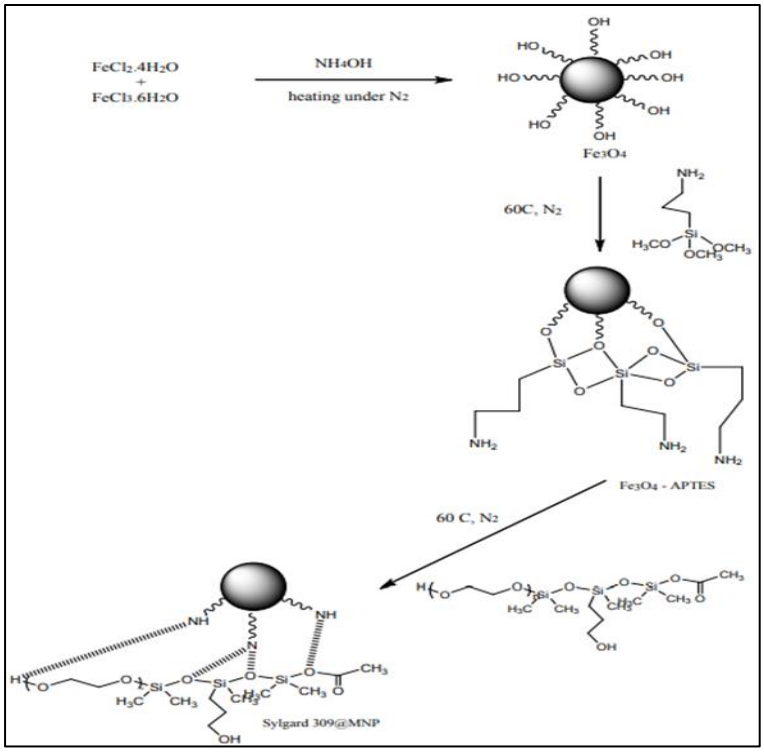

Figure 1. Synthesis of Fe_3O_4@Sylgard 309 nanoparticle [16]

Preparation of nanofluid

Nanofluid preparation was done by sonication (60 min) after adding the modified nanoparticles to the water with a concentration of 0.1 wt.%. Different types of nanofluids were synthesized using different base fluids (PEG, EG) and at different pHs (5.2, 5.9, 7.0, 8.4, 9.4). The dispersion stability and zeta potential of the nanofluids were determined using the Malvern Nano-ZS particle size analyzer.

Results and Discussion

Particle size distribution of synthesized nanoparticles

The results for the synthesis of Fe_3O_4 nanoparticles and surface modification of Fe_3O_4 nanoparticles using APTES and surfactant Sylgard 309 have been published [16]. The paper contains the results of the characterization of Fe_3O_4 nanoparticles coated with APTES and Sylgard 309. The current paper focuses on the application of Fe_3O_4 nanoparticles coated with APTES and Sylgard 309 by studying the particle size di stribution and zeta potential of the nanofluid to improve thermal conductivity. The particle size distribution result showed that the color of Fe_3O_4 changed from black to brown after modification using APTES. Then, the brown color of APTES-modified Fe_3O_4 nanoparticles using Sylgard-309 changed to dark brown. The surface-modified nanoparticle samples are shown in Figure 2. Changes in the color of Fe_3O_4 nanoparticles after surface modification were observed in previous studies [32, 33]. Fe_3O_4 surface modification was done without changing the nanoparticle core (i.e., Fe_3O_4). A study determined that the crystallinity was preserved even after surface modification based on the same peak intensity in the X-ray diffraction (XRD) diffractogram [16].

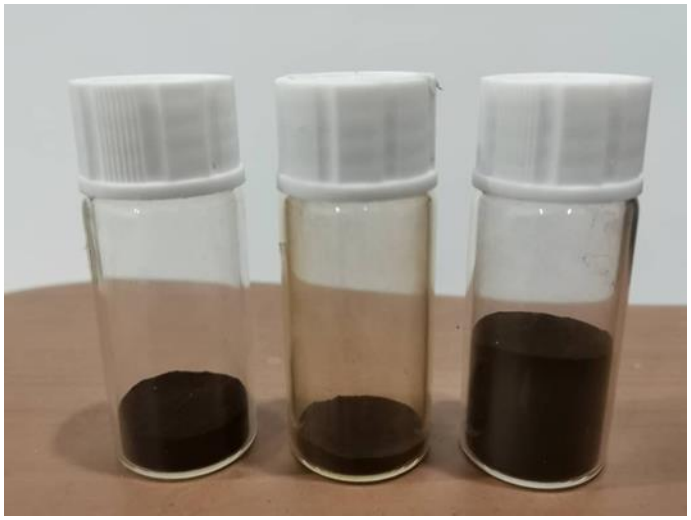

Figure 2. Fe_3O_4 nanoparticles synthesized (left) and modified using APTES (middle) and Sylgard 309 (right)

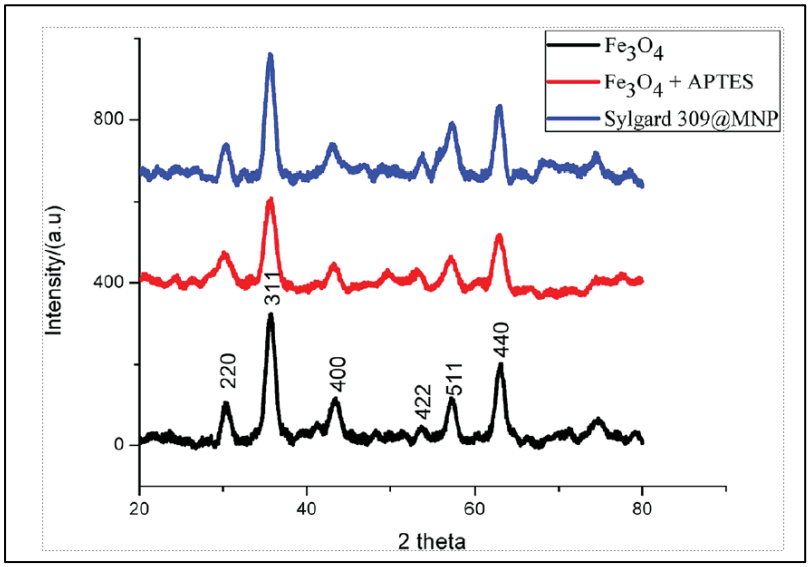

Figure 3. XRD patterns of Fe_3O_4 nanoparticles, Fe_3O_4 + APTES nanoparticles, and Sylgard 309@MNP [16]

In our previous study, XRD was used to identify the crystallinity of Fe_3O_4, Fe_3O_4 + APTES, and Sylgard 309@MNP. As shown in Figure 3, Fe_3O_4 exhibited good crystallinity with diffraction peaks appearing at the 2θ values of 30.42°, 35.59°, 43.59°, 53.63°, 57.50°, and 63.04°, which can be assigned to the (220), (311), (400), (422), (511), and (440) reflections of Fe_3O_4, respectively, which are similar to those of other previous studies [23, 24]. Furthermore, the spectra of Fe_3O_4 + APTES and Sylgard 309@MNP showed approximately identical characteristics of diffraction peaks, revealing that the surface modification of Fe_3O_4 did not change its crystalline phase. The lower intensity of the diffraction peaks was observed in the cases of Fe_3O_4 + APTES and Sylgard 309@MNP, which may be due to the presence of an amorphous layer of APTES and Sylgard 309 on Fe_3O_4 [16].

Based on the particle size distribution shown in Figure 4, the particle size of the synthesized Fe_3O_4 had two peaks, which were 862.2 nm with 89.1% of intensity and 90.53 nm with 10.9% of intensity. This revealed that the diameter of the synthesized nanoparticles was lower than 100 nm. However, there was another peak at 862.2 nm, which was due to agglomeration, and this increased the hydrodynamic size of the nanoparticles in the nanofluid.

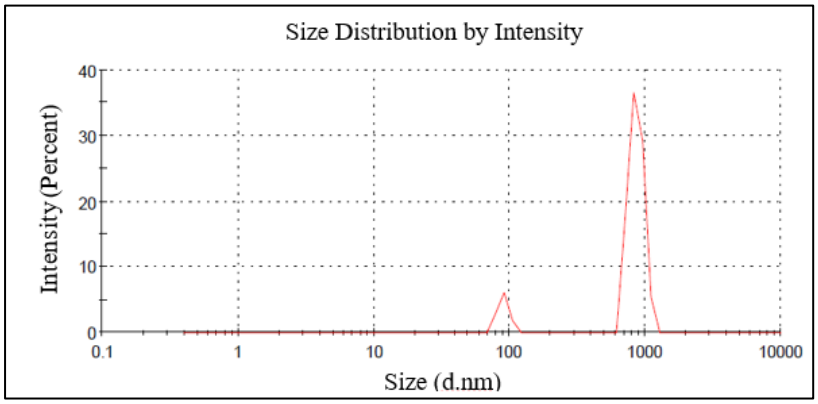

Figure 4. Particle size distribution of synthesized Fe_3O_4 nanoparticles

In the DLS method, an incident laser is generated, which is scattered by the nanoparticles in the colloidal suspension, causing constructive and destructive interference and also resulting in the fluctuation of the scattered light intensity. The fluctuation of the light intensity is then correlated to derive the hydrodynamic radius of the solid particle. The particle diameter detected using the DLS method is the hydrodynamic diameter of the solid particle, which is bounded by the slipping plane.

The slipping plane of the nanoparticle is affected by the aggregation and diffusion of the particle through the boundary of the hydrodynamic structure (slipping plane) into the internal layer [34]. Therefore, if the nanoparticle is not monodispersed in the nanofluid, then the particle size of each nanoparticle cannot be characterized accurately using the DLS method. This is due to the aggregation of nanoparticles in the colloidal suspension, which will result in inaccurate particle size measurement. The reported data of DLS and zeta potential were inaccurate in previous research of nanomedicine research [35].

In Figure 5, the result from DLS showed that the nanoparticles modified using APTES had a larger particle diameter of 1,817 nm. However, after the APTES-modified nanoparticles were characterized using Sylgard 309 (a non-ionic surfactant), the result in Figure 6 showed that the two peaks in the particle size were 73.32 nm with 7.8% of intensity and 482.4 nm with 92.2% of intensity. This proved that the particles modified using APTES caused the aggregation. The change in the particle size distribution could be affected by zeta potential and changes in the zeta potential might be caused by the shift of the slipping plane by molecules characterized on the core nanoparticle surface and also the displacement of the counter ion in the stern layer due to polymer adsorption on the core nanoparticles [36].

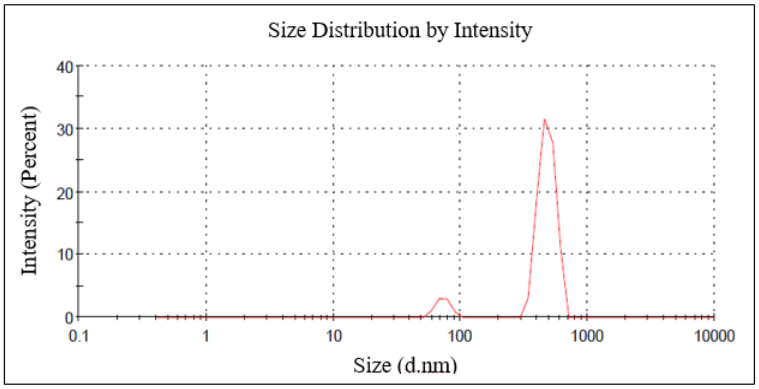

Figure 6. Particle size distribution of synthesized Fe_3O_4@Sylgard 309 nanoparticles

Zeta potential and stability of the synthesized nanofluid

Zeta potential is the parameter used to characterize the electric double layer on the solid/liquid interface. When an ionized solid particle is suspended in the liquid, it will be surrounded by liquid ions with the opposite charge to the surface of the solid particle. Both the solid particle and the liquid layer shell will move together through the liquid. The potential difference between the external liquid shell and the liquid is called zeta potential. Zeta potential is used to describe the behavior of the dispersion of particles in the colloidal system and the stability of the nanofluid [26, 37]. Abadeh et al. examined the effect of the type of surfactant, the amount of surfactant, and pH on nanofluid stability and magnetization [38].

This solid/liquid interface is the boundary of the hydrodynamic structure of the nanoparticles in the colloidal suspension and zeta potential is the potential difference between the internal layer and the external layer of the slipping plane, as shown in Figure 5 Zeta potential is an established parameter in determining the stability of nanoparticle dispersion in nanofluid against aggregation. Zeta potential higher than 30 mV or lower than -30 mV is considered a stable suspension due to charge stabilization between the nanoparticles with high electrostatic repulsive strength. Colloidal suspension with zeta potential higher than 40 mV or lower than -40 mV is considered as having good stability [34, 37].

Based on the zeta potential values measured using the DLS method in Table 1, it can be determined that none of the synthesized nanofluids had enough stability to be

considered as stable colloidal suspension. In the particle size distribution measurement, the results generated are similar to the particle size distribution in which the particle size is affected by the aggregation of the nanoparticles. This is because the particle size distribution increased as the aggregation increased. Furthermore, the pH value will affect the zeta potential of the nanofluid. The zeta potential will affect the dispersive ability of the nanoparticles in the nanofluid, resulting in nanoparticle aggregation. This is in good agreement with previous studies. Zeta potential is usually related to the time needed for the nanoparticles to sediment at the bottom of the nanofluid. The time needed for the nanoparticles to sediment in the nanofluid with a zeta potential value higher than 30 mV or lower than -30 mV is longer than the nanofluid with a zeta potential value closer to 0 mV.

Table 1. Zeta potential and nanoparticle size distribution of water-based nanofluids synthesized at different pHs

pH	**5.2**	**5.9**	**Intensity percentage (%)**	**7.0**	**Intensity percentage (%)**	**8.4**	**9.4**
Particle size, diameter (nm)	163.9	463.9	89.2	482.4	92.2	893.1	1,868
	-	111	10.8	73.32	7.8	-	-
Zeta potential (mV)	-5.56	-4.5	100	-12.4	100	-2.54	-2.62

The zeta potential value was the lowest at pH 7. As the pH value transitioned to a higher or lower value, the zeta potential increased and became closer to 0 mV. However, based on the observation, the sedimentation of the particles at pH 7 occurred earlier than other nanoparticles. This might be due to the nanoparticles being synthesized using Sylgard 309, which is a non-ionic surfactant. This result is in contrast with the statement that the closer the zeta potential value to 0 mV, the shorter the time needed for nanoparticle sedimentation to occur. However, it is still acceptable as the zeta potential of the synthesized nanofluid is not lower than -30 mV and is still considered an unstable nanofluid. The nanoparticles in all water-based nanofluids synthesized at different pHs were found to sediment at the bottom of the nanofluids in a day. Therefore, pH 9.4 was chosen as an optimum pH used for the subsequent study.

In Figure 7, the zeta potential of the water-based nanofluid without the addition of surfactant showed an apparent zeta potential of -5.8 mV, while the zeta potential of the water-based nanofluids synthesized with CTAB and SDS achieved the zeta potential values of 32.3 mV and -41.9 mV, as shown in Figures 8 and 9, respectively. Nanofluid stability improvement was achieved using CTAB and SDS as the surfactant. The zeta potential result of the synthesized nanofluid with CTAB was positive, while the zeta potential result with the addition of SDS was always negative. Both surfactants were able to stabilize the nanofluid as the zeta potential of the synthesized nanofluid was higher than 30 mV or lower than -30 mV. The zeta potential results are in good agreement with the data from previous studies. The time needed for nanoparticle sedimentation to occur in the nanofluids with the addition of CTAB and SDS was longer than the synthesized nanofluid without the addition of surfactant. However, the nanoparticles in the synthesized nanofluid were found to sediment at the bottom of the nanofluid in a day.

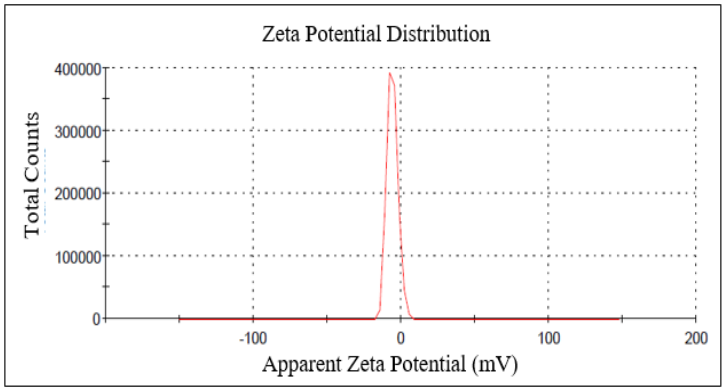

Figure 7. Zeta potential of water-based nanofluid synthesized without the addition of surfactant

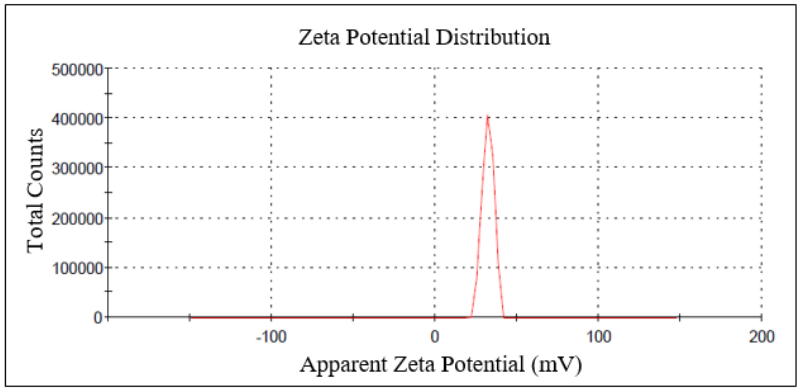

Figure 8. Zeta potential of water-based nanofluid synthesized with the addition of CTAB

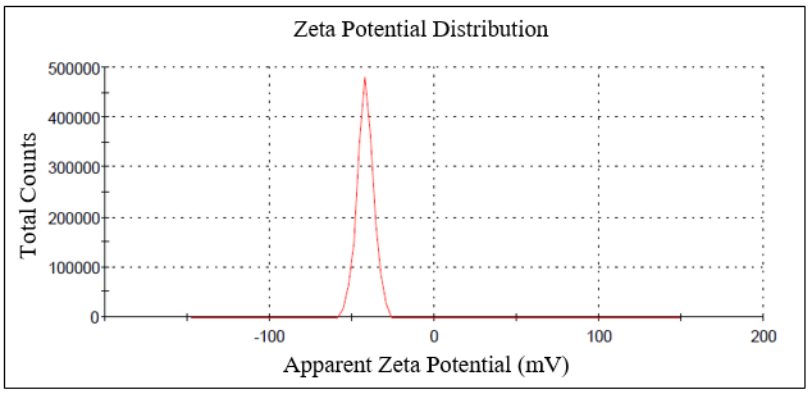

Figure 9. Zeta potential of water-based nanofluid synthesized with the addition of SDS

Nanofluids were synthesized using different base fluids of water, PEG, and EG without any addition of surfactant. Based on the data obtained in Table 2, it was found that the zeta potential value of water-based nanofluid was -2.62 mV, -14.7 mV for EG-based nanofluid, and 3.93 mV for PEG-based nanofluid. The water-based nanofluid recorded a zeta potential closest to zero, which means that it is highly unstable.

EG-based nanofluid was also highly unstable due to the similar zeta potential value to water-based nanofluid. EG-based nanofluid had a zeta potential value that was furthest away from 0 mV. However, based on the observation, nanoparticles in PEG-based nanofluid were able to remain suspended within two days, while the nanoparticles in water- and EG-based nanofluids were only able to remain suspended within one day. This is because PEG is a high viscosity base fluid. Sedimentation is caused by the resultant force acting on the nanoparticles from the stronger gravitational force than the drag force exerted on the nanoparticles by the base fluid [42].

The drag force in a high viscosity base fluid is stronger than a low viscosity base fluid. Therefore, the sedimentation time of the nanoparticles in PEG-based nanofluid was longer.

Table 2. Zeta potential values of nanofluids synthesized using different base fluids

Type of Base Fluid	Water-based at pH 9	EG-based	PEG-based
Zeta potential (mV)	-2.62	-14.7	3.93

Review of previous studies on nanofluid thermal conductivity in solar collectors

Based on previous studies, the application of metal oxide nanofluid in PV/T systems improved the energy generation efficiency compared to the PV/T system utilizing conventional base fluid or PV system alone. Several types of nanofluids from previous studies are summarized in Table 3.

Abareshi et al. synthesized Fe_3O_4 nanofluid using tetramethylammonium hydroxide as the surfactant. The study stated that nanofluid suspension with a zeta potential lower than -30 mV or higher than 30 mV was a stable nanofluid. The nanofluid had a zeta potential value of -41.7 mV, hence it was a stable nanofluid, and the thermal conductivity improvement was 11.5% when the volume fraction of the magnetic nanoparticles was 3 vol% at 40 °C [46].

Al-Shamani et al. prepared TiO_2 nanofluid to be implemented in a thermal collector system of an integrated PV/T module. Based on the results, the TiO_2 nanofluid had an improved thermal conductivity of 12.5% compared to water. The electrical efficiency of the PV/T system utilizing TiO_2 increased by 1% compared to the module utilizing water due to the lower module temperature after exposure to solar irradiation [6].

Based on the previous studies on thermal conductivity, it was shown that the PV/T system utilizing metal oxide nanofluid was able to gain up to 49.4% thermal conductivity improvement compared to the conventional base fluid. However, the results of thermal conductivity improvement of the nanofluid varied. This could be due to different methods used for measuring the thermal conductivity improvement of the nanofluid under different parameters, such as humidity and the surrounding temperature of the environment.

In previous research on magnetic actuated transfer systems, it was shown that it was possible to achieve overall exergy, heat transfer coefficient, and thermal efficiency improvement when the Fe_3O_4 nanofluid was under an alternating magnetic field. However, the difference in the data varied widely. Therefore, it is important to study this particular system to gain more data to determine if any additional factors may cause the discrepancies between these studies on magnetic nanofluids, as well as other nanofluids in heat transfer applications.

Table 3. Summary of thermal conductivity improvement of nanofluids in previous studies

Nanofluid	Concentration	Stabilization Process	Stabilization Analysis	Thermal Conductivity Improvement	Study
• Fe_3O_4/water	•1 wt.% •3 wt.%	• Surfactant – acetic acid • Ultrasonication – 30 min	• Stable in a month • Particle diameter = 45 nm	• No data	22
• TiO_2/water	•0.1 wt.%	• Surfactant – SDS • Ultrasonication bath – 3 h	• Stable in 3 days	• 1%	37
• TiO_2/water	•0.1 vol% •0.3 vol%	• Surfactant – PEG • Pressurized homogenization	• Stable for a month • Ratio of nanoparticle: surfactant = 1:2	• 6%	16
• Al_2O_3/water • CuO/water	•0.8 wt. %	• Surfactant –SDBS • pH: alumina = 8.0, Cu = 9.5	• Zeta potential higher than 40 mV	• Alumina: 15% • Cu: 18%	39
• Al_2O_3/water • CuO/water	•2–10 vol% •2–10 vol%	• Ultrasonication – 3 h	• Stable for a few days	• Alumina: 30% • Cu: 52%	40
• Fe_3O_4/water	•No data	• No data	• No data	• No data	41
• Fe_3O_4/ water	•0–3 vol%	• Surfactant – tetramethylammonium hydroxide	• No data	• 11.5% at 40 ℃	42
• TiO_2/water	•0–2 wt. %	• Ultrasonication	• No data	• 12.5%	6
• Fe_3O_4/water	•0%–0.1%	• No data	• Zeta potential = -46.3 mV	• 33.8% at 40 ℃	14

Conclusion

Fe_3O_4@Sylgard 309 nanoparticles were synthesized and used as the nanofluid to improve the stability and thermophysical properties of a solar collector. The stability and particle size of the nanofluid were analyzed using the DLS method. Water-based nanofluid at pH 7 had the highest zeta potential compared to the same water-based nanofluid at different pHs ranging from 5.2 to 9.4. The stability of the synthesized nanofluid using CTAB and SDS as the surfactant was better than the nanofluid synthesized without the addition of surfactant. EG-based nanofluid had the highest zeta potential value compared to the water- and PEG-based nanofluids. Nanoparticles in PEG-based nanofluid could remain suspended within two days, which were longer than water- and EG-based nanofluids. Therefore, PEG-based

nanofluid has the potential to be used in a solar collector because it has longer time to be effective as a fluid, which is related to the high conductivity in a solar system. The thermal conductivity improvement of the metal oxide nanofluid compared to conventional base fluid in previous studies was reviewed. The review showed that the thermal conductivity of nanofluid was higher than the base fluid up to 49.4%. This result highlights the potential of nanofluid applications in PV/T systems if the stability of the nanofluid can be improved.

Abstract

Colistin is an antibiotic used as a last option to treat bacterial infections; it has a limited therapeutic window and needs to be monitored for dose optimization. This study aimed to optimize liquid chromatography-mass spectrometry conditions for colistin determination in human plasma. The parameters that affect the performance of liquid chromatography and mass spectrometry were investigated by modifying the composition of the mobile phase in isocratic and gradient elution mode, varying concentrations of acetonitrile and formic acid in the mobile phase, column temperature, ionization mode, and collision energy voltage. The gradient elution with water and acetonitrile, both containing 0.1% formic acid, was effectively used to separate the analytes on a Zorbax SB-C8 column maintained at 40°C. The retention times for colistin A, colistin B, and polymyxin B were 4.003, 3.810, and 4.047 min, respectively. Detection was performed with a quadrupole time-of-flight analyzer using electrospray ionization operated in the negative mode. The precursor–product ion pairs were identified at *m/z* 1123.7300/1079.7032 for colistin A, *m/z* 1109.7151/1065.6886 for colistin B, and *m/z* 1157.7159/1113.6889 for polymyxin B (internal standard). The optimum chromatographic condition for the separation and detection of colistin using quadrupole time-of-flight liquid chromatography mass spectrometry was established.

Keywords: colistin, high performance liquid chromatography, mass spectrometry, QTOF-LC/MS, human plasma

Abstrak

Colistin adalah antibiotik pilihan terakhir digunakan untuk rawatan jangkitan bakteria, ia mempunyai julat terapeutik yang sempit dan pemantauan diperlukan dalam mengoptimumkan dos rawatan. Kajian ini bertujuan untuk mengoptima kondisi kromatografi cecair-jisim spektrometri untuk pengenalpastian colistin di dalam plasma manusia. Parameter yang mempengaruhi prestasi kromatografi cecair dan spektrometri jisim dikaji dengan mengubah suai komposisi fasa bergerak dalam mod elusi isokratik dan kecerunan, perbezaan kepekatan acetonitril dan asid formik dalam fasa bergerak, suhu turus, mod pengionan dan pelangaran tenaga voltan. Kaedah kecerunan elusi dengan menggunakan air dan acetonitril di mana kedua-duanya mengandungi 0.1% asid formik digunakan untuk pemisahanan analit-analit pada turus Zorbax SB-C8 dengan suhu tetap 40 ºC. Masa retensi bagi colistin A, colistin B and polymyxin B adalah 4.003, 3.810, dan 4.047 minit. Penganalisa kuadrupel masa penerbangan digunakan untuk tujuan pengesanan dan dikendalikan menggunakan ionisasi semburan-elektro di dalam mod negatif. Pasangan ion prekursor-produk dikenalpasti di *m/z* 1123.7300, 1079.7032 untuk colistin A, *m/z* 1109.7151, 1065.6886 untuk colistin B dan *m/z* 1157.7159, 1113.6889 untuk polymyxin B (piawai dalaman). Kaedah kromatografik untuk pemisahan dan pengesanan colistin yang optimum menggunakan kuadrupel masa penerbangan kromatografi cecair-jisim sepectrometry telah berjaya dibangunkan.

Kata kunci: colistin, kromatografi cecair prestasi tinggi, spektrometri jisim, QTOF-LC/MS, plasma manusia

Introduction

Colistin, also known as polymyxin E, has re-emerged in the clinical setting for the treatment of multidrug-resistant (MDR) gram-negative organism infection due to limited available treatment options. Colistin dosing is difficult; nephrotoxicity remains a significant dose-limiting side effect, and adequate colistin plasma concentration is difficult to achieve, even though the recommendation of colistin dosing from the new guideline is followed [1–3]. Therefore, therapeutic drug monitoring is recommended to ensure safety and efficacy and to improve clinical outcomes [1]. Colistin is administered intravenously or nebulized into the lungs in the form of colistimethate sodium or colistin methanesulfonate sodium (CMS), an inactive prodrug of colistin [4]. CMS consists of two main components, CMS A and CMS B, which are hydrolyzed spontaneously *in vivo* and *in vitro* to form a mixture of partially sulfomethylated derivatives and then converted to the main active compounds colistin A and colistin B [4, 5]. The conversion of CMS to colistin is influenced by time, temperature, pH, and matrices [6–8]. CMS differs from colistin by additional sulfomethyl groups on each of the five diaminobutyric acid residues. Colistin possesses five free amino groups that can be adsorbed by many materials, such as plastic, polystyrene, and soda-lime glass [9]. The loss due to adsorption may lead to inaccurate results, hence misevaluating the amount of colistin. Colistin has poor ultraviolet absorption and no native fluorescence properties; therefore, derivatized prior analysis is required.

Separation techniques using liquid chromatography with fluorimetry detection or coupled with mass spectrometry detection are among the most frequently reported methods for colistin detection [10–14]. These techniques are sensitive and able to measure the concentration of colistin in the clinically relevant analytical range of 0.05-20 µg/mL [15]. Derivatization is necessary for liquid chromatography with fluorimetry detection, and the chromatographic run time is rather long. The liquid chromatography run time varies from 9 to 35 min in the fluorimetry detection method [16–18]. Liquid chromatography with mass spectrometry allows shorter run times and is also able to detect colistin levels 2–7 times lower than fluorimetry. Studies have reported three analytical methods for sample preparation in colistin assays: protein precipitation with solid-phase extraction (SPE) [13,16,19], protein precipitation [20], and SPE [12]. To achieve efficient analysis, sample pre-treatment should be as simple as possible. Complicated procedures should be avoided because of the high chances of the conversion of CMS to colistin during the procedure [12, 20]. The highly acidic protein precipitation may cause significant CMS hydrolysis [12, 21]. SPE's advantage over the protein precipitation procedure is that it can provide a clean extract and a sufficient concentration of analytes. The conversion of CMS to colistin can be minimized using a nonacidic SPE procedure [12].

In liquid chromatography with mass spectrometry (LC/MS) method development, it is critical to optimize

the various analytical columns, mobile phases, and chromatographic settings to improve the peak's shape and achieve effective colistin A and B separation. The strong interaction between the primary amines in colistin with silanol groups in the C18 column caused significant peak tailing and broadening of the mass spectrometry (MS) colistin chromatogram. Therefore, to enhance the chromatographic peak's shape, formic acid [19, 22, 23] or acetic acid [11, 21] were added to an organic solvent or deionized water in various proportions. Several studies have been conducted to overcome this interaction. Wan et al. [24], used gradient elution using a mixture of 0.1 percent formic acid in water and 0.1 percent formic acid in acetonitrile (5 to 70 percent) for the mobile phase. The low concentration of formic acid may improve the shape of the chromatographic peak by providing a proton donor so that the analytes can form a stable performed-ion. Whereas, Ma et al. [21] used one percent acetic acid in an isocratic elution that included acetonitrile and water (80:19). Jansson et al. [20] used a different mixture in the mobile phase consisted of a mixture of 0.03 percent trifluoroacetic acid (TFA) and 25 percent acetonitrile which demonstrated good separation of colistin A and colistin B. However, TFA was reported to reduce MS ionization [25, 26].

Acquisition parameters such as ionization, desolvation, ion transfer, collision cell fragmentation, and mass analysis provide the best signal for precursor and product ionization of colistin required for MS optimization [27]. The fragmentor voltage (FV) and collision energy (CE) are the common parameters used for optimization [23][11]. Other optimized MS parameters include (1) the nebulization process: ion spray voltage, capillary voltage, and nozzle voltage; and (2) the desolvation process: source temperature, drying/desolvation temperature, and gas flow [19][23][12]. Optimum fragmentation of analytes was measured using signal-to-noise ratio and variations in the fragmentation of colistin A and colistin B. The aim of the present study was to optimize liquid chromatography and mass spectrometry for colistin determination in human plasma using quadrupole time-of-flight liquid chromatography mass spectrometry (QTOF LC/MS).

Materials and Methods

Chemicals and reagents

The colistin sulphate, purchased from Toronto Research Chemicals (Canada) and polymyxin B (1 mg/mL) solution, purchased from Sigma-Aldrich were used as standard. HPLC grade acetonitrile and methanol were purchased from Merck (Darmstadt, Germany). Formic acid (Optima^{TM} LC/MS Grade) was purchased from Fisher Chemical (USA). The de-ionized water was obtained using water deionizer Mili-Q® water purification system. For the solid-phase extraction (SPE) procedures, OASIS hydrophilic-lipophilic balance (HLB) polymetric material cartridges were purchased from Waters (USA). The eluent was 0.1% formic acid in methanol and was prepared by an appropriate dilution of concentrated formic acid with methanol. Pooled drug-free human plasma was donated from Blood Bank, Hospital Universiti Sains Malaysia, Malaysia.

Instrumentation

The Agilent Technologies, 6545 Quadrupole Time-of-Flight Liquid Chromatography/Mass Spectrometry (Q-TOF LC/MS) system was used for detecting colistin in human plasma. The LC-MS system consisted of an Agilent Technologies 1260 high performance liquid chromatography (HPLC) equipped with a binary pump and an autosampler. Chromatographic analysis was performed using Agilent MassHunter Workstation System software (version B.04.00) on a Zorbax SB-C-8 column having 150 × 4.6mm ID and 5µm particle size. A precolumn, Agilent Zorbax Reliance Cartridge Guard-Columns having 12.5 × 4.6mm I.D and 5µm particle size was used to protect the analytical column and extend its lifetime. Mass spectrometry equipped with Dual Agilent Jet Stream electrospray ionization (AJS ESI) interface and Q-TOF mass spectrometer that uses a quadrupole, a hexapole (collision cell) and a time-of-flight unit to produce MS/MS spectra.

Drug standard and internal standard

The colistin sulfate standard contains two major components, colistin A and colistin B. Documented molecular mass of colistin A is 1169.46 ± 98.08g/mol with molecular formula $C_{53}H_{100}N_{16}0_{13}$, colistin B is

1155.43 ± 98.08g/mol with molecular formula $C_{52}H_{98}N_{16}0_{13}$ and polymyxin B is 1203.477g/mol with molecular formula $C_{56}H_{98}N_{16}O_{13}$. The composition percentages colistin A and colistin B reported from the manufacturer were 37.91% and 62.09% respectively.

Working solution and spiked plasma

Standard stock solution of 1000 µg/mL colistin sulphate was prepared in deionized water by appropriately weighing the drugs. The stock solutions of colistin sulphate were stored at -20ºC in polypropylene tube. Working solution of colistin sulphate was prepared by appropriately diluting the stock with deionized water. For the preparation of samples, blank plasma was added with appropriate amount of colistin sulphate working solution to obtain a concentration range of 0.5-10µg/ml.

Sample preparation

Prior to solid phase extraction (SPE), all plasma was centrifuged at 2500 rpm for 10 minutes. A 500 µL of plasma was diluted with 500 µL deionized water. A 10 µL of an internal standard (polymyxin B, 2µg) was added. Each SPE cartridge was pre-conditioned with 1 mL of methanol followed by 2 mL of deionized water. 1 mL of samples were loaded to the SPE and wash with 1 mL of deionized water. The analytes were eluted with 1 mL of 0.1% formic acid in methanol and collected in 1.5 mL analytical tube. The solvent was dried under a gentle nitrogen stream. The residue was reconstituted in 50 µL of formic acid 0.1% in deionized water. After the mixture was vortexed, the sample was directly introduced into the QTOF-LC/MS system after mixing.

Chromatographic optimization parameters

In order to determine the most optimum chromatographic condition, the effect of modifying composition of the mobile phase in isocratic (50%A:50%B, 30%A:70%B and 20%A:80%B), gradient elution mode (the linear of solvent B starting 5% to 100% gradient elution with increment 5-10% for 4-10min), varying concentration of formic acid (0.05%, 0.1% and 0.2%) in the mobile phase and column temperature (30, 40, 45 and 50ºC). Reverse phase chromatography was used for the separation of colistin A, colistin B and polymyxin B (internal standard).

Mass spectrometry optimization parameters

The ionization mode (positive or negative ionization) and collision energy voltage (CE) (range of 5v to 35v with 2.5v step up) were investigated for optimization of mass spectrometry. All parameter investigated and experiment conducted for optimization of QTOF-LC/MS conditions are listed in Table 1.

Table 1. Experiment conducted for optimization of QTOF-LC/MS conditions

Parameters	Variants
Type of mobile phase	Solvent A: Formic acid in deionized water Solvent B: Acetonitrile or Formic acid in acetonitrile
Composition of mobile phase in isocratic elution mode	50%A:50%B, 30%A:70%B and 20%A:80%B
Composition of mobile phase in gradient elution mode	The linear of solvent B starting 5% to 100% gradient elution with increment 5-10% for 4-10min.
Column temperature	30, 40, 45 and 50ºC
Ionization mode	Positive ionization (+ ESI) Negative ionization (- ESI)
Collision energy voltage (CE)	Range of 5v to 35v with 2.5v step up

%; percentage, + ESI; positive electrospray ionization, - ESI; negative electrospray ionization, v; volt; ºC; degree of Celsius

Extraction recovery

The recovery (RE) was determined by comparing peak area of colistin A, colistin B and polymyxin B (internal standard) spiked before extraction (α) with the results obtained from analytes spiked after extraction (β).
The formula was used:

$$RE\ (\%) = \alpha \div \beta \times 100 \quad (1)$$

The percentage extraction recovery was obtained for 3 different concentrations; 0.5 mcg/mL (Low), 5 mcg/mL (Medium) and 10 mcg/mL (High).

Precision

Precision was evaluated by replicate analysis of colistin A, colistin B and polymyxin at 3 different concentrations; 0.5 mcg/mL (Low), 5 mcg/mL (Medium), and 10 mcg/mL (High). Precision was expressed as the percentage of the coefficients of variation (CV) by each pool.

Results and Discussion

Sample preparation

The SPE was chosen for the sample pre-treatment of plasma samples to provide a fast and simple procedure. Protein precipitation is the simplest sample pre-treatment method, in which organic solvents such as methanol or acetonitrile are commonly used and mixed with acids such as trichloroacetic acid (TCA) or trifluoroacetic acid (TFA). Researchers have noted that using an acidic pretreatment to deproteinize causes a considerable amount of CMS hydrolysis [12]. Colistin is administered intravenously as the inactive prodrug colistin methanesulfonate sodium (CMS), which is metabolized in the body into a variety of partly sulfomethylated derivatives before being converted to colistin [4]. It is crucial to develop a simple, nonacidic sample pretreatment method due to CMS stability and to reduce the hydrolysis of CMS to colistin during analysis. In this study, a nonacidic solid phase extraction (SPE) method established by Gobin et al. [12] was replicated with some modifications. The Oasis HLB column was used in this study, as it can remove anionic CMS from plasma while retaining cationic colistin A and B. To improve the liquid chromatography analysis and mass spectrometry detection, further evaporation of the eluent is required.

In this study, the eluates were dried at room temperature under a moderate nitrogen stream instead of in a heating block at 45 °C. To obtain reproducible peak areas of colistin A and colistin B, the supernatant was later diluted with deionized water containing 0.1% formic acid. Formic acid was used to reduce peak tailing and improve mass spectrometry ionization efficiency. However, formic acid resulted in CMS hydrolysis [12]. To minimize hydrolysis of CMS after introduction of low acid concentration, the sample were run immediately and total time for workup procedure after the dried sample were diluted with deionized water containing 0.1% formic acid would be no more than 5 hours [12,20]. All precautionary measures taken in this study ensured minimizing the hydrolysis of CMS during the analysis.

Optimization of chromatographic condition: Isocratic and gradient elution

No peaks were detected for any of the mobile phase compositions tested in isocratic mode (50%A:50%B, 30%A:70%B, and 20%A:80%B) (Figure 1). Thus, we investigated a gradient concentration of acetonitrile of up to 100%. Initial gradient elution with water: acetonitrile (from 95:5 to 0:100, v/v, both mobile phases were added with 0.1% formic acid) for 10 min was used for the detection of both colistin and the internal standard. However, all of the analyte peaks were broadening and tailing (Figure 2). This phenomenon has been observed in previous studies [21,24] and has been attributed to the absorption of colistin on the stationary phase of the liquid chromatographic column, which causes significant peak tailing. Colistin is a polycationic peptide with hydrophilic and lipophilic moieties. The tailing effect, probably due to the terminal amine group (hydrophilic) and negative ion from the mild acidic mobile phase, may help to form ion pairs with the polar molecules, increase their hydrophobicity, change their charge status, and change the interaction between the analyte and the stationary phase [21,24].

Formic acid concentration

Different compositions of formic acid were added to the mobile phases, and the concentration of 0.1% formic

acid was sufficient to minimize the absorption of analyte to the stationary phase. Increasing the gradient elution from 10% to 100% of mobile phase B allowed the analyte to achieve good retention, and maintaining 100% of high organic content for 2 min helped achieve better ionization efficiency of the analyte and flush out the remnants of the sample residues (Figure 3).

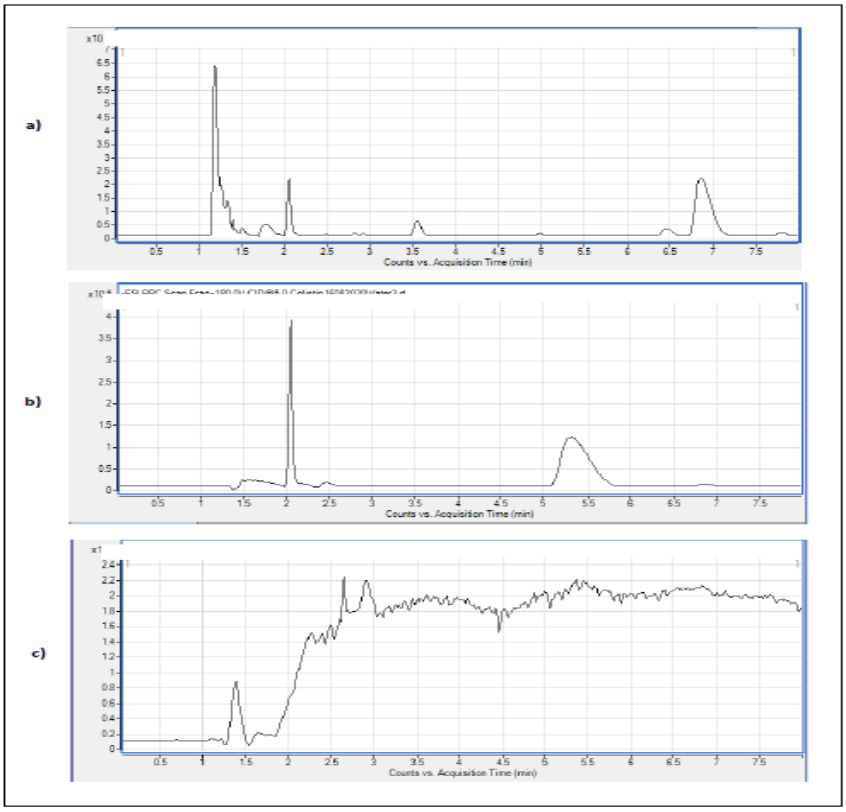

Figure 1. Mass spectrometry chromatogram of the mobile phase compositions tested in isocratic mode a) 50%A:50%B, b) 30%A:70%B, and c) 20%A:80%B

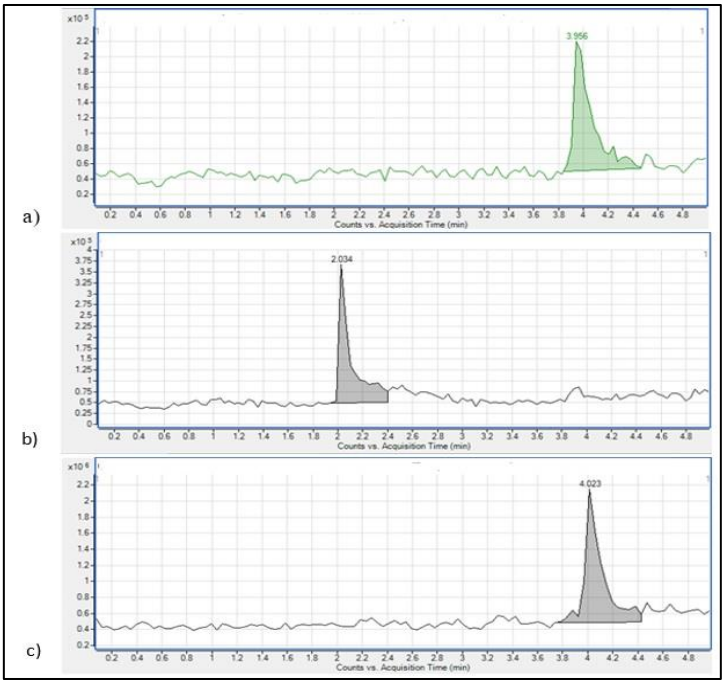

Figure 2. Mass spectrometry chromatogram of a) colistin A b) colistin B and c) polymyxin B (internal standard). Gradient elution 5% of solvent B (ACN-0.1% FA) to 80% for 4 min, total run time 5 min

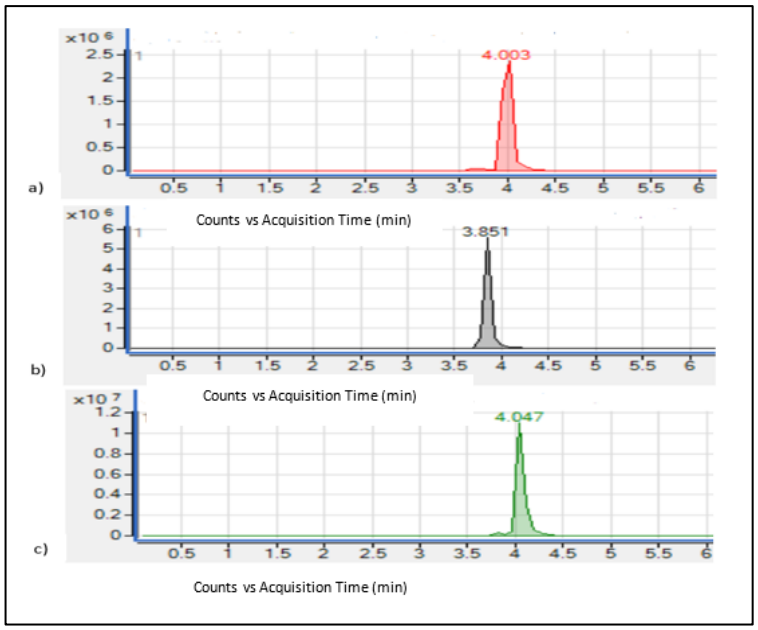

Figure 3. Mass spectrometry chromatogram of a) colistin A b) colistin B and c) polymyxin B (internal standard). Gradient elution 10% of solvent B (ACN-0.1% FA) to 100% for 10 min, total run time 18 min

Column temperature

The column temperatures of 30 ºC, 40 ºC, 45 ºC and 50 ºC were tested for their effects on colistin's peak retention time and area. Gradient elution was tested with mobile phase 5 percent of solvent B (ACN-0.1 percent FA) to 100 percent for 10 min. A higher column

temperature is usually able to produce a better peak shape and allows faster elution of the analytes. Further, it reduces the mobile phase solvent viscosity and, thus, lowers column pressure. However, no effect on the peak area or retention time was observed at high temperatures (Figure 4). Column temperature at 40 ºC was finally selected, as reported by a previous study [28]. The optimization of mobile phase composition, gradient elution program, and column temperature of 40 ºC were able to produce a better peak shape. Even though the mass spectrometry chromatogram peaks overlapped, the separation was done by mass, so the physical separation of the analytes by the chromatographic column was not required [12].

Optimization of mass spectrometry condition

The electrospray ionization (ESI) technique was used to generate precursor and product-ion spectra of the analytes for the identification of colistin A and colistin B. ESI is the preferred method of analysis for most drugs and applies to a broad range of polar to partially non-polar ions [29]. ESI generates positively or negatively charged ions of colistin A and B using positive ESI (+ESI) mode or negative (-ESI) mode. Most studies have reported LC-MS/MS with +ESI mode [13, 22, 30]. Other investigations, however, have reported using the -ESI mode in the LC-MS/MS method [11, 20]. Therefore, both +ESI and -ESI modes were tested for mass spectrometry optimization in this study. The MS-only method was run to identify precursor masses of colistin A and colistin B. After identifying the precursor masses of interest, the targeted MS/MS method was run to identify the precursor ion and product ion. For the acquisition of the full-scan mass spectra, the collision energy was set at 5 v to minimize colistin adduct formation while preventing the fragmentation of the molecular ion.

Formation and selection of precursor masses of Coli stin A and Colistin B

Full-scan mass spectra for both the analytes were acquired in continuum and centroid mode in the mass range of 90–1800 amu. Documented molecular masses from the certificates of analysis of colistin A, colistin B, and polymyxin B were 1169.46 ± 98.08, 1155.43 ± 98.08, and 1203.477, respectively, with molecular formula $C_{53}H_{102}N_{16}0_{16}S$ for colistin and molecular formula $C_{56}H_{100}N_{16}O_{17}S$ for polymyxin B. In +ESI mode, the identified molecular masses of colistin A and colistin B were 1168.78 and 1154.77, respectively. However, in -ESI mode, the identified molecular masses of colistin A, colistin B, and polymyxin B were 1169.5823, 1155.5155, and 1203.477, respectively. After identifying the precursor masses of interest, the targeted MS/MS method was run to identify the precursor ion and the product ion.

Formation and selection of precursor ions of Colistin A and Colistin B

In the +ESI mode, the dual ESI source generated molecular ions into multiple charges, giving rise to the singly charged molecular ions $[M+H]^+$ at *m/z* 1169.7919 and $[M+Na]^+$ at *m/z* 1191.7742 for colistin A. For colistin B, the singly charged ions were $[M+H]^+$ at *m/z* 1155.7762 and $[M+Na]^+$ at 1177.7589. The dominant ion peak in the scan mode mass spectrum was $[M+H]^+$. The precursor ions of colistin A at *m/z* 1169.79 and colistin B at *m/z* 1155.78 for colistin B were set as the targeted precursor ions for the analysis of colistin sulfate in standard solution. Targeted MS/MS method was run, and two dominant product ions were identified at *m/z* 1169.79 → *m/z* 302.1985/728.4976 for colistin A (Figure 5) and at *m/z* 1155.78 → *m/z* 302.1981/728.4963 for colistin B (Figure 5). This result is in contrast with a previous report that identified the product ions at *m/z* 1167.7559 → *m/z* 1123.7266/1079.7014 for colistin A and 1153.7385 → *m/z* 1109.7134/1065.5870 for colistin B [11].

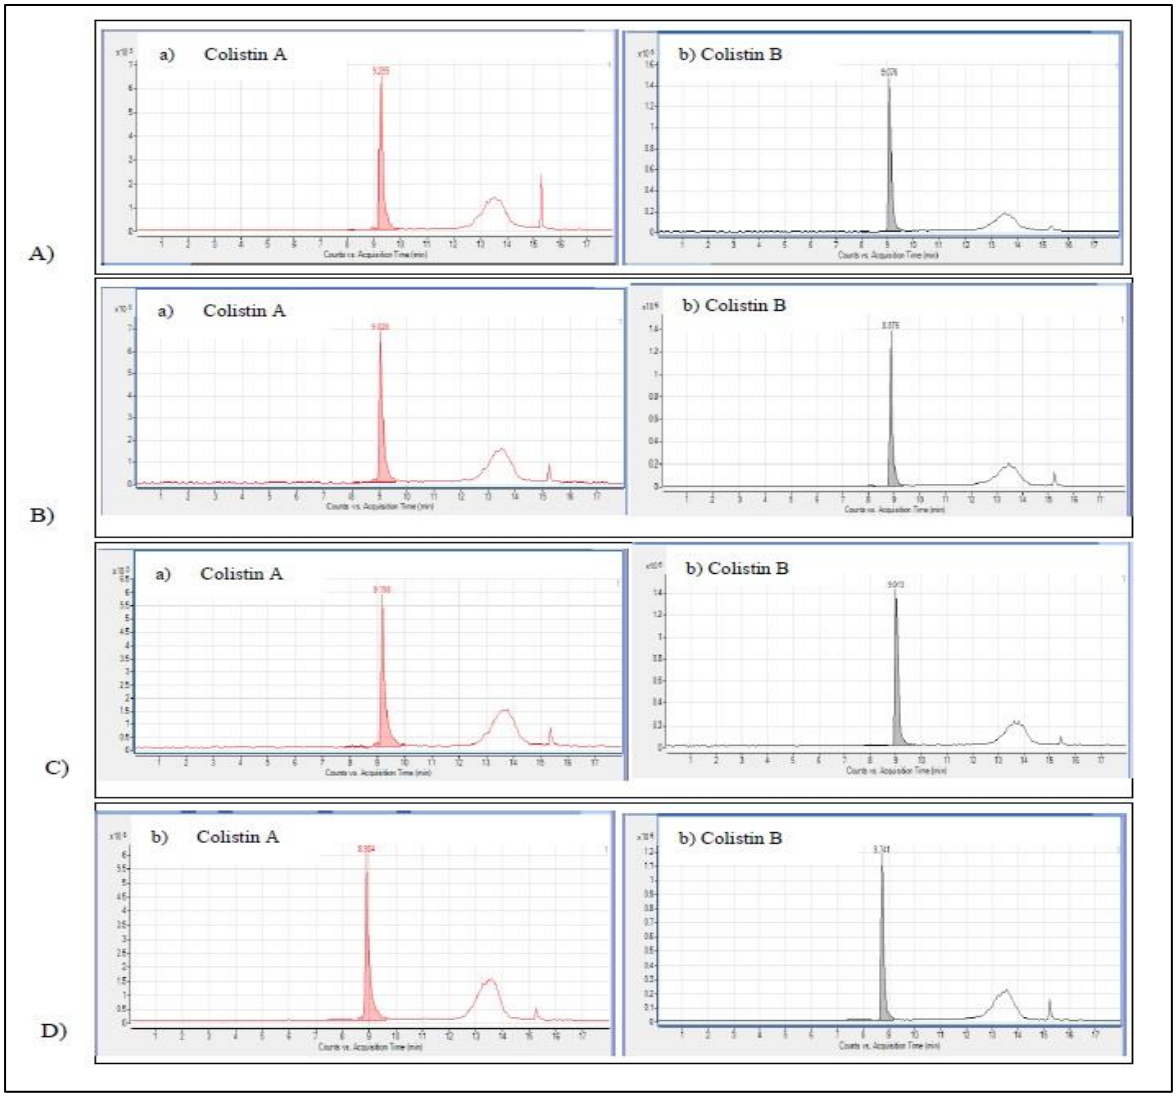

Figure 4. Mass spectrometry chromatogram of colistin A and colistin B when the column temperature was set A: 30ºC, B: 40ºC, C: 45ºC and D: 50ºC. Gradient elution 5% of solvent B (ACN-0.1% FA) to 100% for 10 min

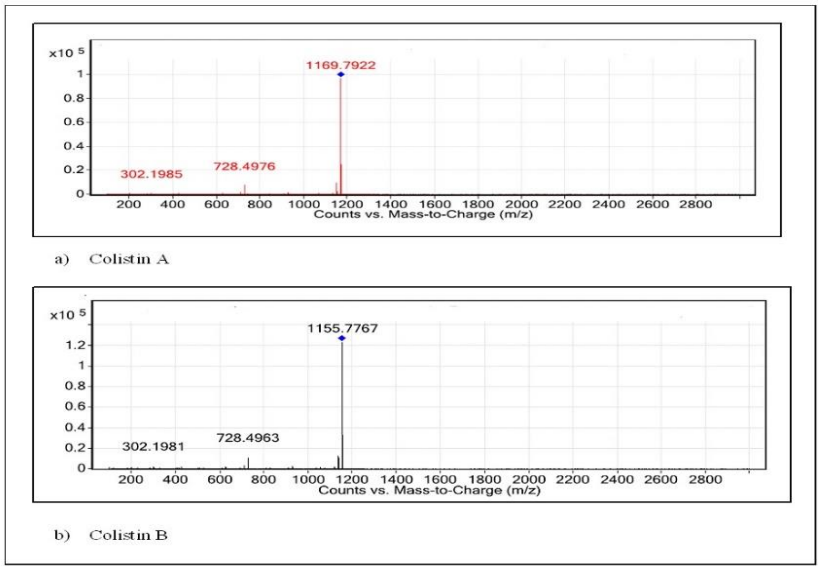

Figure 5. Mass spectrometry spectrum of precursor ion and product ion of a) colistin A, *m/z* 1169.79 → *m/z* 302.1985, 728.4976 and b) colistin B, *m/z* 1155.78 → *m/z* 302.1981, 728.4963 in positive ionization mode (ESI+)

In the -ESI mode, the dual ESI source generated molecular ions into multiple charges, giving rise to singly charged molecular ion $[M-H]^-$ at *m/z* 1167.7683 and doubly charged molecular ion $[M-2H]^{-2}$ at *m/z* 583.377 for colistin A**.** The singly charged ion $[M-H]^-$ for colistin was at *m/z* 1153.7526, with doubly charged molecular ions $[M-2H]^{-2}$ at 576.3714 and $[2M+CL]^-$ at *m/z* 2347.465. For polymyxin B, the singly charged ion $[M-H]^-$ was at *m/z* 1201.7579 and the doubly charged molecular ion $[M-2H]^{-2}$ was at 600.3749. The dominant ion peak in the scan mode mass spectrum was $[M-H]^-$. The $[M-H]^-$ ion, which had a higher intensity, was chosen as the precursor ion for the analytes (colistin A: *m/z* 1167.7683; colistin B: *m/z* 1153.7526; and polymyxin B: *m/z* 1201.7579). Targeted MS/MS method was run and dominant product ions were identified at *m/z* 1167.7683 → *m/z* 1123.7202/1079.697 for colistin A, *m/z* 1153.7526 → *m/z* 1109.7046/1065.6803 for colistin B, and *m/z* 1201.7579 → *m/z* 1157.73/1113.6791 for polymyxin B (Figure 6). This result is similar to a previous finding reported by Gikas et al. [11], in which these product ions arise from the successive loss of 44 Da, which is attributed to the side chain cleavage of CH_3CHO from the L-threonine (Thr) amino acid residue. Colistin A and colistin B presented greater ionization efficiency in -ESI than in +ESI; thus, the -ESI mode was selected for further analysis.

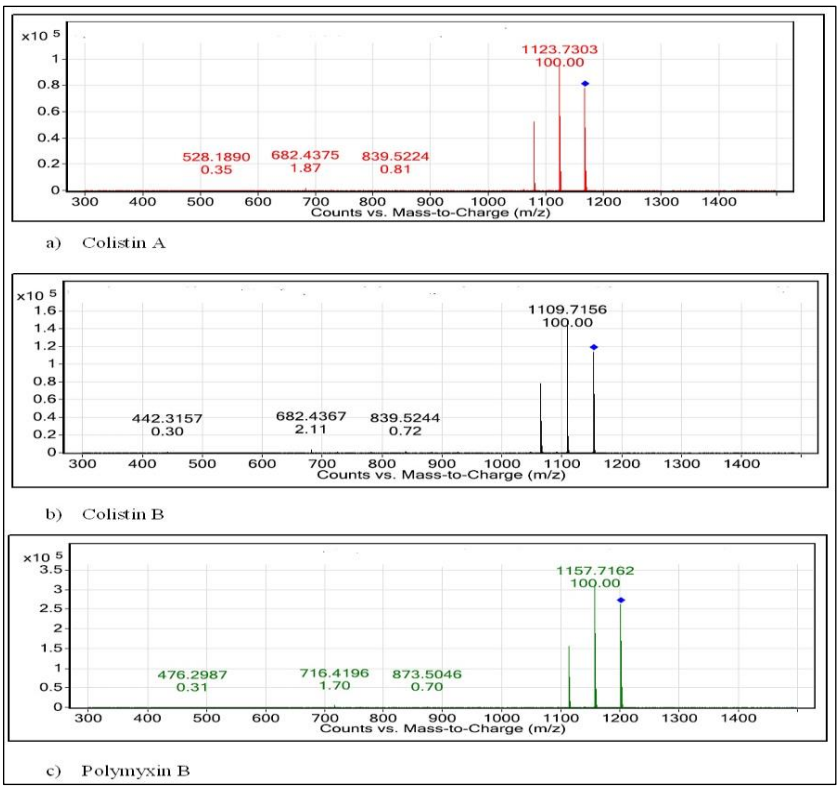

Figure 6. Mass spectrometry spectrum of precursor ion and product ion of a) colistin A, *m/z* 1167.7683 → *m/z* 1123.7202, 1079.697, b) colistin B *m/z* 1153.7526 → *m/z* 1109.7046, 1065.6803 and c) polymyxin B *m/z* 1201.7579 → *m/z* 1157.73, 1113.6791 in negative ionization mode (ESI-)

Optimization of collision energy voltage

The optimum value of collision energy for colistin A, colistin B, and polymyxin B was determined by studying collision energy from 15 to 30v. Figure 7 indicates that when the signal to noise ratio (SNR) for colistin A and colistin B was gradually increased from 18 to 20v, the SNR values became inconsistent with rising collision energy. It was found that 20v provided the best fragmentation of colistin A and colistin B, whereas 22v caused some fragmentation in the form of extra peaks with different m/z, indicating that high collision energy caused colistin A and colistin B to become more fragmented, lowering the detection limit.

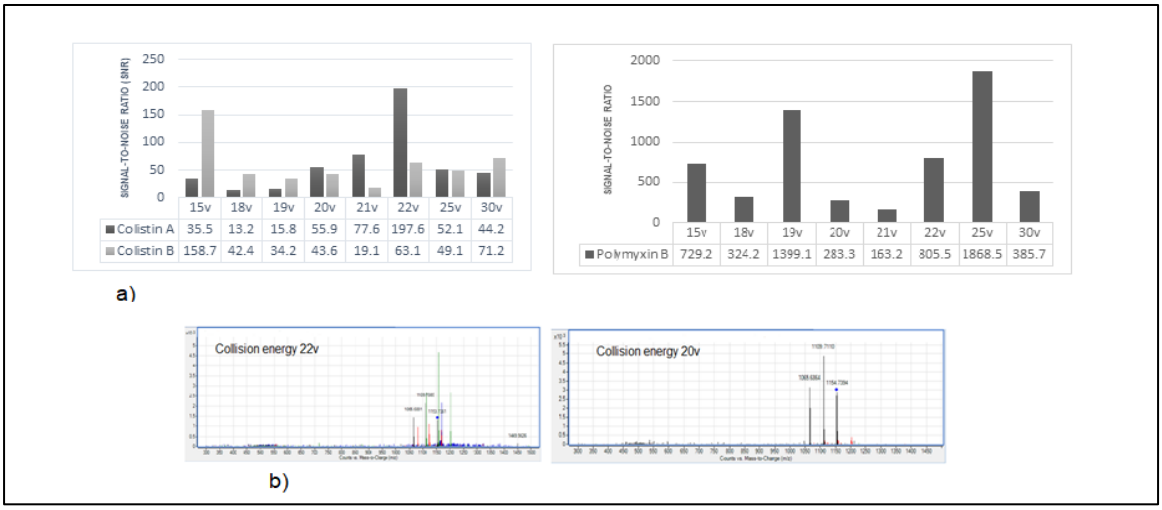

Figure 7. Optimization of Collision Energy Voltage. a) Signal-to-noise ratio of colistin A, colistin B and polymyxin B b) mass fragment for detection of colistin A, colistin B and polymyxin B

Final liquid chromatography and mass spectrometry conditions

A binary mobile phase gradient consisting of 0.1% aqueous formic acid (Solvent A) and acetonitrile with 0.1% formic acid (Solvent B) was selected for chromatographic separation. The gradient elution program used is shown in Table 2. The post run time was 2 min to equilibrate the column with the initial solvent proportions (80% solvent A and 20% solvent B). The injection volume was 5 µL and the column temperature of 40°C.

Table 2. Gradient of the elution program

Time (minutes)	Mobile Phase A (%)	Mobile Phase B (%)	Flow Rate (mL/min)
0	80	20	1
0-8	90-0	10-100	1
8 – 10	0	100	1
10 – 10.1	0 - 95	100 - 5	1.5
10.1 - 16	95	5	1.5

mL/min: milliliter per minutes; %: percentage

The mass spectrometer was operated in the negative-ion mode. The optimal mass spectrometry setup parameters were a 320 °C gas temperature, 8 L/min drying gas, 35 psig nebulizer, 350 °C sheath gas temperature, 11 L/min sheath gas flow, 3500 V Vcap, 3.416 microA capillary, 1000 V nozzle voltage (Expt), and 5.64 microA chamber. The collision energy was optimized as 20 v for colistin A, colistin B, and polymyxin B. For the acquisition of the full-scan mass spectra, the collision energy was set at 2 v to minimize colistin adduct formation while preventing the fragmentation of the molecular ion. Full-scan mass spectra for both the analytes were acquired in continuum and centroid mode in the mass range of 300–2000 amu.

Extraction recovery

Recovery represents the percentage of the analyte still present after sample workup compared with the amount of the analyte initially contained in the sample. The extraction recoveries of colistin A, colistin B, and

polymyxin B at the three concentrations are shown in Table 3. The recovery with various concentrations of the analytes ranged from 78–95%. The coefficients of variation (CV) for the analytes were less than 10% and within the acceptance limit [31].

Table 3. Results of the extraction recovery of colistin A, colistin B and polymyxin B

Concentration (mcg/mL)	Extraction Recovery (%)		
	Colistin A	Colistin B	Polymyxin B
0.5	80.8	82.8	79.7
5	95.4	86.8	83.1
10	78.8	81.8	75.6
Mean	85.00	83.80	79.47
SD	9.06	2.65	3.76
CV	3.6	1.1	1.6

CV: Coefficient of variation; mcg/ml: microgram per milliliter; SD: Standard deviation; %: Percentage

Conclusion

The quadrupole time-of-flight liquid chromatography mass spectrometry (QTOF-LC/MS) condition for the separation and detection of colistin A, colistin B, and polymyxin B was established successfully. The retention times for colistin A, colistin B, and polymyxin B were 4.003 min, 3.81 min, and 4.047 min, respectively. In this study, the separation of analytes was achieved in 18 min using the gradient mode.

Abstract

Utilizing *Calophyllum inophyllum* oil (CIO) and waste-based calcium oxide-potassium carbonate (CaO-K_2CO_3) catalyst can bring down the biodiesel production cost and this has become the main issue. CIO is a non-edible feedstock that has the potential to be used as biodiesel feedstock. The acid value and free fatty acid (FFA) content of CIO were 124.54 mg KOH/g and 62.64%, respectively. The acid values were reduced to 11.21 mg KOH/g with 5.60% of free fatty acid (FFA) by acid-catalyzed esterification reaction using a 12:1 methanol to oil ratio. CIO had iodine value of 94.33 mg I_2/g, 1.37% moisture content, a density of 929.1 kg/m^3, and viscosity of 119.5 mm^2/s. It was extracted using a cold maceration method and was found to be predominantly made up of oleic acid. CaO-K_2CO_3 was used to avoid the problems faced by the single metallic catalysts (CaO and K_2CO_3). It was synthesized using physical mixing and used as a heterogeneous catalyst for the transesterification of CIO to produce biodiesel. The base heterogeneous catalyst was characterized and analyzed using TGA, FTIR, XRD, FESEM-EDX, BET, and Hammett indicators. These analyses have proven that calcium oxide (CaO) and potassium carbonate (K_2CO_3) were well incorporated catalyst. CaO-K_2CO_3 is a moderate catalyst with the basic strength of H ≤9.3. Two parameters, which are methanol to oil ratio and reaction time, were optimized to obtain a higher methyl ester yield. The maximum yield of methyl ester obtained from transesterification of CIO at 65 °C was 86.7% using 6 wt.% of 1:1 CaO- K_2CO_3 and 9:1 methanol to oil ratio within 4 h reaction time. CaO-K_2CO_3 appeared as a promising catalyst in converting CIO to biodiesel.

Abstrak

Kegunaan minyak *Calophyllum inophyllum* (CIO) dan pemangkin kalsium oksida-potasium karbonat (CaO-K_2CO_3) berasaskan sisa boleh mengurangkan kos pengeluaran biodiesel yang telah menjadi isu utama. CIO adalah bahan mentah tidak boleh dimakan

yang berpotensi untuk digunakan sebagai bahan mentah biodiesel. Kandungan nilai asid dan asid lemak bebas bagi CIO adalah 124.54 mg KOH/g dan 62.64%. Penurunan nilai asid telah berkurang kepada 11.21 mg KOH/g dengan 5.60% of asid lemak bebas melalui tindakbalas esterifikasi asid dengan menggunakan metanol pada minyak (12:1). CIO mempunyai nilai iodin value 94.33 mg I_2/g, 1.37% kandungan lembapan, ketumpatan 929.1 kg/m^3, dan kelikatan 119.5 mm^2/s. Ia diekstrak dengan kaedah pemekatan sejuk dan kebanyakannya terdiri daripada asid oleik. CaO-K_2CO_3 digunakan untuk mengelakkan masalah yang dihadapi oleh pemangkin logam tunggal (CaO dan K_2CO_3). Ia disintesis dengan pencampuran fizikal. Pemangkin heterogen telah dicirikan dan dianalisis dengan menggunakan TGA, FTIR, XRD, FESEM-EDX, BET dan Hemmett. Analisis ini telah membuktikan bahawa kalsium oksida (CaO dan K_2CO_3) telah digabungkan dengan baik. CaO-K_2CO_3 merupakan mangkin sederhana dengan kekuatan alkali H_≤9.3. Dua parameter iaitu nisbah metanol kepada minyak dan masa tindak balas telah dioptimumkan untuk mendapatkan hasil metil ester yang lebih tinggi. Hasil maksimum metil ester yang diperoleh daripada transesterifikasi minyak biji CIO pada 65 °C ialah 86.7% menggunakan 6 wt.% CaO- K_2CO_3, nisbah metanol kepada minyak 9:1 selama 4 j masa tindak balas. CaO-K_2CO_3 sebagai mangkin yang dijanjikan dalam perubahan CIO kepada biodiesel.

Kata kunci: Kulit pisang, cangkerang *corbicula fluminea*, metil ester

Introduction

Nowadays, fossil fuels are the dominant energy source worldwide. Human relies heavily on fossil fuels for daily activities because of their reliability and energy efficiency. However, fossil fuels belong to non-renewable energy derived from the remains of ancient animals and plants buried millions of years ago. The burning of fossil fuels leads to an increased rate of environmental deterioration. To overcome this problem, biofuel, such as biodiesel, appears as a promising alternative to fossil fuel for diesel engines [1]. Biodiesel is a form of alternative fuel derived from vegetable oil or animal fat. Biodiesel production leads to a cleaner emission profile and higher energy efficiency compared to fossil fuel [1] and is the most outstanding biofuel due to several excellent properties such as non-toxic and high biodegradability. [2, 3]. The primary obstacle in commercializing biodiesel is the cost since the production of biodiesel from edible oil is not economically viable. The extensive use of edible oils, especially palm oil, for biodiesel production may cause a food crisis. As a result, biodiesel is very expensive to be used as a fuel due to the tremendous demand for edible oils [4]. These issues can be addressed by utilizing low-cost feedstock such as non-edible oil for biodiesel production.

Calophyllum inophyllum (CI), commonly known as Penaga Laut in Malaysia, is a medium-sized plant that grows up to 20 to 30 m high [5;6]. It thrives in sub-tropical, tropical climates, and can grow in harsh conditions [7]. CIO is a good candidate for green energy production due to its high oil content. The seed oil content of CI ranges from 40-75% (dry weight basis), which is greater than Jatropha seed oil (40-60%) and rubber seed oil (40-50%) [8]. CI grows in mixed cultures with minimal cultivation, thus minimum cultivation cost is required [9]. Since CIO is a non-edible oil, the utilization of CIO as a biodiesel feedstock will not interfere with food provision hence reducing the food crisis problem caused by edible oils. In terms of a heterogeneous catalyst, the monometallic catalyst exhibits low stability towards carbon dioxide and moisture. Even though CaO has high catalytic performance, it will leach out Ca^{2+} due to moisture from the surrounding. The leaching of Ca^{2+} deteriorates the quality of biodiesel by reacting with the FFA of the oil resulting in saponification and deactivation of catalyst function. Besides that, it also has low catalytic activity due to the poor basic site on the surface of the catalyst.

Therefore, in this research, a CaO-K_2CO_3 bimetallic catalysts (catalyst compose of two metals) heterogeneous catalyst is used to produce biodiesel. Bimetallic catalysts exhibit a synergistic effect that makes the catalysts superior to monometallic catalysts [10]. The two metallic elements can form an effective bimetallic catalyst although they do not mix each other to form an alloy. They have superior stability towards moisture and carbon dioxide, thus effectively increasing the lifetime of the catalyst [11]. In addition, bimetallic catalysts have a larger surface area and stronger basic strength resulting in better catalytic performance. Due to these reasons, researchers have mixed CaO or magnesium oxide (MgO) with other monometallic catalysts to increase the selectivity and catalytic activity

of the catalyst [12]. This study aims to investigate the possibility of using CaO-K_2CO_3 as a heterogeneous base bimetallic catalyst for biodiesel production from CIO. To the best of our knowledge, the synthesis of CaO-K_2CO_3 bimetallic catalyst in catalyzing the transesterification of CIO for biodiesel production has never been reported.

Materials and Methods

The CI fruits were collected from the UiTM landscape to obtain the seed oil as feedstock for fatty acid methyl ester production. Banana peels and *corbicula fluminea* were obtained from a local stall in Pahang. ACS grade of methanol, chloroform, Thin Layer Chromatography (TLC) plate, and isopropanol were purchased from Merck KGaA (Germany). AR grades of n-hexane, sulphuric acid and petroleum ether were obtained from Bendosen and Fisher Scientific, respectively. Iodine resublimed from R&M Chemical and potassium hydroxide (KOH) extra pure from Loba Chemie were also used in this study. HPLC grade n-heptane (99%) and C_{17} methyl heptadecanoate as the internal standard for methyl ester were purchased from Friedemann Schmidt. Phenolphthalein (H_= 9.3), 2,4-Dinitroaniline (H_= 15.0), and 4-nitroaniline (H_= 18.4) from Sigma-Aldrich were used as Hammett indicators.

CI fruits were dried under the sun for five days. The seeds were obtained from the crashed outer layers of the dried fruits and were washed with warm water to remove dirt and impurities. Then, the seeds were dried in an oven at 100℃ overnight to remove moisture content. The dried seeds were then ground into fine powder for further extraction [13, 14]. A total of 200 g of powdered seed was placed in a 500 mL beaker. The extraction solvent of n-hexane was then poured into the beaker until the powdered seed was completely covered. The beaker was sealed with aluminum foil and kept for 5 days. The seed oil was separated from the powdered seed by filtration. Subsequently, the seed oil was separated from n-hexane using a Buchi R-100 rotary evaporator at 70 °C. The extracted oil was then transferred to 30 mL vials and kept in the refrigerator.

The bimetallic catalyst was prepared in a 1:1 CaO/ K_2CO_3 molar ratio. The washed clamshells were dried under the sun for two days and crushed using a pestle and mortar. The *corbicula fluminea* shell fine powder was then calcined at 900 °C using a tube furnace. Banana peels that contained K_2CO_3 were sectioned and cut into several pieces. The peels were dried in an oven at 100 °C overnight before grounding the dried peels using a grinder. The banana peels fine powder was then calcined using a tube furnace at 550 °C. A bimetallic catalyst with a CaO/ K_2CO_3 molar ratio of 1:1 was prepared by physically mixing (ball milling) the same ratio of CaO and K_2CO_3. The catalysts were characterized and analyzed using Thermogravimetric Analysis (TGA), X-ray diffraction (XRD), Brunauer-Emmett-Teller (BET), Field Emission Scanning Electron Microscopy and Electron Dispersive X-ray (FESEM-EDX), and Fourier Transform Infrared Radiation (FTIR) analyses. Furthermore, Hammett indicators were also used to determine the basicity of the catalyst. High contents of FFA in CIO were converted to triglyceride using a sulfuric acid catalyst. The conversion of FFA was performed at 60 °C for 2 hours using methanol to oil ratio of 12:1 and 1 wt.% catalyst [13]. This procedure was repeated with the same methodology to reduce the acid value of the oil to less than 5 mg KOH/g oil.

The resulting mixture was transferred to centrifuge tubes to separate excess methanol and contaminants from triglyceride [14]. Transesterification reactions were carried out in a 50 mL round bottom flask equipped with a condenser, thermometer, and magnetic stirrer immersed in a water bath. A total of 5 g of CIO was added to the calcined catalysts and methanol mixture. The mixture was refluxed under constant 500-600 rpm magnetic stirring with a 1:1 CaO/ K_2CO_3 ratio, 6 wt.% catalyst loading, 65 °C reaction at varied reaction times (2 - 5 hours), and several methanol to oil ratios (7:1, 9:1, 11:1, 13:1 and 15:1). After the transesterification reaction, the product mixture was cooled to room temperature. Then, the product mixture was centrifuged at 4000 rpm for 5 min to separate the desired product from the by-products. The FAME content in the sample was analyzed using GC-FID. GC-FID (Agilent 7890A GC-System) with a polar capillary column (MEGA-Wax, 30 m length, 0.32 mm internal diameter, and 0.50 µm film thickness). Samples were prepared by mixing

20 mg of the methyl ester with 400 µL of internal standard using a micropipette. A total of 10 mg/mL of methyl heptadecanoate (C_{17}) was used as an internal standard. For each sample analysis, a sample volume of 1µL was injected into GC. The carrier gas was helium, which had a linear velocity of 40 cm s^{-1}. The initial oven temperature was 190 °C with a 2 min equilibration interval. The temperature of the oven was raised 10 °C per minute until it reaches 230 °C and held for 8 min. The methyl ester content was observed and calculated following the EN14103 European regulation procedure.

Results and Discussion

The characterization of CIO was performed based on acid value, FFA %, iodine value, moisture content, density, and viscosity to determine seed oil quality before transesterification reaction following standard test methods (ASTM D1298; ASTM D1298). The acid value and FFA content of CIO were 124.54 mg KOH/g and 62.64%, respectively in which the values reduced to 91% (acid value: 11.21 mg KOH/g, FFA: 5.60%) after the esterification reaction. It has an iodine value of 94.33 mg I_2/g, 1.37 % moisture content, a density of 929.1 kg/m^3, and viscosity of 119.5 mm^2/s. Oleic acid (73.21%) is predominantly found in the seed oil followed by linoleic acid (13.5%) and palmitic acid (11.7%) play a major FFA in CIO. A similar observation of abundant fatty acids was seen in previous research [8; 14].

Based on Figure 1(a), a weight loss occurred in a single stage ranging between 600 °C and 780 °C. The decreasing TGA thermal curve indicates the thermal decomposition of calcium carbonate ($CaCO_3$) to CaO [15]. The CaO product was stable after 780 °C in which 55% of the sample weight remained. About 44% of TGA weight was loss from $CaCO_3$ suggesting the elimination of carbon dioxide. Meanwhile, as shown in Figure 1(b), involving four stages of the decomposition phase. Firstly, 9.57% of weight loss between 41 °C and 194 °C was attributed to the dehydration of banana peels from the loss of moisture content [16;17]. In the second stage, the volatile matter contents such as hemicellulose, cellulose, and lignin were broken down [18]. This led to a drastic weight loss (39%) of the sample resulting in the lowest value in the DTA plot curve between 200 ℃ and 400 ℃. The final stage ranging between 800 °C and 1000 °C was associated with the solid decomposition of the sample.

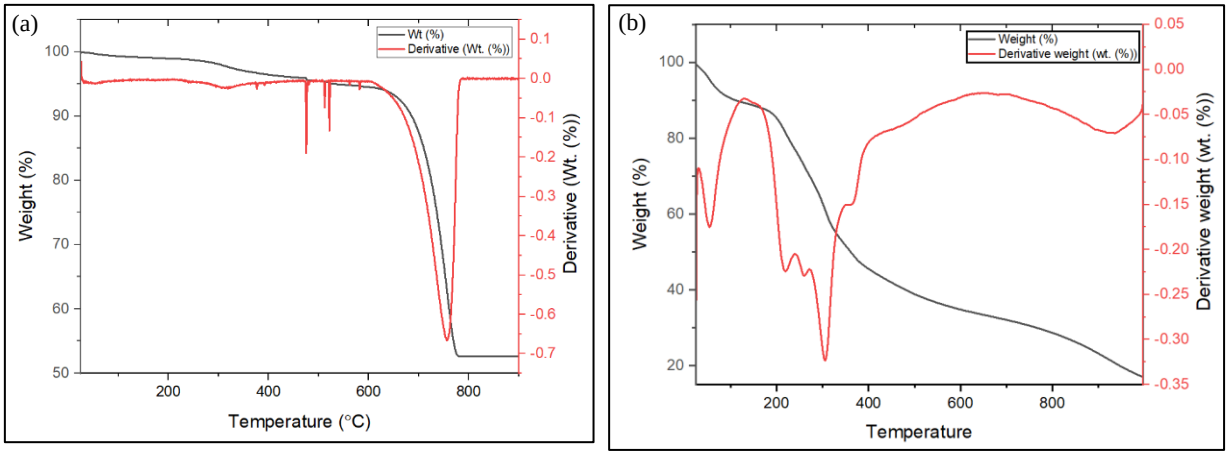

Figure 1. TGA/DTA curve of (a) uncalcined *corbicula fluminea* shells (UCFS) and (b) uncalcined banana peels (UBP)

Based on Figure 2, the peaks of calcined *corbicula fluminea* shells (CCFS) observed at 2θ = 32.484°, 37.635°, 54.109°, 64.404°, and 67.644° were attributed to lime (CaO). $CaCO_3$ was completely transformed into CaO. The appearance of sharp and narrow peaks in CCFS defined the highly crystalline structure of the catalysts [19]. The XRD pattern of calcined banana peels (CBP) presented the characteristic peaks associated with K_2CO_3. It was found that the species exhibited at 2θ value of 43° and 67.7° referred for UBP

and 2θ value of 32.48°, 40.679°, 50.326°, 57.94°, 66.513°, and 73.82° referred for CBP. After thermally calcined at 600 °C, it was observed that K_2CO_3 appeared as the main component of CBP. Compared to CBP, there were small and unclear peaks found in UBP, indicating the importance of the calcination process in producing catalysts with higher crystallinity. The XRD pattern revealed that the CCFS has higher crystallinity compared to CBP. The characteristic peaks of CaO-K_2CO_3 at 2θ = 29.80°, 40.694°, 50.298°, 50.89°, 66.54°, and 73.906° were attributed to K_2CO_3 while the peaks exhibited at 2θ = 32.379°, 37.553°, 54.035°, 64.403°, and 67.611° were assigned to CaO. CaO and K_2CO_3 were considered the principal constituents in the bimetallic catalyst.

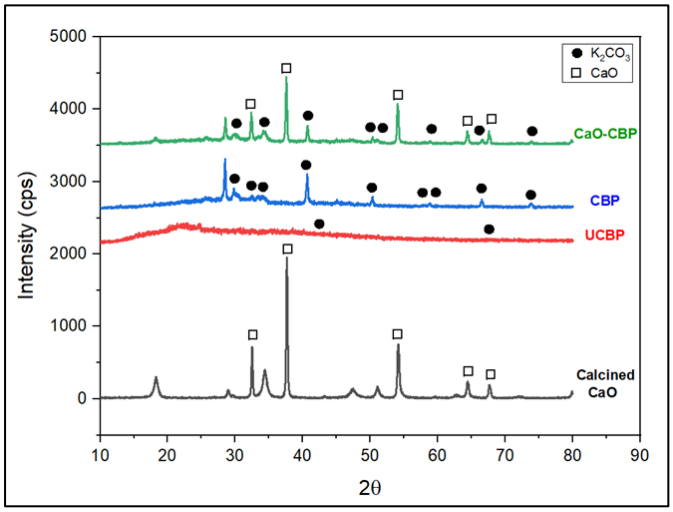

Figure 2. XRD pattern of CCFS, UBP, CBP and CaO-K_2CO_3

The FTIR spectra were used to identify the functional groups involved in CCFS, UBP, CBP, and CaO-K_2CO_3. The intense broad IR peaks at 3436.52 cm^{-1} (CCFS), 3420.60 cm^{-1} (CaO-K_2CO_3), 3436.63 cm^{-1} (CBP), and 3447.11 cm^{-1} (UBP) were assigned to the bending and stretching vibration of O-H bonds indicating the presence of water molecules on the surface of the catalysts [20]. The weak peaks observed at 874.43 cm^{-1} (CCFS), 869.48 cm^{-1} (CaO-K_2CO_3), 669.09 cm^{-1} (CBP), and 667.71 cm^{-1} (UBP) may be due to the stretching vibration of metal-O bonds. The peaks indicated the presence of carbonates in the catalysts at 1384.51 cm^{-1} (CaO-K_2CO_3), 1384.26 cm^{-1} (CBP) and 1384.58 cm^{-1} (UBP), which were assigned to C-O bending and stretching vibration. However, based on Figure 3, the peak at 1384 cm^{-1} was strong only in the calcined catalysts, CBP and CaO-K_2CO_3, representing K_2CO_3. The sharp characteristic bands at 3643.77 cm^{-1} (CCFS) and 3643.97 cm^{-1} (CaO-K_2CO_3) show the presence of the hydroxide (OH) group of calcium hydroxide ($Ca(OH)_2$). The production of this group may be via the hydration reaction between CaO and water molecules. The peak of 1419.83 cm^{-1} in CCFS was assigned to the symmetrical and unsymmetrical O-C-O stretching attached to CaO [21].

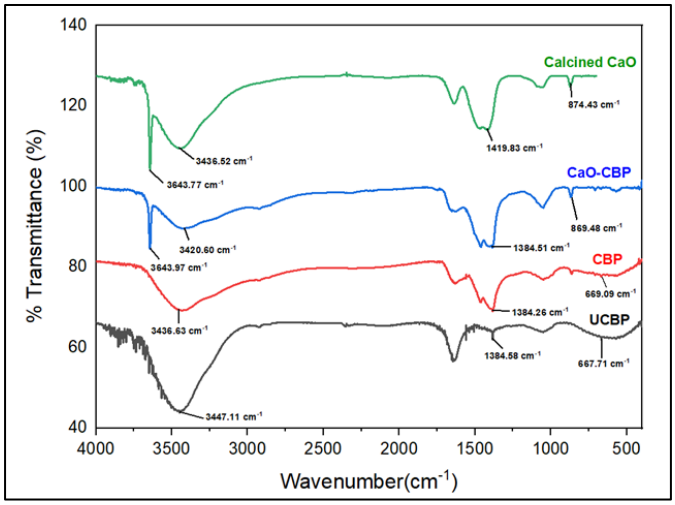

Figure 3. FTIR spectra for CCFS, UBP, CBP and CaO-K_2CO_3

The Hammett indicators used in this analysis are phenolphthalein (H_= 9.8), 2,4-dinitroaniline (H_= 15.0), and 4-nitroaniline (H_= 18.4). CaO-K_2CO_3 turned the colorless phenolphthalein into pink, but the yellow color of 2, 4-dinitroaniline and 4-nitroaniline remains unchanged indicating the basic strength within the range of 9.8 < H_ < 15.0. According to Ngaosuwan et al. [22] the La_2O_3/CaO developed from the eggshells by physical mixing indicated the basic strength within the range of 7.2 < H_ < 9.8. CaO-K_2CO_3 that was synthesized in this work showed higher basicity compared to bimetallic catalyst in the previous study.

The Brunauer-Emmett-Teller (BET) analysis was used to determine the BET surface area, pore volume, and pore size of the catalysts. It was observed that the BET surface areas of both calcined compounds, CCFS and CBP were greater than the uncalcined samples. Thus, it can be concluded that the calcining process contributes to the enhancement of the catalyst's surface area. The pore volume and pore size of the corbicula fluminea shell was discovered to be in an increasing trend from 0.0106 cm^3/g to 0.0358 cm^3/g and 155.8632 Å to 157.1291 Å, respectively after calcination process. The same trend was observed in banana peels, whereby the pore volume and pore size increased from 0.0031 cm^3/g to 0.0205 cm^3/g and 25.8222 Å to 51.3117 Å, respectively. This was expected to provide a better interaction between the oil sample and catalysts. On the other hand, CaO-K_2CO_3 was found to have a BET surface area of 22.5885 m^2/g demonstrating a greater surface area compared to CBP and CCFS. The bimetallic catalyst was expected to contain a greater catalytic property than a monometallic catalyst. However, the pore volume and pore size of CaO-K_2CO_3 were smaller compared to CCFS and CBP. It was suspected that the pore of the catalyst was blocked by CCFS on the CBP [23].

The agglomerated particles of CCFS with irregular shapes were observed in Figure 4 (a). In contrast, Figure 4(b) reveals the irregular structure of UBP with a smooth surface. Calcination plays a significant role in the morphology of banana peels. After the calcining process, the catalyst structure changes dramatically. Figure 4(c) demonstrates a porous morphology of CBP. The cross-sectional view of CBP shows the presence of multiple pores. The microstructure possesses a rough surface with aggregated particles on top of the surface. The binding of CaO on the surface of CBP is illustrated in Figure 4 (d). The agglomerated structures of CCFS fill the pores of CBP in which it binds with CBP forming a bimetallic catalyst. CaO serves as a medium to fill the available voids in CBP with the aim to enhance the surface area of the catalysts hence diminishing the pore volume. EDX analysis was performed to determine the surface elemental composition of the catalysts. Figure 5 shows the EDX spectra of CCFS, UBP, CBP, and CaO-

K_2CO_3 bimetallic catalyst. The spectra show a significant amount of carbon, oxygen, potassium, and calcium on the catalysts. CCFS has 55.36% of O, 30.87% of Ca, and 13.77% of C. UBP has 45.58% of O, 25.49% of K, and 24.67% of C whereas CBP has 51.83% of O, 29.57% of K, and 16.42% of C. CaO-K_2CO_3 consists of 47.32% O, 22.19% Ca, 20.26% C, and 10.24% K.

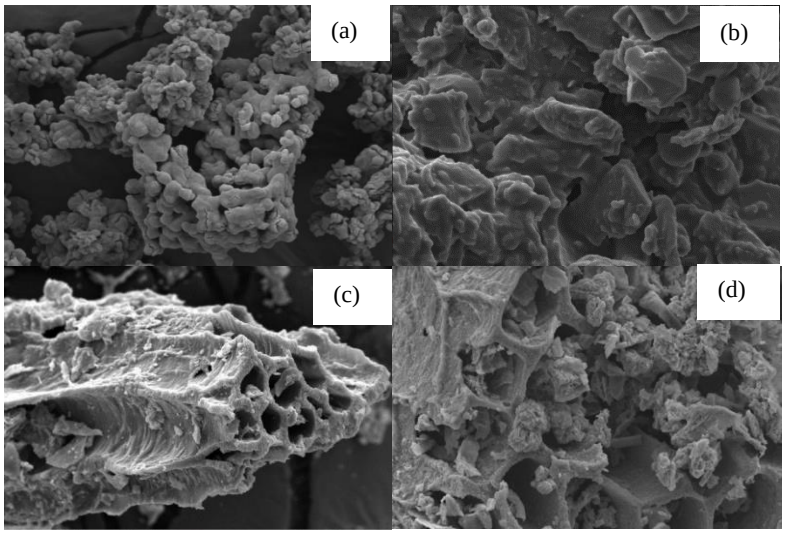

Figure 4. FESEM photographs of (a) CCFS, (b) UBP, (c) CBP and (d) CaO-K_2CO_3 under magnification of 5000

Since the stoichiometric molar ratio of methanol to oil for the transesterification process is 3:1, an excess amount of methanol is required to drive the equilibrium towards biodiesel production. Therefore, the 7:1 molar ratio was taken as the starting value for investigation [24]. As shown in Figure 6(a), the yields of the biodiesel increased as the methanol to oil ratio increased from 7:1 to 9:1. In this study, the molar ratio of 9:1 is determined as the optimum methanol to oil ratio with an 81.4% yield of methyl ester. When the methanol to oil ratio was further increased beyond the optimum ratio (9:1), the biodiesel yields gradually dropped. Glycerol, the side product of the transesterification reaction could dissolve in the excess of methanol and inhibit the reaction of methanol with triglyceride and catalyst. This reaction hampers the separation of glycerol from methyl ester and thus, reduces the methyl ester yield [24]. Therefore, methanol to oil ratio of 9:1 was used to optimize the transesterification of CIO since it produced the highest yield of methyl ester of 81.4 % at 65 ℃ using 6 wt.% 1:1 CaO-K_2CO_3 in 3 h reaction time.

The methyl ester yield increased as the reaction duration increased from 2 to 4 hours. However, after an optimal reaction duration, a further increase in the reaction time will reduce the methyl ester conversion. Since transesterification reaction is a reversible process, the backward or reverse reaction started when equilibrium has been achieved. This would lead to the loss of methyl ester and soap formation [25]. Thus, it is significant to determine the optimal reaction time to obtain a higher biodiesel yield [26]. Therefore, the optimal reaction time was 4 hours with 86.7% biodiesel yield at 65 ℃ using 6 wt.% of 1:1 CaO-K_2CO_3 and 9:1 methanol to oil ratio.

Conclusion

In this study, a heterogeneous CaO-K_2CO_3 bimetallic catalyst derived from *Corbicula fluminea* shell and banana peels was synthesized and successfully utilized in the transesterification of CIO for the conversion of biodiesel. Bimetallic catalyst CaO-K_2CO_3 was synthesized by physical mixing of CaO and K_2CO_3. Bimetallic catalysts CaO-K_2CO_3 characterized using TGA, XRD, FTIR, FESEM-EDX, BET, and Hammett indicators revealed the potential to be utilized as a solid catalyst in biodiesel conversion. A maximum of 86.7% of methyl ester yield could be obtained at 65 °C using a 9:1 methanol to oil ratio and 6 wt.% of 1:1 CaO-K_2CO_3 at 4 hours reaction time. Using waste materials is an eco-friendly approach that minimizes the cost of catalysts and adds value to these waste materials. Biodiesel from CIO is considered cost-effective renewable energy.

Abstract

Animal fat plays an important role in processed meat products as it is responsible for improving some physicochemical and sensorial qualities of the final products. However, consumption of high-fat food products is linked to a higher risk of various cardiometabolic diseases such as type 2 diabetes mellitus and cardiovascular diseases. Eggplant has the potential to be used as a fat replacer, but different types of eggplants could produce various results. Thus, this study aimed to produce reduced-fat chicken sausages re-formulated with five different types of eggplants [Round Asian Eggplant (RAE), Pearl Red Eggplant (PRE), Pea Eggplant (PE), Round Black Eggplant (RBE), and Green Thai Eggplant (GTE)] as the fat replacers. The chicken sausages were evaluated for physicochemical and sensorial properties and compared to sausage containing only chicken fat as the control. The RAE, PRE, and PE sausages had the lowest fat content at 4.34%, 6.30% and 7.64%, respectively, thus can be claimed as reduced fat chicken sausages. There were no significant differences among all formulations in terms of ash, moisture, protein, cooking loss, water holding capacity, springiness, and cohesiveness. The sensory analysis revealed that consumers accepted the RAE and PRE sausages compared to the control and the least preferred was PE. This was supported by the PCA, which positively proposed lower fat content (4.34%) and higher a^* value (3.21) while rejecting higher pH (6.35) and b^* values (15.88) of the reduced-fat-chicken sausages. In conclusion, eggplants can be used as fat replacers to produce reduced-fat chicken sausages with Round Asian Eggplant being the best option.

Keywords: chicken meat products, fat mimetics, fat replacers, healthier meat products, low-fat sausages

Abstrak

Lemak haiwan memainkan peranan penting dalam produk daging yang diproses kerana ia bertanggungjawab untuk menambah baik beberapa kualiti fizikokimia dan deria rasa produk akhir. Walau bagaimanapun, pengambilan produk makanan tinggi lemak dikaitkan dengan risiko yang lebih tinggi untuk pelbagai penyakit kardiometabolik seperti diabetes mellitus jenis 2 dan penyakit kardiovaskular. Terung mempunyai potensi untuk digunakan sebagai pengganti lemak, tetapi jenis terung yang berbeza boleh menghasilkan keputusan yang pelbagai. Oleh itu, kajian ini bertujuan untuk menghasilkan sosej ayam kurang lemak yang dirumus semula menggunakan lima jenis terung yang berbeza [*Round Asian Eggplant* (RAE), *Pearl Red Eggplant* (PRE), *Pea Eggplant* (PE), *Round Black Eggplant* (RBE), dan *Green Thai Eggplant* (GTE)] sebagai pengganti lemak. Sosej ayam telah dinilai untuk sifat fizikokimia dan deria rasa dan dibandingkan dengan sosej yang mengandungi hanya lemak ayam sebagai kawalan. Sosej RAE, PRE, dan PE mempunyai kandungan lemak terendah masing-masing pada 4.34%, 6.30%, dan 7.64%, oleh itu boleh diperakukan sebagai sosej ayam kurang lemak. Tiada perbezaan yang ketara antara semua formulasi dari segi abu, kelembapan, protein, kehilangan berat memasak, kapasiti memegang air, keanjalan dan kepaduan. Analisis deria rasa mendedahkan bahawa pengguna menerima sosej RAE dan PRE berbanding dengan kawalan dan yang paling tidak disukai adalah PE. Ini disokong oleh PCA, yang secara positif mencadangkan kandungan lemak yang lebih rendah (4.34%) dan nilai *a** yang lebih tinggi (3.21) sambil menolak nilai pH (6.35) dan *b** (15.88) yang lebih tinggi untuk sosej ayam dikurangkan lemak. Kesimpulannya, terung boleh digunakan sebagai pengganti lemak untuk menghasilkan sosej ayam kurang lemak dengan *Round Asian Eggplant* menjadi pilihan terbaik.

Kata kunci: produk daging ayam, lemak mimetic, pengganti lemak, produk daging yang lebih sihat, sosej rendah lemak

Introduction

The growing concerns about the potential health risks associated with the consumption of high-saturated fat have caused the meat industries to modify traditional meat products or develop new formulations with lower fat contents and better fatty acid profiles [1,2]. Fat contributes to the flavour, texture, colour, mouthfeel, and appearance, so it is not completely removed from meat product formulations [3], alternatively, the fat is replaced with plant-based ingredients that function similar to fat but reduce the total fat, calories, and cholesterol content [4,5]. According to the Nutrient Comparative Claims, a food product is claimed as reduced fat if it has at least a 25 per cent lower fat content than the original product [6].

Eggplant (*Solanum melongena)* also known as brinjal, berenjena, aubergine or melanzane is an edible fruit that originated in India [7] and is commonly cultivated in Asia, Europe, Africa, and the Near East [8]. The eggplants are grouped based on the fruit shape into three botanical types: dwarf (*S. melongena var. depressum*), egg-shaped (*S. melongena var. esculentum*) and long and slender in shape (*S. melongena var. serpentinum*) [9,10]. They are an excellent source of dietary fibre and vitamins such as vitamin B6, vitamin K, vitamin C, niacin, and folate in addition to minerals including potassium, copper, magnesium, manganese, and molybdenum [11, 12]. Eggplant fruits are suitable plant-based ingredients to be incorporated into meat products due to their characteristics. For example, Akesowan and Jariyawaranugoon [13] reported that the incorporation of 2.73% w/w of eggplant powder shows positive attributes towards shrinkage, cooking yield and firmness of chicken nuggets extended with white button mushroom. Ammar [11] proved that the addition of 5 to 10% w/w eggplant pulp can successfully produce high-fibre chicken nuggets with some positive attributes such as water holding capacity and cooking yield and sensory evaluation. Eggplant powder added to pork sausage formulations produced sausages with a higher moisture and protein content and lower fat content [14]. Zhu et al. [15] also reported that eggplant powder mixed with soybean oil and used as a fat replacer improved the water- and fat-binding, texture, and sensory properties of pork sausages.

However, no study has evaluated the different types of eggplants as fat replacers. In addition, the best variables to describe the meat products added with eggplants could further increase the understanding of eggplants' functionalities. Therefore, this study determined the

physicochemical and sensory properties of chicken sausages with five different eggplants: Round Asian Eggplant (RAE), Pearl Red Eggplant (PRE), Pea Eggplant (PE), Round Black Eggplant (RBE) and Green Thai Eggplant (GTE) as the fat replacers. The most discriminant variables of the newly formulated chicken sausages were selected by using a chemometric approach based on multivariate statistics. The outcomes are expected to highlight the potential of eggplants as fat replacers in the production of healthier meat products and could also be a reference for further research.

Materials and Methods

Preparation of chicken sausages

Five different types of eggplant fruits [Round Asian Eggplant (RAE), Pearl Red Eggplant (PRE), Pea Eggplant (PE), Round Black Eggplant (RBE) and Green Thai Eggplant (GTE)] were purchased from the local market in Bandar Sri Damansara, Selangor. The eggplants were separately rinsed with clean water and boiled for five minutes to make them softer and stop the enzymatic browning before being mashed using mortar and pestle into paste form. Frozen chicken breasts were purchased from a meat shop (Sri Ternak, Sri Kembangan, Selangor). The chicken breasts were ground using a mincer machine (Hobart 4822, USA). The control chicken sausage was formulated with 70% chicken meat, 10% fat, 10% corn starch, 1.25% salt, 0.5% sugar, 0.5% black pepper, 0.25% STPP and 7.5 % ice water. For the treatment of fat-replaced chicken sausages, the fat was replaced either by RAE, PRE, PE, RBE, or GTE at 10% of the total weight of the formulation. The minced chicken meat and other ingredients were placed into the bowl cutter (K3 Model-BenchType, Taiwan) and mixed for 10 minutes, then, added with the eggplant paste and continued mixing for another 6 minutes. The mixture was weighed into approximately 30 g portions and stuffed into the sausage casings, boiled for 10 minutes, taken out and cooled down in iced water. The casings were removed and the sausages were vacuum-packed in a polyethylene bag.

Proximate analysis

Proximate compositions of the chicken sausages were determined according to the AOAC methods [16]. Moisture content was determined by using the oven drying method where the chicken sausages were heated to 105 °C overnight and the moisture content was calculated based on the weight loss of the chicken sausages. Ash content was determined by igniting the chicken sausages at 550 °C using the furnace (Method No. 930.05). For crude fat, the Soxhlet extraction method was used where the weight of fat extracted petroleum ether was measured (Method No. 930.09). The crude protein content was determined by using the micro-Kjeldahl method (Method No. 978.04). The carbohydrate was calculated by the difference. The percentage of fat reduction was calculated based on the fat reduced in the newly formulated sausage against the fat of the control sample.

Water holding capacity (WHC)

Each chicken sausage was pre-weighed at 1.5 g and placed in a centrifuge tube with a filter paper (Whatman No. 1) and centrifuged for 15 minutes at 4000 g at 20°C using a centrifuge (KUBOTA 5800, Japan). The dried chicken sausages were then re-weighed, and the reading was recorded. WHC was determined using the following calculation [17]:

$$\text{WHC (\%)} = \frac{\text{(water weight before centrifuge - water weight after centrifuge)}}{\text{the sample weight}} \times 100 \quad (1)$$

Cooking loss

The chicken sausages were pan-fried evenly for 5 minutes using a non-stick pan with the internal temperature reaching 75°C. The cooking loss of the chicken sausages was determined by measuring the initial weight and final weight after cooking the sausages as follows [17]:

$$\text{Cooking loss (\%)} = \frac{\text{(initial weight – final weight) of chicken sausage}}{\text{the initial weight of chicken sausage}} \times 100 \quad (2)$$

pH analysis

The pH values were analyzed before the manufacture of chicken sausages. Five g of meat batter from each chicken sausage sample were homogenized with 40 mL of distilled water. Then the pH values of the chicken sausages were measured using a pH meter (Jenway Model 3505 pH meter, UK) [17].

Colour measurements

The colour of the chicken sausage was measured using a colourimeter (Minolta spectrophotometer CM 3500d, Japan) and the colour reading includes lightness (L^*), redness (a^*) and yellowness (b^*). The equipment was standardized using a white colour standard [17].

Texture analysis

The texture measurement of the chicken sausages was conducted using a computer-assisted TA-XT2i Texture Analyzer (Stable Micro Systems, UK). A compression test was used to determine hardness (g), cohesiveness (mm/mm), chewiness (g/m^3) and springiness (mm/mm). The test was carried out by using a 75 mm compression platen type probe with a 25 kg load cell at a pre-test speed of 2.00 mm/sec, test speed of 2.00 mm/sec and post-test speed of 5.00 mm/sec, a distance of 10.00 mm and auto-trigger type (5.0 g) [17].

Sensory analysis

A Hedonic test was conducted to evaluate the appearance, colour, texture, flavour, aroma and overall acceptability between the chicken sausages incorporated with different types of eggplant and against the control. A nine-point hedonic scale was used to evaluate the chicken sausages ranging from 9 (like extremely) to 1 (dislike extremely) by 30 untrained panellists [18].

Statistical analysis

Data obtained was analyzed using one-way ANOVA to identify significant differences among the means of various chicken sausages treatments using Tukey's test ($p<0.05$). The statistical program used was Minitab software, release 19 (Minitab Inc., Pennsylvania, USA). The results were expressed as means ± SD (standard deviation) of three replicates [18].

Dataset pre-processing

The distributions of (1) physicochemical properties, i.e., proximate, WHC, cooking loss, pH, colour measurement and texture values and (2) sensory properties were evaluated by developing the box and whisker plot (BWP) at a significant level (α) of 0.05 using XLSTAT-Pro (2017) statistical software (Addinsoft, Paris, France). The outlier presence of which values exceeded three times the box's height marked with a dot or '×' was evaluated to confirm the dataset variability. The BWP skewness was also examined to confirm the transformation of physicochemical and sensory properties as a whole dataset. The dataset distribution is deemed positively skewed or right-skewed when its mean value is larger than the median value, and vice versa; hence, the dataset is then subjected to transformation before correlation and principal component analyses (PCA) [19].

Correlation analysis

The correlation between the physicochemical and sensory properties was carried out using Pearson correlation to measure the strength (weak, moderate, or strong) and direction (positive and negative) of the linear relationship between two variables. In this study, the strong, weak, and moderate correlation were determined by correlation matrix (CM) value; $|0.000| < R < |0.300|$ for weak, $|0.300| < R < |0.700|$ for moderate and $|0.700| < R < |1.000|$ for strong CMs [20].

Principal component analysis

The PCA of Pearson correlation was carried out at α of 0.05 to (1) identify the variables with different factor loadings and (2) suggest the significant variables that might contribute to the formulations of chicken sausages. The dataset was transformed into smaller sets of new independent variables denoted as principal components (PCs). The cumulative variability of the PCs was examined to determine the percentage of the dataset explained in the formulations. At the same time, physicochemical properties and sensory properties variables were ranked based on their factor loadings: Strong for $FL \geq |0.750|$, moderate for $|0.500| < FL < |0.749|$ and weak for $FL \leq |0.499|$. Based on these FLs, the contribution of each physicochemical and sensory property and their intercorrelation in the formulations

were examined and further explained [20].

Results and Discussion

Proximate composition

Table 1 shows the proximate analysis of the fat-replaced chicken sausages compared to the control. There were no significant differences ($p<0.05$) between the sausages regarding the ash, moisture, protein and carbohydrate contents. Although the eggplants provide minerals such as calcium, magnesium, phosphorus, potassium, iron, copper and zinc [21], their addition to chicken sausages did not significantly increase the ash content, with fat-replaced chicken sausages containing between 1.27% w/w to 2.08% w/w ash compared to the control of 1.43% w/w. The moisture content was probably not affected due to the similar water-binding ability of the eggplants to chicken fat. The high-water retention properties of the eggplant fibres also contribute to the moisture content of the meat products [11], which is positive as fat controls moisture release from the inner layers of the meat products [21]. Cengiz and Gokoglu [23] also showed an insignificant ($p>0.05$) effect on moisture content for frankfurter-type sausages incorporated with citrus fibre and soy protein concentrate as fat replacers.

Table 1. The proximate composition of the fat-replaced chicken sausages with eggplants compared to the control with fat

Sample[1]	Ash (% w/w)	Moisture (% w/w)	Protein (% w/w)	Carbohydrate (% w/w)	Fat (% w/w)	Fat Reduced Against Original Formulation (% w/w)
Control	1.43 ± 0.07^{a}	67.62 ± 2.13^{a}	11.76 ± 0.89^{a}	3.21 ± 3.46^{a}	15.98 ± 1.42^{a}	Not related
RAE	1.75 ± 0.06^{a}	72.92 ± 2.03^{a}	12.25 ± 0.77^{a}	8.74 ± 2.00^{a}	4.34 ± 2.10^{c}	71.95 ± 15.94^{a}
PRE	1.27 ± 0.71^{a}	68.22 ± 7.96^{a}	10.89 ± 1.94^{a}	13.32 ± 7.62^{a}	6.30 ± 2.23^{c}	60.17 ± 14.77^{ab}
PE	1.68 ± 0.46^{a}	70.52 ± 2.47^{a}	11.38 ± 1.05^{a}	8.79 ± 3.46^{a}	7.64 ± 0.54^{bc}	51.78 ± 6.93^{ab}
RBE	1.69 ± 0.18^{a}	70.65 ± 1.15^{a}	11.86 ± 0.45^{a}	7.50 ± 0.37^{a}	8.30 ± 0.48^{bc}	47.61 ± 7.68^{ab}

[1]RAE: Round Asian Eggplant, PRE: Pearl Red Eggplant, PE: Pea Eggplant, RBE: Round Black Eggplant, and GTE: Green Thai Eggplant.
[a-c]Mean ± SD with different letters is significantly different (P<0.05) within the same column.

According to San José et al. [24], although protein content varies in different types of eggplants, it is generally low with not less than 1 g per 100 g. There were no significant differences in the protein content of the sausages as expected. Similarly, there was no significant effect ($P>0.05$) on the carbohydrate content of the sausages, however, the carbohydrate content of the fat-replaced chicken sausages (4.28–13.32% w/w) was higher compared to the control (3.21% w/w), most probably due to the carbohydrate content of the eggplants. Similarly, Bunmee et al., [25] also observed an increase in carbohydrate content in beef patties incorporated with purple eggplant flour. The addition of carbohydrate-based components may contribute to a higher amount of carbohydrates in meat products [26]. Nevertheless, all fat-replaced chicken sausages produced had protein (7.03–14.14%) and carbohydrate (6.69–21.59%) contents similar to various commercially available chicken sausages [27].

All fat-replaced chicken sausages had a significantly reduced fat content, except for sausages incorporated with GTE (11.47% w/w), compared to the control (15.98% w/w), with chicken sausages incorporated with RAE (4.34% w/w) and PRE (6.30% w/w) having the lowest fat content. This agreed with the previous studies by Kahar et al. [28] and Ramle et al. [18], which reported that the replacement of animal fat with plant resources can lower the fat content of meat products. These results confirmed that the use of eggplants as a fat replacer reduces the fat content of meat products except for the addition of GTE. The RAE sausages had the highest ($p<0.05$) fat reduction compared to the control (71.95% w/w), while the GTE sample was the lowest (28.25%

w/w) (Table 1). All chicken sausages incorporated with different types of eggplants had more than 25% fat reduction, so according to the Food Regulations 1985 [6], they can be claimed as fat-reduced sausages.

Water holding capacity (WHC), cooking loss, and pH

WHC indicates the ability of the chicken sausages to bind water under no influence from outside forces and determines the juiciness in conjunction with the flavour, texture, and colour of meat products [29]. Table 2 shows no significant differences ($p>0.05$) in the WHC for all the chicken sausages. The fat in the control formulation could entrap water molecules thus retaining the WHC value, and eggplants can hold the water due to their hydrophilic nature and porous texture of the fibres [30]. In addition, eggplant particles may fill the space around the protein gel matrix and bind water within which also increases the WHC [31]. The WHC data was predicted to be directly proportional to the moisture content, with a higher WHC indicating stronger development of the protein network that entraps the water within the meat products due to the enhanced intermolecular cross-linking between myofibrillar proteins and eggplant [32].

Table 2. The water holding capacity (WHC), cooking loss and pH of the fat-replaced chicken sausages with eggplants compared to the control with fat

Sample[1]	WHC (% w/w)	Cooking Loss (% w/w)	pH
Control	99.97 ± 0.03[a]	10.75 ± 1.86[a]	6.36 ± 0.03[a]
RAE	99.58 ± 0.41[a]	8.24 ± 1.73[a]	6.26 ± 0.12[ab]
PRE	99.90 ± 0.03[a]	7.21 ± 1.67[a]	6.20 ± 0.06[b]
PE	99.41 ± 0.90[a]	7.12 ± 1.52[a]	6.35 ± 0.02[ab]
RBE	99.93 ± 0.05[a]	10.00 ± 3.33[a]	6.31 ± 0.02[ab]
GTE	99.66 ± 0.49[a]	12.83 ± 2.61[a]	6.33 ± 0.02[ab]

[a-b]Mean ± SD with different letters is significantly different (P<0.05) within the same column.

Cooking loss is one of the important parameters to evaluate the quality of meat products and is defined as the percentage of weight loss due to heat treatment and cooking loss depends on the capacity of the gel matrix to immobilise fat and water in finely comminuted meat products [33]. There were no significant differences between the fat-replaced sausages compared to the control chicken sausages (Table 2). The cooking loss of the control sausages was attributed to moisture evaporation and fat leakage due to melting during cooking [34], whereas the cooking loss of the eggplants-incorporated sausages could be due to moisture loss. However, since no notable difference was observed between control and eggplant-incorporated sausages, it can be concluded that not much fat was released from the control sausages, while the eggplants used in this study had water retaining ability during cooking similar to the fat. Nevertheless, the GTE and RBE sausages both had high cooking losses near to the control's value, most probably due to the high-fat content as reported in Table 1. Cooking loss can be an indicator of the WHC of meat products that are mostly influenced by factors such as moisture, fat, protein content and processing methods (heating, cutting, grinding) [35, 36] and is supported by the cooking loss and WHC results, where both showed no significant difference among the chicken sausages. Through hydrogen bonding, the WHC of the myofibrillar protein improves promoting emulsion stability which contributes to the reduced cooking loss of low-fat sausages [31].

No significant difference in pH was observed between the control and all chicken sausages, except for the sausages incorporated with PRE. This indicated that eggplants did not affect the acidity of the sausages and eventually would not influence the taste. Various studies have shown that the replacement of fat with plant-based ingredients did not have a notable effect on the pH of meat products. For example, Das et al., [37] reported that the pH of the meat product was not significantly

affected by the addition of soy protein. The addition of other proteins like gelatin in low-fat sausages also did not affect the pH value of the low-fat sausages [38].

Colour and texture properties

Colour is an extrinsic factor that influences customer satisfaction and preferences for meat products [39]. Colour variation can result from the protein-fat interactions, structural proteins and the homogeneity of the cut surface [40]. The colour of the chicken sausages was significantly affected by the addition of different types of eggplant as the fat replacer (Table 3). The lightness (L^*) decreased significantly compared to the control, in line with the results reported by Park et al. [41]. The colour change may be caused by the hydration of the additional dietary fibre (hydrocolloids) as the added fibres were mostly white or egg-coloured [42]. According to Dingstad et al. [43], at least 60 per cent of consumers are willing to purchase sausages when the L^* value was between 62.3 and 68.5. The chicken sausages did not achieve the desired lightness and even become darker after heating, but the L^* values were in the range of commercial chicken sausages (44.42–65.54) [27] with RAE and PRE being most similar to the control. The other darker chicken sausages were influenced by the colour of the eggplant.

In terms of the redness (a^*) and yellowness (b^*), only PE showed a significantly lower value compared to the control, indicating that most eggplants used did not reduce the red colour and alter the yellowness of the chicken sausages. The redness (a^*) of meat products results from the presence of several heme proteins, haemoglobin and myoglobin in the meat and the red colour is the main attribute of meat products [44]. The degree of redness is the general metric used to indicate the freshness of meat and meat products, and meat sausages with higher a^* values usually are more attractive to consumers and have the best market approval rate [45]. Meanwhile, the yellow colour intensity could increase if the fat in sausages was replaced with yellow-coloured plants [46]. Thus, this showed that the colour characteristics of all the eggplants gave yellowness (b^*) values close to the control chicken sausage except for PE. To conclude, most of the eggplants used as the fat replacer did not alter the colour of the chicken sausages, especially RAE and PRE with lightness, redness and yellowness values similar to the control.

Table 3. The colour (L^*, a^*, b^*) and texture properties of the fat-replaced chicken sausages with eggplants compared to the control with fat

Sample[1]	Colour Measurements			Texture Properties			
	Lightness (L^*)	Redness (a^*)	Yellowness (b^*)	Hardness (g)	Springiness (mm/mm)	Cohesiveness (mm/mm)	Chewiness (g/m^3)
Control	55.14 ± 0.87^{a}	2.63 ± 0.16^{ab}	14.30 ± 0.67^{b}	10418 ± 1539^{b}	0.92 ± 0.02^{a}	0.40 ± 0.02^{a}	3835 ± 799^{b}
RAE	53.11 ± 0.37^{ab}	2.45 ± 0.11^{b}	13.20 ± 0.61^{b}	14998 ± 1286^{ab}	0.91 ± 0.02^{a}	0.39 ± 0.04^{a}	5269 ± 301^{ab}
PRE	53.05 ± 0.66^{ab}	2.69 ± 0.01^{ab}	13.55 ± 0.37^{b}	15654 ± 2706^{a}	0.90 ± 0.02^{a}	0.44 ± 0.02^{a}	6260 ± 1243^{a}

The texture of meat products often influences consumer preference. Table 3 shows the texture properties of the fat-replaced chicken sausages with eggplants against the control. Among the five different types of eggplants used, PRE-fat-replaced chicken sausage had significantly ($p<0.05$) high hardness (15654 g) and chewiness (6260 g/m^3) values compared to control, with no significant differences observed in both the hardness and chewiness of the other chicken sausages compared to the control. A similar result was found by Choe and Kim [47] that the addition of wheat fibre mixture increased the hardness of chicken sausages. Other studies also reported that the replacement of fat with various types of fibres increased the hardness of other

types of meat products [48, 49]. The meat proteins used in fat encapsulation were reduced when fat replacers were used to replace animal fat, thus more meat proteins should be utilised through the gel structure of the meat matrix to achieve an acceptable texture [50]. These changes in textural properties may be due to dietary fibre, which can bind water and absorb fat [5]. In addition, reducing the fat could lead to increased hardness and chewiness [49].

There were no significant differences in the springiness and cohesiveness of all the chicken sausages which indicates that the replacement of animal fat with different types of eggplants gave the same springiness and cohesiveness to the final products. Similar results were obtained by Choi et al. [51], for reduced fat chicken sausage containing brewer's spent grain dietary fibre with no significant difference in the value of cohesiveness among all the samples. To summarise, the eggplants did not change the textural properties of the fat-replaced chicken sausages compared to the control except for the PRE.

Sensory properties

Table 4 summarises the sensory analysis of the chicken sausage with different types of eggplant used as the fat replacer. The sensory attributes were appearance, colour, texture, flavour, aroma and overall acceptability and all play important roles in consumer preferences to determine the palatability of food products [39]. The panellists rated the PE chicken sausages the lowest compared to the other fat-treated chicken sausages and control, with the other fat-replaced chicken sausages scoring similarly to the control. These results agree with that obtained by Ammar [11], which indicates that the addition of eggplant pulp powder did not affect the sensory scores of chicken meat nuggets compared to the control. These results also suggested that there was no decrementing effect on the sensory properties of chicken sausages after the addition of different types of eggplants except for PE. This is a very important characteristic since additional ingredients could negatively affect the sensory properties of meat products owing to their strong taste and flavour [46], thus changing the attractiveness of food and affecting consumer choice [51].

Table 4. Sensory properties of the fat-replaced chicken sausages with eggplants compared to the control with fat

Correlation of physicochemical and sensory properties

Figure 1 (a) and 1 (b) depict the BWP of the physicochemical and sensory properties of the chicken sausages. Among the variables, carbohydrate, moisture, ash, WHC, cooking loss, pH, *a**, chewiness, cohesiveness, overall acceptability, aroma, flavour, texture, and appearance had outliers marked with a dot or (×), which indicated high variability within the dataset. The plus (+) sign in Figure 1 (a) and Figure 1 (b) indicates the mean value for each variable, where only ash, cooking loss, chewiness, cohesiveness, aroma and colour had a similar mean value compared to the median, indicating low or no skewness of the dataset distribution. Other variables showed right and left skewnesses in their dataset distribution, hence, they were transformed before correlation analysis.

The Pearson correlation test was used to determine correlations between two variables, i.e., the physicochemical and sensory properties (Table 5). The correlation matrix (CM) investigated the strength (weak, moderate, or strong) and direction (positive and negative) of the linear relationship between these two variables. Positive and negative correlations between two variables at $|0.700| < R < |1.000|$ indicated strong CM, $|0.300| < R < |0.700|$ for moderate CM and $3|0.000| < R < |0.300|$ for weak CM. From Table 5, hardness and chewiness had eight strong and moderate CMs followed by *a**, *b**, cooking loss, carbohydrate with seven, and pH, fat, and fat reduction with six strong and moderate CMs. All sensory evaluation variables had five overall strong and moderate CMs. Among these variables, several two matched variables had positive and strong CMs., e.g., hardness and chewiness (R = 0.92), flavour and overall acceptability (R = 0.85), appearance and colour (R = 0.77), cooking loss and springiness (R = 0.73), and carbohydrate and fat reduction (R = 0.70), which denoted that these variables had a proportional relationship to each other.

The positive correlation between hardness and chewiness is similar to a study by Varga-Visi et al. [53], which indicated that there was a strong CM between hardness and chewiness of low-fat turkey sausages. In addition, this result was also supported by De Angelis et al. [54] and is probably due to the addition of the fat replacer which contains fibre which increases the hardness and chewiness of the product [55]. The positive correlation between appearance and colour might be explained by the panellists rating the appearance based on the colour of the chicken sausages, which is supported by the sensory properties results tabulated in Table 4, which shows that PE scored the lowest value for both appearance and colour. A positive correlation between flavour and overall acceptability aligned with the results obtained by Andersen et al. [56], which explained that flavour is the main factor to determine product acceptability. The polymers present in the fat replacer might limit water mobility and inhibit water release during cooking, thus, affecting the texture profile analysis which includes the springiness of the meat product [57]. Furthermore, Garcia-Santos et al. [58] also showed that carbohydrate content significantly affects the fat reduction of sausage.

Fat and fat reduction (R = -0.99), pH and carbohydrate (R = -0.72) and fat and carbohydrate (R = -0.72) were negatively and strongly correlated indicating that these variables had an inverse proportional relationship. Jin et al. [59] showed that there are no significant changes in the pH in Pearson's correlation test on emulsion-type pork sausages. Generally, the pH of the meat product is affected by both the raw meat and the additives [60]. The incorporation of starch significantly decreases the fat percentage of emulsion-type sausage, and these ingredients may be able to replace the voids created by the reduced fat and give more high-molecular carbohydrates to the emulsion-type sausage [61]. Although these variables rendered strong and moderate CMs, the CM value only explained the correlation between two variables [20], so PCA was performed [62].

Association of the physicochemical and sensory properties of the chicken sausages

The PCA was performed to identify (1) variables with different factor loadings and (2) significant variables that might contribute to the formulation of the chicken sausages. Table 6 shows the factor loading (FL) of each variable in their respective principal component (PC). The number of PCs generated was based on the number of variables, and as the number of PC increased, the eigenvalue (EV) and dataset variability (DV) decreased, while cumulative explained variability (CEV) increased. This was evident as PC1 had the highest EV and DV and the lowest CEV. The increment of PC numbers indicated that more variables explained the dataset in this study,

hence, all physicochemical and sensory properties variables were explained until PC5. However, among these variables, those with strong (FL ≥ |0.750|) and moderate (|0.500| < FL < |0.749|) FL were the significant variables that explained the formulation of chicken sausages.

Table 6. Factor loading of variables in principal components (PCs) for the formulation of the reduced fat-chicken sausages

Variables	Factor Loading (FL)[1,2]

[1]*FL ≥ |0.750| = strong factor loading and |0.500| < FL < |0.749| = moderate factor loading*

[2]*Factor loading with bold value indicated strong and moderate factor loading in the principal component*

Chewiness (FL = 0.7965), hardness (FL = 0.7659), fat reduction (FL = 0.7681), fat (FL = -0.7573), carbohydrate (FL = 0.7015), overall acceptability (FL = -0.6089), flavour (FL = -0.5969), cooking loss (FL = -0.5600) and a* (FL = -0.5383) had strong and moderate FL in PC1 (Table 6). Texture with an FL value of -0.4904 was considered moderate FL since the FL value was nearer to |0.500|. Variables with the same positive or negative signs were positively correlated. For instance, chewiness, hardness, fat reduction, and carbohydrate were positively correlated, while fat, overall acceptability, flavour, cooking loss, *a** and texture had a similar correlation. Meanwhile, the chewiness, hardness, fat reduction, and carbohydrate had negative correlations to the latter, as shown in Figure 2(a), where chewiness, hardness, fat reduction, and carbohydrate are located nearer to each other, and the fat, overall acceptability, flavour, cooking loss, *a** and texture

resided in the opposite direction. Accordingly, it is proposed that chewiness, hardness, and carbohydrate content negatively affect the overall acceptability, flavour and texture of the RAE formulated sausages since these variables fell in the RAE group in Figure 2(b). Also, the fat content and *a** value related to the redness of the sausages rendered a positive effect on the overall acceptability and flavour of the GTE formulated sausages in Figure 2(b).

In PC2, the overall acceptability (FL = 0.6591), pH (FL = -0.6572), b* (FL = -0.6133), flavour (0.5931), appearance (FL = 0.5686), colour (FL= 0.5443), and aroma (FL= 0.5307) had strong and moderate FL. Likewise, these variables were positively correlated with (1) overall acceptability, flavour, appearance, colour and aroma, and (2) pH and *b**, while (1) and (2) were negatively correlated to each other. These correlations indicated that pH and *b** value of the sausages negatively affected the overall acceptability, flavour, appearance, colour and aroma (Figure 2a), especially in PE sausages and controls (Figure 2b). Moreover, the RAE and RBE formulations had the best overall acceptability, flavour, appearance, and colour since these variables were located in the RAE and RBE groups. No correlation was present for all variables in PC1 and PC2 since they were located at 90° in Figure 2(a). However, the overall acceptability had moderate FL in both PC1 and PC2.

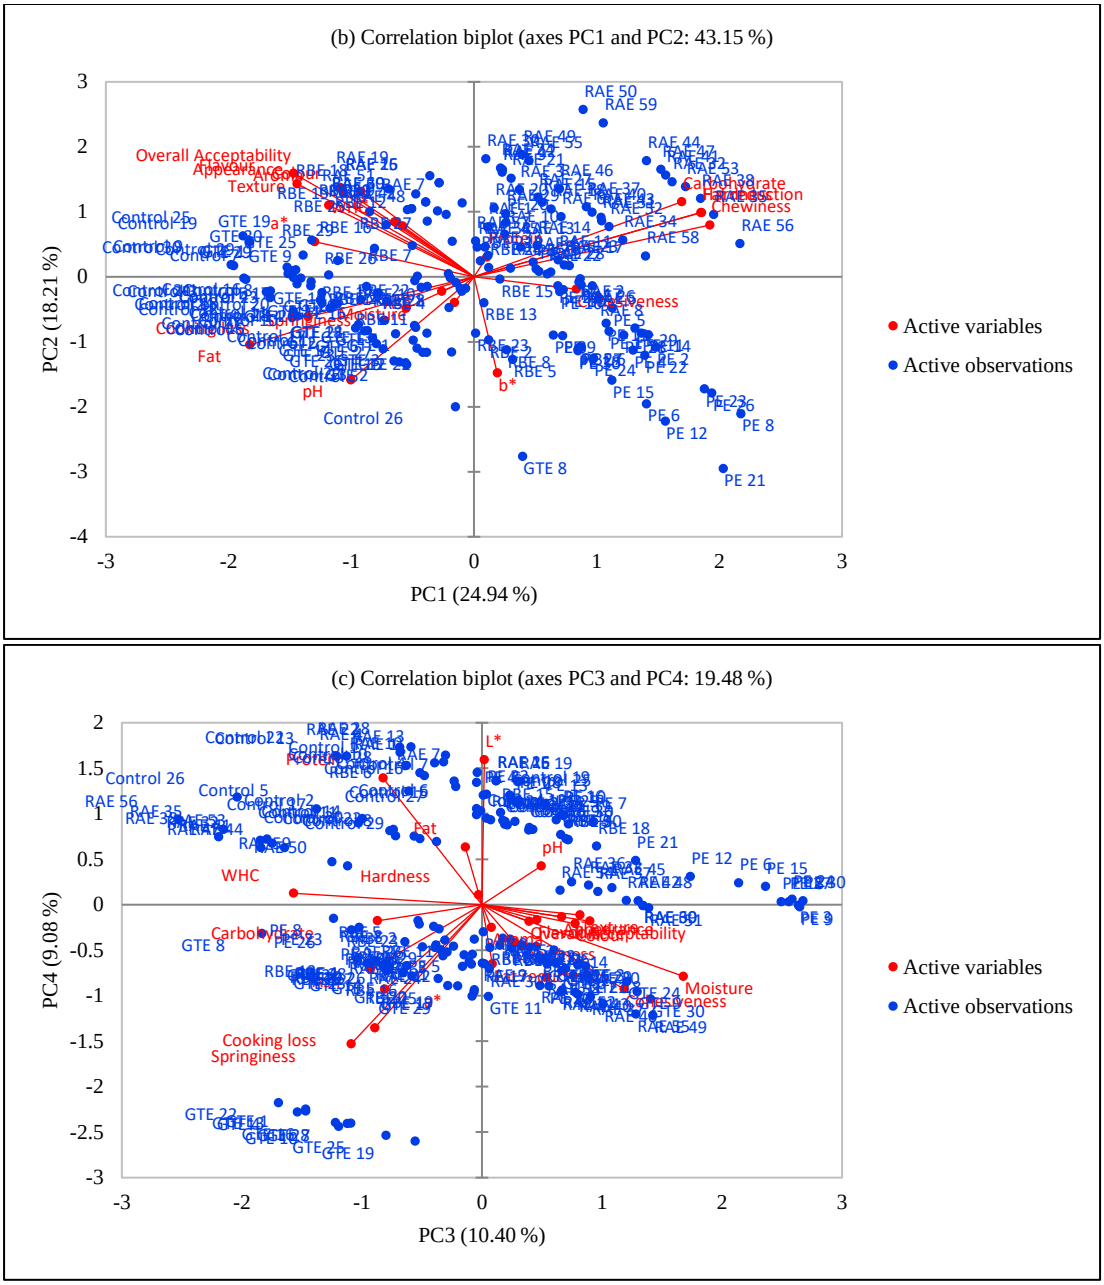

Figure 2. (a) Variable plot (PC1 and PC2), (b) correlation biplot of (PC1 and PC2) and (c) correlation biplot of (PC3 and PC4) of variables and formulations of reduced-fat-chicken sausage

WHC (FL = -0.6157) and moisture (FL=0.6587) in PC3 were negatively correlated while springiness (FL = -0.6014) and cooking loss (FL = -0.5317) in PC4 were positively correlated. Similarly, *L** (FL = 0.6245) and protein (FL = 0.5457) in PC4 were positively correlated. The WHC and moisture were dominant in RAE and GTE, respectively, while both springiness and cooking loss were dominant in GTE (Figure 2(c)). Figure 2(c) also depicted that both the *L** value and protein were dominant in the control, RAE and PE. The cohesiveness did not achieve moderate or strong FL, while ash was only found in PC5, indicating they were very unlikely to

affect the formulation. Nevertheless, although some variables in PC3, PC4 and PC5 had strong and moderate FL, they played less important roles in dictating their influences on the sensory evaluation since they were present in higher PC numbers with low DV. Based on the PCA, overall, the panellists rated the chicken sausages based on the most discriminant variables, which were the fat content (4.34% ± 2.10), *a** value (3.21 ± 0.29), pH (6.35 ± 0.02), *b** value (15.88 ± 0.65). The RAE sample was positively selected due to its low-fat content and high *a** value, while the PE sample was less preferred due to its high pH and *b** values.

Conclusion

In conclusion, the incorporation of eggplants as fat replacers in chicken sausages' production can be considered a successful strategy. Despite many positive results of the majority of the eggplants, three types of eggplants; the Round Asian Eggplant (RAE), Pearl Red Eggplant (PRE) and Pea Eggplants (PE) had lower fat values compared to the control, and therefore, can be claimed as reduced-fat meat products. Further analysis using the principal component analysis, the panellists were influenced to positively rate the sample with the lowest fat content and high *a** value, which represents the RAE sample while rejecting the PE sample due to high pH and *b** values. Therefore, based on the overall result, Round Asian Eggplant (RAE) can be considered the best eggplant type with the highest potential to be used as a fat replacer in the production of reduced-fat chicken sausages.

Abstract

The formed β-cyclodextrin- angelwing complexes were characterized using Fourier transform infrared spectrometry (FTIR) and sodium dodecyl sulfate-polyacrylamide electrophoresis (SDS-PAGE) to mask the bitterness of angelwing clam protein hydrolysate. The shift of O-H stretching to a lower wavenumber and the reduction of the intensity of band C=O and C-H indicated the formation of β-cyclodextrin- angelwing clam hydrolysate complexes. SDS-PAGE analysis showed a lower number of band distributions, revealing the effects of β-cyclodextrin on the mobility of protein during gel electrophoresis. The physicochemical properties of angelwing clam hydrolysate (BH), kneading method hydrolysate (KMH), and physical mixture hydrolysate (PMH) were studied. When compared to functional properties, BH outperformed KMH and PMH. Meanwhile, KMH and PMH showed a higher water holding capacity and a lower oil holding capacity than BH. While the solubility, foaming properties and emulsifying properties of KMH and PMH were lower than BH, the values were still comparable with others of higher sources of protein hydrolysate. Therefore, KMH and PMH can be one of recent potential functional food ingredients.

Keywords: physicochemical analysis, functional properties, angelwing clam, β-cyclodextrin, inclusion complex

Abstrak

β-siklodekstrin-mentarang-hidrolisat kompleks yang terbentuk dicirikan menggunakan spektrometer transformasi inframerah Fourier (FTIR) dan elektroforesis gel poliakrilamida-sodium dodekil sulfat (SDS-PAGE). Peralihan peregangan bilangan gelombang O-H yang lebih rendah dan pengurangan intensiti pada gelombang C=O dan C-H menunjukkan pembentukan kompleks hidrolisat β-siklodekstrin-mentarang hidrolisat. Analisis SDS-PAGE menunjukkan jumlah pengedaran bilangan jalur yang lebih rendah membuktikan pengaruh β-siklodekstrin pada pergerakan protein dalam elektroforesis gel. Sifat fizikokimia mentarang hidrolisat (BH), Kaedah menguli hidrolisat (KMH) dan campuran fizikal hidrolisat (PMH) telah dikaji. Dalam membezakan ciri-ciri fungsi, BH menunjukkan ciri-ciri fungsi yang lebih baik daripada KMH dan PMH. KMH dan PMH menunjukkan daya tahan air yang lebih tinggi dan daya tahan minyak yang lebih rendah berbanding BH. Keterlarutan, sifat berbuih dan sifat pengemulsi KMH dan PMH adalah lebih rendah daripada BH, walaubagaimanapun nilainya masih boleh dibandingkan dengan sumber hidrolisat protein yang tinggi. KMH dan PMH dianggap sebagai salah satu potensi ramuan makanan.

Kata kunci: analisis fizikokimia, sifat kefungsian, mentarang, β-siklodekstrin, kemasukan kompleks

Introduction

Cyclodextrin molecules are cyclic oligosaccharides referred to as α, β, γ-cyclodextrin. They are composed of six, seven, and eight glucopyranose units, respectively linked by -1,4 linkage. Alpha cyclodextrin typically forms a complex with low molecular weight molecules and a compound with an aliphatic side chain. While γ-cyclodextrin can accommodate larger molecules such as steroids, the cost is expensive. β-cyclodextrin is the most accessible, cheap, and effective, as well as its cavity size is suitable for a wide range of guest molecules [1, 2]. Previous studies reported that among various flavor encapsulation techniques, molecular inclusions in β-cyclodextrin molecules are the most effective [1, 3]. Different types of guest molecules such as drugs, steroids, ionic liquids, and dyes have been used as host and guest interactions with β- cyclodextrin to change the properties of the guest molecules into the desired form. However, there is a lack of studies involved in the interactions of host and guest molecules between β-cyclodextrin and protein hydrolysates. Protein hydrolysates have been used for various purposes in foods such as flavor enhancers, protein supplements, and beverage stabilizers [4]. According to previous research, angelwing clam hydrolysate has the potential to be a good source of food ingredients because it consists of high protein content at 74.41%, low fat content at 3.43%, and high total essential amino acids, ranging from 32.94% to 54.17% [5].

Since the protein hydrolysate produced from angelwing clam species has a bitter flavor, its application for human consumption is limited [6]. Therefore, the study of inclusion complexes between β-cyclodextrin and angelwing clam protein hydrolysate is essential to mask the bitter taste. The inclusion complex of these host and guest systems occurred through various interactions such as hydrogen bonding, van der walls interaction, hydrophobic interactions, and electrostatic attraction, all of which alter the photochemical and photophysical properties of the guest molecules [7]. Thus, the physical, chemical, and biochemical properties of guest molecules will be changed [2]. The inclusion of cyclodextrins exerts a profound effect on the physicochemical properties of guest molecules [8]. However, it is still unknown whether entrapment in the internal cavity of β-cyclodextrins could affect their physicochemical properties since there is no information regarding the physicochemical properties of complex formation between protein hydrolysate and β-cyclodextrins. Thus, the current study focused on determining the characteristics and the effects of protein hydrolysate on its physical and chemical properties after forming a complex with β-cyclodextrin.

Materials and Methods

Materials

Angelwing clams were purchased from Pantai Remis, Selangor, Malaysia. The clams were placed on ice and transported to the laboratory. Upon arrival, the clams were washed and their flesh was separated manually before they were then stored at -20°C prior to further processing. Meanwhile, bromelain (1.5 AU/g) was obtained from Novozymes Sdn. Bhd., Malaysia and stored at 4°C until further used.

Preparation of angelwing clam hydrolysates

Angelwing clam hydrolysate was prepared according to the method described by Normah and Nurul Fasihah (2014). 500 grams of angelwing clam flesh was mixed with 531.33 mL of distilled water and then minced in a blender [5]. The mixture was transferred into 1 L beaker, then placed in a water bath. The water bath was set at 45°C and the pH of the mixture was adjusted to 6 using 1.0 N NaOH or 1.0 N HCl. Once the temperature and pH were constant, bromelain (enzyme substrate ratio of 3%) was added and hydrolysis was performed for two hours. The mixture was continuously stirred at the speed of 200 rpm using a stirring propeller. The pH was kept constant throughout the hydrolysis by the addition of 1.0 N NaOH. At the end of the hydrolysis, the reaction was terminated by heating the mixture at 90 ºC for 15 minutes in a water bath. Then, the mixture was centrifuged (Hettich ZENTRIFUGEN, UNIVERSAL 320R) at 10000 rpm and 4 ºC for 20 minutes. The supernatant was collected and freeze dried using biomedical freeze dryer (Alpha 1-4, Martin Christ). The resulting hydrolysate was named as Angelwing clam hydrolysate (BH).

Preparation of angelwing clam hydrolysate –β-cyclodextrin complexes

Angelwing clam hydrolysate and β-cyclodextrin were mixed in a ratio of 1:0.8 (v/w) using the following methods:

Physical mixing method

For the physical mixing method, the hydrolysate was prepared according to the procedure mentioned earlier, except that β-cyclodextrin was added to the supernatant at a ratio of 1:0.8 (v/w) at a temperature of 38.5±1 °C. The mixture was consistently agitated at 150 rpm for 12 minutes using an incubator shaker (Innova 4080 INCUBATOR SHAKER, United States). The product was then freeze dried using biomedical freeze dryer (Alpha 1-4, Martin Christ) [3]. The resulting hydrolysate was named as physical mixed hydrolysate (PMH).

Kneading method

The procedure for physical method was imitated. However, after agitation, the sample was placed in a mortar and grounded for 45 minutes. The product was freeze dried. The resulting hydrolysate was named as kneaded method hydrolysate (KMH).

Characterization

Angelwing clam hydrolysate- β-cyclodextrin were characterized using Fourier transform infrared spectroscopy (FTIR) and sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE).

Fourier Transform Infrared spectroscopy

The functional group analysis was performed using FTIR (Avatar 360, Thermo Nicolet, USA) as according to Normah and Nurul Fasihah [9]. The sample was ground in an agate mortar until the particle size was measured approximately at 2.5 micron and the surface of the solid appeared shiny. 0.08 g of powdered potassium bromide (KBr) was added into the mixture and grounded for about 30 seconds. The mixture was scraped into the middle and grounded for another 15 seconds. The sample and KBr should be finely grounded to avoid the mixture from scattering infrared radiation excessively. The mixture was then placed in an evacuable mold and subjected to a pressure of 10 to 20 MPa. Perkin Elmer spectrum software was used to control the spectrometer and data were collected over the wavenumber range 4000-400 cm^{-1} with a resolution of 4 cm^{-1} and collection spectra of 16.

Sodium dodecyl sulfate polyacrylamide gel electrophoresis

One gram of hydrolysate was mixed with 10 ml deionized water and filtered using a membrane filter with a pore size of 0.45 µm. 6.5 µL of the solution was then mixed with 2.5 µL NuPAGE®LDS sample buffer (4X) and 1 µL NuPAGE® Reducing Agent (10X). The mixture was heated at 70 ºC for 10 minutes. 15 µL sample was loaded into each well of the SDS-PAGE system each comprised of a 12% resolving gel and a 5% stacking gel. Benchmark™ protein ladder with the range of 220 to 10 kDa was used as a marker. Electrophoresis was performed using the XCell Surelock electrophoresis cell (Bio-Rad Laboratories, Hercules, CA, USA). Electrophoresis was run for 50 minutes at 100-125 mA/gel. After the running process, the gels were washed with 100 mL of ultrapure water and were stained with Coomassie Brilliant Blue dye**.**

Solubility

Solubility, in this study, was determined according to the method by Klompong et al. [10]. A total of two hundred milligrams of samples were dispersed in 20 ml of deionized water, and the mixture's pH was adjusted between pH 2 and 10. The mixture was stirred at room temperature for 30 minutes and centrifuged at 7500 ×g for 15 minutes (5420, KUBOTA, JAPAN). The protein content of each supernatant was determined using Kjedhal (Vapodest 50s, Gerhardt, Germany). The following equation was used to calculate the nitrogen solubility index (NSI):

$$\text{NSI (\%)} = \frac{\text{Protein content in supernatant}}{\text{Total protein in sample}} \text{ x } 100 \quad (1)$$

Water holding capacity

The water holding capacity (WHC) was determined using the method outlined by Diniz and Martin [11]. Triplicate samples (0.5 g) were analyzed. Each sample was dissolved in 10 ml of distilled water in centrifuged tube and vortexes for 30 seconds. The dispersions were allowed to stand at room temperature for 30 minutes, and then centrifuged at 2800 ×g for 25 minutes (5420, KUBOTA, JAPAN). The supernatant was filtered, and the volume was accurately measured. The difference between the initial volumes of distilled water added to the protein sample and the supernatant volume was retrieved. The result was reported as the amount of water absorbed per gram (g) of protein hydrolysate in milliliter (mL).

Oil holding capacity

The oil holding capacity (OHC) was determined using the method described by Shahidi et al. with a slight modification. A 10 mL of soybean oil was added to 500 mg samples into a centrifuge tube [12]. The mixture was centrifuged for 25 minutes in 3800 ×g (5420, KUBOTA, JAPAN). The amount of oil absorption was determined by measuring the volume of oil before centrifugation and the amount of oil supernatant after centrifugation. The analysis was done in triplicate.

$$\text{OHC (mg/mL)} = \text{volume before centrifuge (mg/mL)} - \text{volume of supernatant (mg/mL)} \quad (2)$$

Emulsifying properties

The emulsifying activity index (EAI) and the emulsion stability index (ESI) were determined using the method described by Klompong et al. (2007) with a slight modification [10]. A total of 300 milligrams of sample was dissolved in 30 ml of deionized water. The solution was then mixed with 10 ml sunflower oil, and the pH was adjusted between 2 and 10. The mixture was homogenized (IKA T25 digital ULTRA-TURRAX) at the speed of 14000 rpm for 1 minute. 15 µl of aliquot emulsion was pipetted from the bottom of the container at 0 and 10 minutes after homogenization. After that, the sample was then mixed with 5 ml of 0.1 % sodium dodecyl sulphate solution. The absorbance of the diluted solution was measured at 500 nm using a UV-VIS spectrophotometer (Perkin Elmer Instrument Lambda 35, USA). This data calculated EAI and ESI using the following equation:

$$\text{EAI } (m^2/g) = (2 \text{ x } 2.303 \text{ x } A_{500})/(0.25 \text{ x protein weight (g)}) \quad (3)$$

where; A_{500} = the absorbance at 500 nm.

$$ESI \text{ (min)} = A_0 \, x \, \Delta t \, / \Delta A \quad (4)$$

Where; $\Delta A = A_0 - A_{10}$,

$\Delta t = 10 \, min, A_0$ is the absorbance at zero min and A10 is the absorbance at 10 min, at 500nm.

Foaming properties

Foaming capacity and stability of hydrolysate were measured using the method of Sathe and Salunkhe [13]. A set of 3-gram samples were dissolved in 100 ml of distilled water, with its pH was adjusted between 2 and 10. The protein solution was whipped at 16000 rpm for 3 minutes using a homogenizer (IKA T25 digital ULTRA-TURRAX) and poured into a 100 ml graduated cylinder. The total sample volume was taken at 0 minutes for foam capacity, and up to 60 minutes for foam stability. Foam capacity and stability were then calculated using the equation below:

$$\text{Foam capacity (\%)} = [(A - B)/B] \text{ x } 100$$

Where; A = the volume after whipping (mL) at 0 min and B = the volume before whipping (mL) at 0 min.

$$\text{Foam stability (\%)} = [(A - B)/B] \times 100$$

Where; A = the volume after standing (mlL) at 60 min and B = the volume before whipping (mL).

Statistical analysis

The data were analyzed using Analysis of Variance (ANOVA) to determine statistical significance at the 5% level. The Duncan Multiple Range Test (DMRT) was used to identify mean differences. Statistical analysis was performed using the Statistical Package for Social Science (IBM SPSS Statistics for Windows, Version 20.0. [14].

Results and Discussion

Fourier transform infrared spectroscopy

The complexation of Angelwing clam hydrolysate (BH) and β-cyclodextrin was investigated using FTIR. The formation of a complex between the mixture of β-cyclodextrin and BH is desired to gain a better product with a less bitter taste. As illustrated in Figure 1, the O-H stretching vibration of all samples exhibited a different profile. The peak of KMH and PMH were 3368.04 cm^{-1} and 3370.62 cm^{-1}, respectively, meanwhile β-cyclodextrin and BH were at 3400.70 cm^{-1} and 3375.25 cm^{-1}, respectively. The broad hydroxyl (O-H) peak shown in β-cyclodextrin indicated that β-cyclodextrin contained water molecules. However, it was found that this pattern was narrowed in the complexes of KMH and PMH, showing that this pattern gave a good indication of the formation of the inclusion complex. This study is in line with the study by Crupi et al., who observed a decrease in the frequencies of O-H bands during the formation of inclusion complexes, indicating a reduction of water molecules in the cyclodextrin cavity due to the entrance of guest molecules inside the cavity [15]. However, BH showed high frequencies at 3375.25 cm^{-1}. This is probably because the protein contents in BH have a high amount of hydrogen bonds formed between dipolar groups of carboxylic acid and amide [16].

The stretching regions of the C=O group can be found approximately 1650 cm^{-1} to 1540 cm^{-1}. As shown in Figure 1, the frequencies of β-cyclodextrin and BH were at 1647.33 cm^{-1} and 1640 cm^{-1}, respectively. KMH and PMH showed lower frequencies compared to their BH at 1642.01cm^{-1} and 1643.11 cm^{-1}, respectively. The intensity of this band appeared to be reduced, indicating that the carbonyl group was used for complexation.

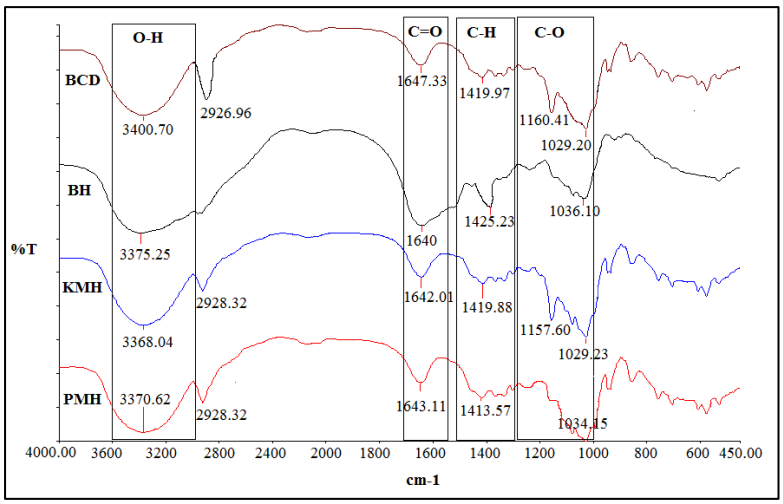

Figure 1. FTIR spectrums of (BCD) β-cyclodextrin, (BH) angelwing clam hydrolysate, (KMH) kneaded method hydrolysate and physical mixed hydrolysate (PMH)

The stretching region of alkane (C-H) were found between 1300 cm^{-1} and 1512 cm^{-1}. The wavenumbers for BH and β-cyclodextrin were 1425.23 cm^{-1} and 1419.97 cm^{-1}, respectively. While KMH and PMH had the peak frequencies at 1419.88 cm^{-1} and 1413.57 cm^{-1}, respectively. The intensity of this band appeared to be reduced for KMH and PMH. Thus, this indicated that the C-H group was also used in the complexation process.

The spectrums within the range of 1160 cm^{-1} to 1020 cm^{-1} were associated with the C-O stretching peaks. It can be seen in β-cyclodextrin and BH at frequencies of 1029.20 cm^{-1} and 1036.10 cm^{-1}, respectively. KMH and PMH peaks had lower frequencies compared to BH at 1029.23 cm^{-1} and 1034.15 cm^{-1}, respectively. The frequencies of modified hydrolysate and its constituent molecule showed a declining pattern, indicating the formation of an inclusion complex. The lower frequencies of KMH and PMH compared to BH were due to the new formation of intermolecular hydrogen bonding, which weakened the strength of interatomic C-O bonds [15]. Thus, C-O stretching of KMH and PMH is shifted to a lower wavenumber than BH [2].

The same pattern as for KMH and PMH in FTIR spectrum analysis reveals the formation of an inclusion complex between BH and β-cyclodextrin. However, the current study was insufficient to determine which method was better. Even though the patterns in the spectrum of KMH and PMH were similar, kneading is a more effective method for forming complexes between angelwing clam hydrolysate and β-cyclodextrin than physical mixing. This is supported by previous research which demonstrated that the morphology of BH- β-cyclodextrin complex was more distinct in KMH rather than PMH [6]. Although the FESEM image of the PMH confirmed the presence of crystalline hydrolysate, BH particles were observed either partially mixed or loosely adhered to the surface of β-cyclodextrin. On the contrary, a drastic change was observed in the morphology of BH and β-cyclodextrin in KMH complex, with both molecules losing their original shape [6].

Sodium dodecyl sulfate polyacrylamide gel electrophoresis

Figure 2 shows the SDS-PAGE patterns for Flesh, BH, KMH and PMH. There was a noticeable difference in SDS-PAGE profiles between samples. Following electrophoresis, BH showed more than eleven subunits at 160 kDa, 90 kDa, 80 kDa, 70 kDa, 50 kDa, 40 kDa, 30 kDa, 25 kDa, 20 kDa, 15 kDa, 10 kDa and <10 kDa. Whereas KMH showed only two subunits at 70 kDa and 60 kDa. Meanwhile, PMH showed more than three subunits at 50 kDa, 20 kDa and <10 kDa (see Figure 2). BH showed many bands distributions at lower molecular weights, which indicated the presence of hydrophobic peptides due to the high hydrophobic of proteins. This is bound to more SDS reagent and thus a faster migration in polyacrylamide gels [17]. However, KMH and PMH had the least bands distributions at lower molecular weights. This is the effect of inclusion complex formed by the hydrophobic peptide inserted into β-cyclodextrin cavity, which then reduced the denaturation effect on protein by SDS reagent.

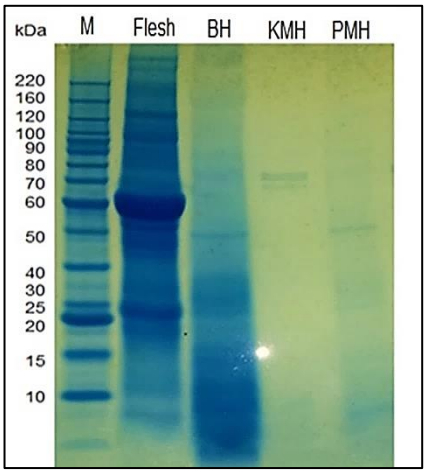

Figure 2. Molecular weight distribution of angelwing clam hydrolysate (BH), hydrolysate from kneading method (KMH) hydrolysate from physical mixing method (PMH)

The difference in SDS-PAGE profiles between samples also revealed the formation of the inclusion complex in KMH and PMH. Different bands distribution in Figure 2 shows that β-cyclodextrin influenced the mobility of proteins in polyacrylamide gel electrophoresis. The

least band presented in KMH indicated the low fragmentation of protein by anionic surfactant of sodium dodecyl sulfate (SDS). This is attributed to that β-cyclodextrin groups were possibly grafted covalently onto the surface of proteins and formed intramolecular inclusion complexes with nearby hydrophobic residues of the protein, thus reducing the denaturation of protein [18]. This study also corroborated with Rozema and Gellman, who found that β-cyclodextrin is one of the carbohydrate molecules that is known to stabilize protein folding and function as an artificial chaperone that refolds protein structure and inhibits aggregation [19].

Solubility

The pH-solubility profiles of BH, KMH and PMH proteins are shown in Figure 3. It was found that the protein solubility of BH, KMH and PMH in water at different pH (pH 2 to pH 10) showed the same pattern curve. Protein solubility of BH, KMH and PMH were significantly different ($p < 0.05$) and soluble over a wide pH range with a solubility of greater than 50%. BH, KMH and PMH presented minimum protein solubility at pH 4 with values of 86.03%, 65.27% and 70.79%, respectively, and a maximum protein solubility at pH 10 with values of 99.02%, 70.33% and 82.28%, respectively. This indicates that in general, protein's solubility decreases as the pH increases until it reaches the isoelectric points and then increases [20]. Proteins are amphoteric molecules, which means that when exposed to an acidic medium at pH lower than their isoelectric point, they behave as positive ions and repel each other, resulting in their good dispersity. ON the other hand, as the pH value approaches the isoelectric point, solubility decreases. Similarly in alkaline solutions, at pH values higher than the isoelectric point, protein molecules transform into negative ions, increasing their solubility [21]. However, not all protein hydrolysates have an isoelectric point at pH 4. Previous studies showed that peanut protein had an isoelectric point at pH 4.5, as seen from its drastically reduced solubility at this pH [22]. This result indicated that protein solubility is directly related to the pH of the solution and the isoelectric point of protein.

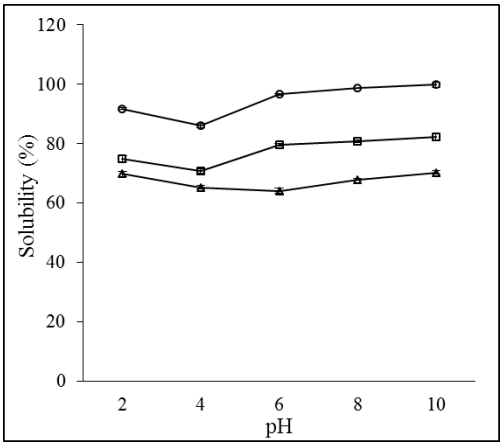

Figure 3. Solubility of Angelwing clam hydrolysate (BH =●), physical mixed hydrolysate (PMH =▲) and kneaded method hydrolysate (KMH = ■). Bars represent standard deviation from triplet determination

Solubility in BH was higher than KMH and PMH due to the lower molecular weight of peptides during hydrolysis which was generated by reducing the secondary structure in protein [23]. The solubility of KMH and PMH was slightly lower compared to BH which proved the formation of an inclusion complex between the guest and host compounds of BH and β-cyclodextrin. According to previous studies by Rahman [24] and Sanjoy et al. [25], the solubility of the inclusion complex is higher than the solubility of β-cyclodextrin if the guest molecules are highly soluble in water. However, the solubility of the inclusion complex is lower than β-cyclodextrin, but will have a higher solubility than its guest molecule if the guest molecule has poor solubility in water. This explains the reason for a lower solubility between KMH and PMH. To conclude, these studies revealed that a physicochemical property of a complex is different from that of β-cyclodextrin and its guest molecule.

Water holding capacity and oil holding capacity

According to Table 1, the water holding capacity of BH, KMH and PMH were significantly different ($p < 0.05$), with BH having lower water holding capacity than KMH and PMH at 4.60 mL/g, 5.349 mL/g and 5.572 mL/g, respectively. According to Amiza et al. water holding capacity values were influenced by the

solubility of the samples [23]. However, Tang et al. reveals the high protein solubility was not necessarily related to the high-water holding capacity. The lower water holding capacity of BH was probably related to its lower molecular weight, leading to a smaller interface surface area [22]. Besides, decreased water holding capacity might be attributed to the hydrolytic degradation of the protein structure, in which physical entrapment plays an important role in the adsorption of water [23].

Table 1: Water holding capacity and oil holding capacity of hydrolysate and the modified

Functional Properties	**BH**	**PMH**	**KMH**
Water Holding Capacity (mL/g)	4.60^{b}±0.24	5.35^{a}±0.17	5.57± 0.25
Oil Holding Capacity	5.16^{a}±0.05	3.96^{b}±0.04	3.44^{c}±0.01

Values are expressed as means ± standard deviation from triplicate determinations. Different letters within rows indicate significant difference at $p < 0.05$

The higher value of WHC in KMH and PMH indicated the effects of β-cyclodextrin on water holding capacity. The changes in water holding capacity in the samples were probably due to the inclusion complex between BH and β-cyclodextrin, which had changed the molecule structure of KMH and PMH. This study corroborated previous studies indicating that the binding strength of proteins was mainly dependent on their molecular structure [26]. Therefore, the changes in molecular structure produced from the complexes PMH may have significantly altered its water holding capacity in KMH and PMH.

The mechanism of fat absorption is mostly attributed to the physical entrapment of the oil. The oil holding capacity (OHC) obtained from BH was significantly ($p <0.05$) higher (5.16 mL/g) than KMH (3.44 mL/g) and PMH (3.96 mL/g) as shown in Table 1. This agrees with a previous study in which the oil holding capacities of BH possessed a higher oil holding capacity [27]. The high oil holding capacity of BH could be due to its higher surface hydrophobicity and degree of hydrolysis as suggested by Kristinsson and Rasco [28]. On the contrary, low oil absorption might be because the presence of a large proportion of hydrophilic groups and polar amino acids on the surface of the protein molecules after the complex was formed with β-cyclodextrin [13].

Foaming properties

The foaming capacity and stability were significantly ($p<0.05$) higher than KMH and PMH at all pH values (pH 2 to pH 10). The results suggested that BH had a more flexible protein structure in aqueous solutions and interacted strongly at the air–water interface to form more stable foams when compared to the KMH and PMH. In addition, hydrophobic had improved the foaming capacity and had made the protein more flexible [29]. Hydrophobic residues of protein in KMH and PMH were found less in SDS-PAGE studies. This is proved by less band distribution in polyacrylamide gels at lower molecular weights. This occurs due to sodium dodecyl sulphate (SDS) preferentially binds to hydrophobic regions of proteins. Therefore, hydrophobic proteins bind a higher amount of SDS than hydrophilic proteins, resulting in faster migration on SDS-PAGE [17]. This study revealed that β-cyclodextrin gave an effect on foaming properties by forming an inclusion complex with hydrophobic amino acids residues, thus causing hydrophobic residues to be hidden and less exposed.

The effect of pH on foaming capacity and foaming stability of BH, PMH and KMH are shown in Figures 4 (a) and (b). The lowest foam capacity and stability was observed at pH 4 among BH (74.33%, 70.33%), PMH (37.00%, 31.17%) and KMH (29.50%, 26.16%). The relationship between foaming properties and pH for BH, PMH and KMH was similar to the relationship between protein solubility and pH. In this study, the foaming

properties of the hydrolysate samples were found to decrease at pH 4, and to increase at pH 6. However, there was a slight decrease in alkaline pH. The changing foaming properties at different pH values showed that net charge had an influence on the adsorption of proteins at the air-,water-interface [9]. However, BH showed an increase in foaming properties as the pH continued to increase. This is agreed in previous studies, which demonstrated that as the pH increased, deprotonation of the acidic and basic groups occur, and when the net charge is increased, the foaming properties of protein are also enhanced [30].

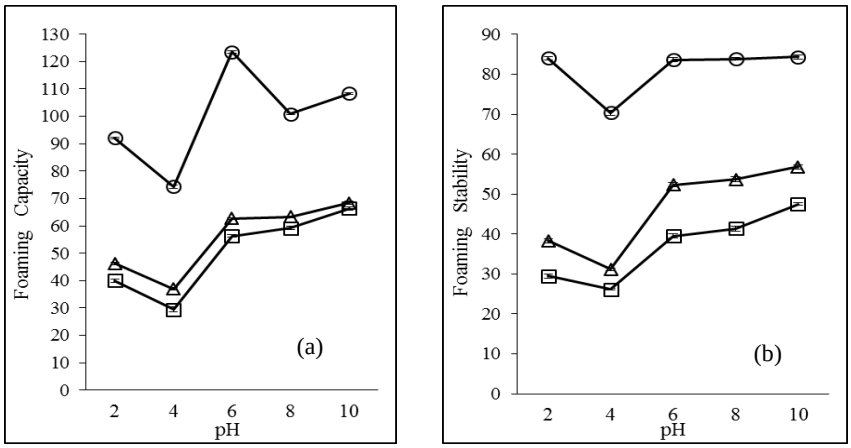

Figure 4. (a) Foaming Capacity and (b) Foaming Stability of Angelwing clam hydrolysate (BH=○), hydrolysate produced by physical mixing (PMH=Δ) and hydrolysate produced by kneading method (KMH= □). Bars represent standard deviation from triplicate determination

Emulsion properties

Emulsifying activity index (EAI) and emulsion stability index (ESI) of hydrolysate are shown in Figure 5. BH had a higher emulsion activity index at all pH values (pH 2 to pH 10) compared to KMH and PMH. This supports Mutilangi et al. as the higher solubility of hydrolysate results in higher EAI [29] because hydrolysate with higher solubility could rapidly diffuse and adsorb at the interface [10]. However, both KMH and PMH showed lower EAI across all pH ranges compared to BH, due to the complex formation between β-cyclodextrin and BH. This complex formation reduced the ability of the oil to form stable oil-in-water emulsions because β-cyclodextrin is not a surfactant, therefore, does not have the tendency to lower the surface tension between two liquids and thus, does not promote the oil-in-water emulsion. However, BH contains surface active material and promote oil-in-water emulsion due to the presence of hydrophilic and hydrophobic groups with their associated charge [31, 32]. Besides that, the lower EAI values in PMH and KMH are probably because of the extensive degradation of protein caused by further methods used to debitter the hydrolysate, such as kneading and rapid shaking in an incubator shaker.

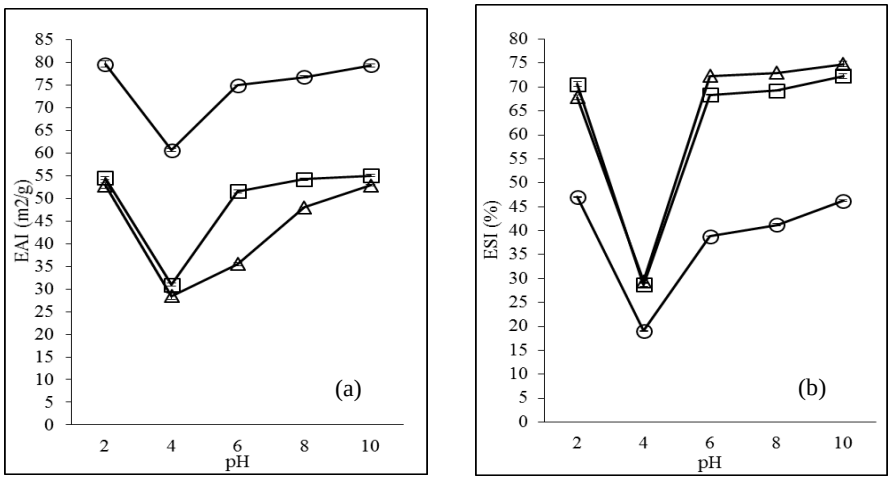

Figure 5. (a) Emulsifying activity index and (b) Emulsion stability index of Angelwing clam hydrolysate (BH=○), hydrolysate produced by physical mixing (PMH= Δ) and hydrolysate produced by kneading method (KMH= □)

At pH 10, the emulsion activity indexes of BH, PMH and KMH were significantly different ($p < 0.05$), with maximum values at 79.30%, 52.87% and 55.01%, respectively, whereas the emulsion stability index were at 46.55%, 74.81% and 69.63%, respectively. However, the minimum emulsion activity index in BH, PMH and KMH at pH 4 (isoelectric point) were 60.58%, 28.45% and 30.91%, respectively whereas the emulsion stability index was 19.01%, 29.41% and 28.71%, respectively. The results indicated that emulsion properties were pH-dependent, with alkaline pH significantly improving emulsion capacity over acidic pH. The tendency was similar to protein solubility (see Figure 3). For instance, protein solubility was low at pH of 4, implying that protein adsorption at the oil–water interface would be diffusion controlled. However, at pH range of 6 to 10, as protein solubility increased, the activation energy barrier prevented protein migration from taking place in a diffusion dependent manner. An increase in protein solubility facilitated interaction between the oil and aqueous phases [20]. The emulsion stability of BH was significantly lower than that of KMH and PMH due to its lower molecular weight (refer Figure 2). Although small peptides diffuse rapidly toward the interface are effective in producing emulsions, they are less efficient at stabilizing emulsions, because they may not readily agglomerate to produce a fat-globule membrane due to charge repulsions [33].

Conclusion

The characterizations of complex formation between BH and β-cyclodextrin are shown through FTIR analysis. The changes in the FTIR peak patterns of the complexes were compared with their corresponding peaks of pure BH and β-cyclodextrin. The difference in the peak patterns of O-H stretching profiles reveals the complexation formation in KMH and PMH. The low frequency in the C=O stretching vibration and C-H stretching vibration of KMH and PMH also reveals the formation of complex between BH and β-cyclodextrin. Low fragmentation of proteins in polyacrylamide gels in KMH and PMH is compared to BH, proving that the inclusion complex had formed by grafting the β-cyclodextrin molecule to the protein surface and reducing the denaturation of protein by SDS reagent. The physicochemical analysis shows that β-cyclodextrin influences the functional properties of hydrolysate. Despite that BH has a good quality of nitrogen solubility index, the solubility of BH is reduced when it forms a complex with β-cyclodextrin. As a result, the decreased solubility in KMH and PMH has an effect on their water and oil holding capacities, as well as foaming emulsifying properties. Even though, the functional properties of KMH and PMH are slightly reduced after the complex formation between BH and β-cyclodextrin,

their reducing values remain within the best ranges for all protein hydrolysates studied.

Abstract

The use of biopolymer composite materials in the usage of magnetic nanoparticles for the removal of heavy metal pollutants has received little attention, despite their remarkable physical and chemical properties that suggested their huge potential as promising adsorbents. . Therefore, various sorbents for heavy metals removal have been prepared including surface-modified magnetic nanoparticles (MNPs). MNPs are susceptible to oxidation in the air and agglomeration in solvents rendering them to lose their essential adsorbent properties. Silica coating has proven to prevent degradation of the MNP and functionalizes the surface with silanol groups. A fundamental understanding of various surface modifications would be beneficial for near future research as well as industrial applications. Thus, this article aims in reviewing the most recent advances for surface modification of MNPs materials, including biopolymer materials, focusing on the chemistry preparation, characterization, optimization, mechanisms of adsorption, isotherms and kinetic models in order to remove various metals in water.

Keywords: magnetic nanoparticles, functionalization, modification biopolymer, heavy metals, water environment

Abstrak

Pengunaan komposit bioplimer sebagai nanozarah bermagnet untuk penjerapan logam berat kurang mendapat perhatian, walaupun ianya mempunyai ciri fizikal dan kimia yang luar biasa yang menjadikan komposit bioplimer sebagai penjerap berkesan. Oleh itu, pelbagai penjerap untuk penyingkiran logam berat telah disediakan termasuk permukaan nanopartikel bermagnet yang diubah suai (MNPs). MNPs mudah teroksida di udara dan mudah bergumpal dalam pelarut menyebabkan bahan ini kehilangan ciri-ciri

penjerapan yang penting. Salutan silika telah dibuktikan menghalang kemerosotan MNPs serta menyebabkan permukaan tersebut berfungsi dengan kumpulan silanol. Pemahaman yang baik tentang pelbagai pengubahsuaian permukaan akan memberi manfaat untuk penyelidikan masa hadapan serta aplikasi industri. Maka, artikel ini bertujuan untuk membincangkan dengan lebih mendalam kemajuan terkini dalam pengubahsuaian permukaan MNP termasuk bahan biopolimer, fokus terhadap penyediaan secara kimia, pencirian, keadaan penjerapan optimum, mekanisme penjerapan, model isoterma penjerapan dan model kinetik yang digunakan untuk penyingkiran bahan pencemar ion logam yang berbeza dalam persekitaran air.

Kata kunci: nanopartikel bermagnet, kefungsian, biopolimer pengubahsuaian, logam berat, persekitaran air

Introduction

Pollution from heavy metals (lead, cadmium, and copper) poses a serious risk to human lives as well as the environment (water, soil, and air) across the world. Metallic elements with relative densities are greater than those of water, greater than or equal to 5 g/cm, and the potential to be hazardous even at low concentrations are referred to as heavy metals. [1]. These heavy metals (lead, cadmium, and copper) are non-biodegradable, and therefore, tend to bioaccumulate in the biological and ecological system over a prolonged period, potentially causing damage to living organisms. The discharge of a high concentration of heavy metals into the environment could be from mining, agricultural, domestic, and industrial activities [1, 2]. The dumping of effluents into water bodies could cause harm to aquatic environments. Thus, due to health threats of the heavy metals, the industries that have the potential in polluting the 'water bodies should treat their effluents sufficiently before releasing them to fit into the environmental guideline standard. To prevent long-term exposure, it is essential to monitor contamination levels from their drainage source. Non-essential heavy metals such as mercury (Hg), lead (Pb), arsenic (As), cadmium (Cd), and antimony (Sb) are listed in several regulatory bodies as contaminants in various water matrices. The World Health Organization (WHO) and the United States Environmental Protection Agency (USEPA) have stipulated regulatory limits for Pb to be 0.005 mg/L as well as 0.015 mg/L in drinking water, considering its dangerous impacts on the environment and humans [3, 4, 5]. The limits for Hg, Cd, and As in drinking water are 2, 5, and 100 µg/L, respectively [6]. Some heavy metals (i.e. zinc (Zn), copper (Cu), iron (Fe), and selenium (Se) are essential because they are required for various biological processes and physiochemical functions in most kinds of living organisms [7]. These categories of metal elements remain safe to all living organisms as long as their concentrations are within acceptable threshold values stipulated by regulatory bodies.

Several techniques for removing heavy metals from the water include precipitation [8], ion exchange [9], coagulation [10], and floatation [11]. However, these methods exhibited several disadvantages and limitations due to their high cost, low effectiveness, disposal of sludge, and inaptness to a wide variety of pollutants. The issue with the disposal of the resulting waste and/or sludge using these techniques makes adsorption a more promising choice due to its reusability of sorbents thus, being the more economical and easy separation method of materials because of the magnetic property of MNP full term? (MNPs). Adsorbents have been prepared from agricultural wastes [9, 12], clay [13], zeolite [14], activated carbon [15] and biopolymers [12]. A new class of material and organic-inorganic hybrid material have become more popular in creating high-performance adsorbents. Magnetic polymeric-based and/or silica-based nanoparticles showed the potential to remove metal through surface modifications. The modified hybrid materials have better properties than the original components. Thus, the surface coating of magnetic nanoparticles (MNPs) is one of the fundamental challenges that stands against researchers for the utilization of these materials for water purification. Recently, MNPs materials received greater attention due to their unique properties in terms of readiness to be modified and nontoxic properties. The MNPs were prepared and used as cores shells. Chemical co-precipit ation was mostly recommended since it was considered the easiest and the fastest method with less hazardous c hemical and procedure requirements. This method invol ved the preparation starting from the aqueous mixtures of solutions of Fe(II)/Fe(III) and salt solution by adding a base solution under an inert atmosphere at room temp erature with a slight increase in temperature [14, 15].

The MNPs have a high surface area which yields a lot of active sites for various modifications, but due to the setbacks of agglomeration, the active site could be reduced, and this was a major challenge for the preparation of MNPs. The surface coating with inorganic or organic surfactants can be an alternative method to remedy the agglomeration of the MNPs. For instance, the use of certain inorganic capping agents such as silica (SiO_2) has a unique physical and chemical property that could generally be applied during this process. Meanwhile, SiO_2 is more chemically stable in acidic media, thus, suitable to be used for surface coating of the MNPs. Thus, this could curb the process of agglomeration and serve as a protection for the MNPs in acidic environments. The surface coatings are done with the use of SiO_2 immediately as the next step after the preparations of MNPs. The SiO_2 layer is usually coated on the MNPs surface by the application of the Stober method whereby the SiO_2 were used to cover the surface of the MNPs to form the silica coated magnetite (Fe_3O_4/SiO_2) nanoparticle core-shell system [16]. After the SiO_2 coating, the next step was the functionalization of the MNPs surface. There are several techniques designed to functionalize MNPs surfaces. However, the easiest way is to graft the acid-functionalized group-containing compound with an organic mixture for example oleic acid [17] and n-octadecyl phosphonic acid [17], or it could be done directly onto the surface of MNPs dependent on Lewis acid/base interaction, which will change the MNPs into a hydrophobic adsorbent. Additionally, a silane coupling agent could be directly immobilized onto the surface of MNPs. For instance, amino-group functionalization of MNPs could be achieved through direct salinizing the MNPs with 3-aminopropyltriethoxysilane (APTES) or indirectly onto the surface of the silica-coated MNPs. This paper reviews the advancements in the synthesis of MNPs materials and surface modification with functional groups (e.g, $-NH_2$, -COOH, or -SH). The use of biopolymer organic components containing polysaccharides obtained from sporopollenin, alginate, chitin, and chitosan used as adsorbent composites for the removal of metal ions pollution in aqueous solutions were discussed. The focus was made on the preparation chemistry, characterization, and optimization, mechanisms of adsorption, isotherms, and kinetic models, for the removal of various metals in water.

Chitosan-based MNPs adsorbent

Chitosan (CS) is the major derivative of chitin which could be produced by the process of the deacetylation of the chitin in basic conditions, it is known for its good and outstanding properties such as biocompatibility, biodegradability, antibacterial properties, and non-toxic properties [18,19]. The structure of CS was composed of a linear-linked polysaccharide of randomly distributed (β-4)-linked-D-glucosamine (deacetylated unit) and N-acetyl-D-glutamine (acetylated unit). It has several commercial and biochemical uses [20]. In addition, it is known for its exceptional ability as an effective adsorbent due to its amino ($-NH_2$) and hydroxyl (-OH) functional groups in their molecules which served as attraction sites toward metal ions. The adsorbents prepared from chitosan-based MNPs for removing metal in water are tabulated in Table 1 [21-37]. In 2018, Song et al. [21] prepared a novel magnetic thiolated/quaternized/chitosan composite (Fe_3O_4/SH/CS) using an inverse suspension technique. The Fe_3O_4 was prepared as a precursor followed by the incorporation of the CS and the SH components. The purpose of the addition of CS was to boost the adsorbent's adsorption capacity through their functional groups. All results from this characterization confirmed the presence of -OH, -NH, and -SH in the composite, as well as the composition of the adsorbent, which revealed the synthesis process was successful. The composite showed high removal efficiency for Hg(II), Pb(II), As(V), Zn(II), As(III), Cu(II), and Cd(II) in basic conditions (pH 6 to 9). Pb(II) showed the highest adsorption capacity of 235.63mg/g while the maximum adsorption capacities values for the other metal ions were 66.27, 67.69, 28.00, 33.99,13.63 and 16.34 mg/g for As(V), As(III), Cu(II), Hg(II), Zn(II) and Cd(II) respectively. Additionally, the Freundlich isotherm was more fitted for all the metal ions due to the correlation coefficient (R^2) values ≥ 0.99, than the Langmuir, indicating heterogeneous adsorbate and multilayer adsorbent interaction sites. The kinetic process fitted best to pseudo-second order where the R^2 values were ≥ 0.99, indicating the chemisorption process. The adsorbent showed excellent reusability for Pb(II) (as model ion) where the removal efficiency for the Pb(II)

was achieved at 93% at 5 cycles.

A new adsorbent from attapulgite (ATP), ethylenediaminetetraacetic acid (EDTA), and chitosan to form the composite adsorbent (Fe_3O_4/ATP/ EDTA/CS) was performed by Sun and co-workers [22] The process of synthesis was done first by combining ATP and Fe_3O_4, followed by the addition of CS gel beads to the Fe_3O_4/ATP nanoparticles, where glutaraldehyde (GA) was employed as the cross-linker. Finally, gel beads-Fe_3O_4/ATP/CS were modified by EDTA to form the new Fe_3O_4/ATP/EDTA/CS adsorbent via amidation reaction (i.e., formation of amide through the reaction between carboxylic acid and amine by using a coupling agent such as EDTA) to further enhance removal efficiency. The magnetic material structural formation was confirmed by FTIR with Fe-O spectrum at 571 cm^{-1}, 1663 cm^{-1} (C=N) vibration that showed a reaction took place between CS and GA, 1631 cm^{-1} ($-COO^-$), 1398 cm^{-1} (C-O) indicating a carbonyl group had been introduced to EDTA and that the synthesis of the new adsorbent was successful. The maximum adsorption ability of the fabricated Fe_3O_4/ATP/EDTA/CS adsorbent material was 368.32, 267.94, and 220.31 mg/g, onto Pb(II), Cu(II), and Ni(II) in that order. The adsorption capacities of Fe_3O_4/ATP/ CS were 224.15, 144.47, and 105mg/g for Pb(II), Cu(II), and Ni(II), respectively, with lower values when compared to those of Fe_3O_4/ATP/EDTA/CS. These results demonstrated that the chelation by EDTA had greatly enhanced the adsorption capacity of the main adsorbent; Fe_3O_4/ATP/EDTA/CS. The procedure of adsorption better fitted the kinetics of pseudo-second data with R^2 values 0.9998, 0.9978, and 0.9967 for Pb(II), Cu(II), and Ni(II), respectively, indicating a chemisorption process. Additionally, the authors discovered that the adsorption mechanism to be homogeneous adsorbate and monolayer active sites interaction with high R^2 values 0.9995, 0.9950, 0.9958 Pb(II), Cu(II), and Ni(II), respectively, satisfying Langmuir isotherm than the Freundlichs' physisorption process. Consequently, the adsorbent could still demonstrate good adsorption capacity of repetitive use (5 cycles) by retaining its potential ability > 89% for Pb(II), Cu(II), and Ni(II), thus this indicated its capability to save cost. Chen et al. [23] explored Champ cellulose (*Millettia speciosa*) as well as chitosan to prepare magnetic hydrogels (MSCC/CS hydrogel) composite adsorbent for the removal of Cu(II). The purpose of adding CS was to enhance the adsorption process through the presence of amino-functional groups. The characterization results of functional groups involved in the synthesis process and the mechanisms of interactions demonstrated that electrostatic attraction was involved, with amino groups dominantly operating in the Cu(II) adsorption mechanism. The FTIR characterization showed the functional groups of -OH for cellulose at a broad peak at 3421 cm^{-1} and subsequent adsorption peaks at 2902 cm^{-1} and 1429 cm^{-1} for C-H stretching vibrations in methyl and methylene, respectively. Other peaks at 1429 cm^{-1} and 1371 cm^{-1} for C-H bending vibration as well as -NH_2 from CS were observed, indicating successful synthesis. The results from the adsorption kinetic process revealed the pseudo-first order kinetic process had a better match than the pseudo-second-order kinetic process, which had an R^2 value of 0.9822 for the adsorption of Cu(II). Therefore, physisorption dominated the process. The adsorption isotherm revealed that the Freundlich model had a higher R^2 value of 0.9975 than the Langmuir isotherm, indicating a heterogeneous and multilayer adsorption of Cu(II) onto the adsorbent. The results of the thermodynamic analysis showed that the Cu(II) adsorption process was spontaneous and endothermic, with values for G and H of -6.04KJ/mol and +18.79KJ/mol, respectively. The ΔS value was at +0.8KJ/mol which also implied the randomness of the process as well as endothermic. Furthermore, the increment in pH increased the adsorption capacity of MSCC/CS hydrogel due to the interaction of Cu(II) on the adsorbent's negative parts. On top of that, the authors reported that the adsorbent had reasonable reusability, with an adsorption efficiency of > 75% for 5 consecutive cycles.

Elanchezhiyan et al. [24] developed magnetic kaolinite (MKa) that immobilized in chitosan beads(CB) by a simple co-precipitation method (MKa/4%CB). The MKa was prepared first before CB was introduced into the mixture and applied for the removal of Cd(II) and Pb(II) from a wastewater ecosystem. The purpose of the modification with CB is to enhance the adsorption process through some amino functional group's

addition. Findings from FTIR characterization revealed the presence of Fe-O spectra between 580 and 630, a shift of spectra from 3430 cm^{-1}, 1629 cm^{-1}, 630 cm^{-1}, to 3438 cm^{-1}, 1631 cm^{-1}, 636 cm^{-1}, and 585 cm^{-1} for magnetic kaolinite. In addition, the peaks with chitosan shifted from 3430 cm^{-1}, 1639 cm^{-1}, 1596 cm^{-1}, and 142 cm^{-1}1 to 3457 cm^{-1}, 1655 cm^{-1}, 1676 cm^{-1}, and 1460 cm^{-1}, respectively, for -OH, -CH, -CN and -NH_2 vibration stretching, thus confirming successful synthesis process. The adsorption mechanism of both metals unto MKa/4%CB was through ion-exchange and coordination bonding, due to the more active sites of -NH_2 and -OH functional groups contributed by CB. The optimization factors were achieved at pH 6, initial concentration of the adsorbate of 20mg/L, adsorbent dosage as 100mg, temperature 25°C, and shaking speed at 200rpm. The adsorption isotherm studies fitted with Langmuir, which indicated homogeneous and monolayer adsorption sites were available as compared to heterogeneous sites. Additionally, the calculated adsorption capabilities were 90.9 and 88.5 mg/g for Pb(II) as well as Cd(II). The adsorption kinetic data plot demonstrated that both metal ions fitted into the pseudo-second order, thus demonstrating a chemisorption process. Synthesized adsorbents could be used for 4 cycles without any substantial adsorption capacity reduction. Huang et al. [25] prepared a phosphorylated(P), CS-coated Fe_3O_4/SiO_2 NPs adsorbent ($Fe_3O_4/SiO_2/CS/P$) and used it to remove Pb(II). The purpose of phosphorylating the adsorbent was to enhance the Pb(II) adsorption performance of the adsorbent and also alter the selectivity of other metals' adsorption. At pH 6.0, the researchers conducted multi-ions solution competitive assays. The results revealed that $Fe_3O_4/SiO_2/CS/P$ had a 10-fold greater ability to remove Pb(II) than other metals, with a distribution coefficient of 0.75 L/g, while $Fe_3O_4/SiO_2/CS$ exhibited highly discriminating sorption towards Ag, according to the multi-ions solution competitive trial. The removal of Pb(II) improved when compared to the uncoated silica adsorbent due to the presence of P. The $Fe_3O_4/SiO_2/CS/P$ could provide greater acidity protection against any probable Fe leaching after the acidity studies at pH 1. Furthermore, the XPS and FTIR spectral analyses showed that the exceptional adsorption process and the discriminatory tendency to remove Pb(II) were mostly manipulated by coordination connecting phosphate groups on the adsorbent surface of the material. The Langmuir adsorption capacities were 151.8, 131.8, 27.7 and 25.8mg/g for $Fe_3O_4/SiO_2/CS/P$, $Fe_3O_4/CS/P$, $Fe_3O_4/SiO_2/CS$, Fe_3O_4/CS, with the R^2 values 0.999, 0.986, 0.933 and 0.945, respectively; indicating a monolayer - surface-active sites interaction with a homogeneous adsorbate. The kinetic adsorption of Pb(II) unto $Fe_3O_4/SiO_2/CS/P$, $Fe_3O_4/CS/P$, $Fe_3O_4/SiO_2/CS$, and Fe_3O_4/CS revealed the best fit for pseudo-second order than the -pseudo-first order with R^2 > 0.992, thus indicating a chemisorption process.

Liu et al. [26] synthesized magnetic anaerobiotic granule sludge/chitosan (M/CS/AnGS) composite adsorbent and applied it for Pb(II) and Cu(II) removal from the water solution. The purpose of the modification is to enhance the process of adsorption through the addition of some functional groups. The FTIR revealed the presence of broad band spectra for -NH_2 and -OH were responsible for the adsorption and confirmed the success of the synthesis process. The optimum parameters influencing the adsorption capability of the CS/AnGS were an adsorbent dosage of 16 mg, pH 6, and a short contact time of 30 min. The highest adsorption capacities were 97.97 and 83.65 mg/g for Pb(II) and Cu(II), respectively. These were higher than the works of Zhang et al. [27] with 50.4 and 57.1mg/g for Pb(II) and Cu(II) in that order. The adsorption kinetics model of Pb(II) and Cu(II) is better suited to the pseudo-second order compared to the pseudo-first order with the R^2 values of 0.999 and 0.993, respectively, suggesting the chemisorption adsorption process. The Langmuir isotherm showed monolayer active site adsorption with R^2 of 0.9801 and 0.9920 respectively, indicating homogeneous adsorbate and a monolayer active site. Zhang et al. [24] prepared magnetic cyanoethyl chitosan beads (M/CNS/CS) and applied them for Co(II) removal from wastewater. The magnetite was prepared through co-precipitations and the cyanoethyl was used for the functionalization of the composite. The adsorption capacity towards Co(II) was enhanced by the grafting of cyanoethyl groups onto the CS. The FTIR revealed the presence of broad band spectra for -NH_2 and -OH around 3000-3700 cm^{-1} in chitosan, 1598 $cm^{-1,}$ and 1132 cm^{-1} for -NH_2, and a new band at 2250 cm^{-1} for -CN

spectrum due to the successful synthesis of M/CNS/CS. Hence, -CN, OH and -NH_2 were responsible for the removal of Co(II). The optimal factors were achieved at pH 6.72, contact time 4h, initial concentration of cobalt ions 500 mg/L, and temperature 308K. Additionally, the second-order model, as well as the Langmuir model data, were the best fittings with the coefficient of regression R^2 >0.99. This indicated that the chemisorption process and a monolayer surface-active sites interaction. The adsorption capability of 17.92 mg/g was less when compared to the adsorption capacity of 34.92mg/g obtained by Lee, et al. [42]. In that study, they used the same purpose of treatment of wastewater containing Co(II) heavy metal ions. The thermodynamic factors indicated endothermic and spontaneous process with the values as ΔH = +28.76KJ/mol, ΔS = +128.7J/mol and ΔG = -12.22KJ/molK.

Zhang et al. [27] synthesized a facile magnetic-responsive CNT/chitosan aggregate adsorbent (CNT/CS) and applied it for the removal of various contaminants via a two-step approach. The purpose of the modification is to enhance the adsorption process through the addition of some active sites due to functional groups. FTIR characterization revealed the spectra of 3450-3500 cm^{-1} for -OH stretching vibration in CNT, 1656 $cm^{-1,}$ and 1595 cm^{-1} due to carbonyl group of CNT, and 3480 cm^{-1} and 3375 cm^{-1} for -OH and -NH_2, respectively, which showed the formation of CS on top of CNT, thus confirming successful synthesis process of the adsorbent. The result of adsorption capacity for heavy metals by CNT/CS aggregate observed the order of Fe(III)>Cu(II)>Pb(II)>Zn(II), with adsorption capabilities of 68.8, 57.1, 50.4, and 16.6 mg/g in that order, perhaps due to electro positivity sequence. The mechanism of interaction was mainly du pi-pi stacking, cation-pi interactions, hydrophobic effect, and chelation tendencies of the metal ions. Meanwhile, the performance of CNT/CS was better than CNT alone due to the presence of the functional groups -OH, and -NH_2 on the CS which enhanced the removal of the contaminants. The isotherm kinetics for the metal ions well supported the kinetic isotherm model of pseudo-second order with $R^2 \geq 0.997$, close to unity implying a chemisorption adsorption process. Since the adsorbent could be reused as it could retain over 78% of its original worth, the CNT/CS material demonstrated great potential in the removal of multiple pollutants from aqueous mixtures.

The adsorbent's crosslinked CS/g/PMAM through the method of grafting CS with poly(methacrylamide (g/PMAM) was synthesized by Sutriman and co-workers. They applied for removal of Cu(II) and Cd(II) in aqueous solution [28]. The modified CS was to improve acid resistance and also enhance the adsorbent's adsorption capacity toward the removal of metal ions in aqueous solutions. FTIR characterization showed the presence of -OH and -NH_2 functional groups at spectral bands of 3423 cm^{-1} and 1615 cm^{-1} in chitosan and bands shifted to 3423 cm^{-1} and 1623 cm^{-1} to confirm the successful synthesis of the adsorbent CS/g/PMAM. By comparing the functional groups, C-O, C=O, -OH, -NH_2, and C-NH_2, the X-ray photoelectron spectroscopy (XPS) analysis revealed that adsorption of both metal ions occurred on the surfaces of the adsorbent by chelation via C-O, C=O, and C-NH_2 functional groups. The behaviors of crosslinked CS/g/PMAM from metals were investigated. It was revealed that the solution pH played a major role in adsorption Cu(II) and Cd(II) favored pH 4 and pH 5, respectively. Their Langmuir maximum adsorption capacities were 140.9 mg/g and 178.6 mg/g, respectively, with a better fit than the Freundlich isotherm data proposing monolayer adsorption than the Freundlich isotherm. Pseudo-second order indicated a better fit (R^2 = 0.999) than pseudo-first order, indicating that chemisorption or electron transfer was the dominant mechanism onto the crosslinked CS/g/PMAM. Additionally, the X-ray photoelectron spectroscopy (XPS) analysis revealed that adsorption of both metal ions occurred on the surfaces of the adsorbent by chelation via C-O, C=O, and C-NH_2 functional groups. Pooladi et al. [29] synthesized a new adsorbent of chitosan-hydroxyapatite-MNPs (CS/HAP/Fe_3O_4) and applied it for the removal of Cu(II) and Zn(II) from aqueous solutions. The purpose of the modification was to introduce some new functional groups active sites for the adsorption of the metal ions. The authors used chitosan and HAP because the two materials were low-cost and easily accessible, acquired from shrimp shells as well as bone ash, respectively. The adsorbent performances of CS/HAP/Fe_3O_4 were better than the

HAP/Fe_3O_4 due to the surface modification with the functional groups of the CS when compared. The FTIR characterization results showed the presence of the functional groups of -OH and -NH_2 to confirm the success of the synthesis process. The optimized removal experiment parameters employing fundamental composite design (CCD) together with response-surface-methodology (RSM) were 65 min contact time for Cu(II), initial concentration of 2.87 mg/L, Zn(II) initial concentration of 2.61 mg/L, pH 5.5 and adsorbent dosage 0.018g. The adsorption capabilities for Cu(II) and Zn(II) were 3.659 and 6.497mg/g, respectively. The authors attributed the low adsorption capacities that resulted to the synergistic negative influence of the cation on each other's adsorption behavior and perhaps their differences in the electrochemical series. The acquired adsorption isotherm data were well fit by the Temkin and Langmuir isotherms for Cu(II) and Zn(II), respectively, with coefficients of determination R^2 of 0.987 and 0.987, respectively, as compared to the Freundlich isotherm with R^2 of 0.912. The adsorption kinetics were pseudo-second order kinetic models for Zn(II) and Cu(II) with $R^2 \geq 0.99$ indicating that the adsorption was chemisorption and a spontaneous process.

Feng et al. [30] synthesized magnetic/chitosan/bentonite (Fe_3O_4/CS/BT) aggregate adsorbent using organic components materials and applied it for the remediation of acid mine drainage containing Cr(VI). The purpose of the modification was to enhance the adsorption process. FTIR characterization showed the presence of -OH and -NH_2 functional groups at spectral bands of 3423 cm^{-1} and 1615 cm^{-1} in CS and bands shifted to 3423 cm^{-1} and 1623 cm^{-1} to confirm the successful synthesis of Fe_3O_4/CS/BT. The authors discovered that the adsorbent aggregates had excellent magnetism (20.0emu/g), high stability, and good performance for the removal of Cr(VI) with the maximum adsorption capability of 62.1mg/g from the synthetic aqueous solutions. The adsorption isotherm fitted into the Langmuir isotherm proposing monolayer adsorption more than the Freundlich isotherm. Additionally, the kinetic information well fitted into the pseudo-second kinetics indicating the chemisorption process. On top of that, the thermodynamic factors demonstrated that Cr(VI) adsorption towards Fe_3O_4/CS/BT was exothermic as well as spontaneous in nature. The solution pH was an important factor for adsorption and was enhanced at pH 2.0 accordingly to the law of pKa. Besides that, Fe_3O_4/CS/BT was discovered to possess an exceptional adsorbent quality for actual acid mine drainage remediation of metals containing Ni, Zn, Fe, Cu, Cr, Pb, and Cd, with all their percentage removal > 84%. A study by Sun et al. [31] developed biopolymer chitosan/tannin (CS/TA) as an adsorption paper material for removing Cu(II) and Cd(II) from alkaline water solutions. The purpose of the chitosan was to promote flocculation on the paper material while both chitosan and tannin played the role of cross-linking on the paper material for modification. The FT-IR characterization revealed three distinct peaks at 1688, 1600, and 1200 cm^{-1}, which correspond to the stretching spectral vibrations of C=O, -C=C- of the benzene ring, as well as -C-O- in the tannin, correspondingly. As a result, CS could substantially encourage flocculation of tannin in the CS/TA adsorbent. The CS/TA adsorbent removal ability might have been primarily supported by a complexation formation mechanism, with the maximum adsorption capacity accomplished at pH 9. Langmuir isotherms accurately matched the adsorption data with an R^2 value of 0.9904, which was higher than Freundlich with an R^2 value of 0.984, thus indicating a favorable monolayer surface adsorption, with outstanding Cu(II) and Cd(II) adsorption capacities of 684.93 and 813.01mg/g, respectively. The adsorption of the various heavy metals unto CS/TA was preferential in the order of Cu(II) > Cd(II) and that Cu(II) competed with Cd(II) for active binding sites at concentrations more than or equivalent to 200 mg/L.

Huang et al. [32] prepared a new adsorbent sodium alginate/carboxymethyl chitosan (SA/CCS) hydrogel beads polyacrylamide (SA/CCS/P) and modified kaolin (SA/CCS/K) in which a simple polyacrylamide modification kaolin procedure was developed to enhance the adsorption performance towards the removal of Cu(II). FTIR results showed the presence of the functional groups of -OH, -NH_2, and -COOH which were responsible for the adsorption of Cu(II). The Langmuir adsorption capacities of adsorbents SA/CCS, SA/CCS/K, and SA/CCS/P, were 4.306, 4.621, and

5.515mg/g, respectively, showing that the modification due to polyacrylamide successfully enhanced the adsorption process and the increase due to presence of its functional groups. The increase proved that the adsorption of SA/CCS/P was better than the other adsorbents and therefore remained a good candidate for the removal of Cu(II) ions. The trend showed a substantially low removal ability which could be due to low interaction. The maximum adsorption capacity of Cu(II) onto SA/CCS/P was 5.516mg/g. Finding from both the kinetic and isothermal studies revealed that both Langmuir isotherm and pseudo-second were fitted into the adsorption process with both R^2 greater than 0.999. This indicated a homogeneous surface and monolayer as well as chemisorption process. Furthermore, adding kaolin was modified to reduce the tendency of coexisting ions interference. The adsorption capacity remained above 82% after 5 cycles of the reused adsorption-desorption experiment. Zhang et al. [33] synthesized a versatile adsorbent from EDTA and chitosan biofunctionalized magnetic bamboo biochar (E/CS/M/BB) and applied it for the removal of methyl orange (MO), Cd(II), and Zn(II). Magnetite was prepared by the co-precipitation method before the addition of the bamboo biochar, while GA served as a cross-linker between the magnetic chitosan and the bamboo biochar (BB) to form E/CS/M/BB. It was found that EDTA reacted with E/CS/M and BB via the amidation method to finally obtain the new adsorbent. By comparison of the adsorbent's adsorption performance, E/CS/M/BB was better than BB due to the electrostatic attractions pi-pi bond, and hydrogen bonding, which were enhanced via the $-NH_2$ and $-COO^-$ functional groups from EDTA. FTIR characterization results showed the functional groups of -OH, C=O, C=C, C-O, N-H, and $-NH_2$ to confirm the successful synthesis process. The maximum adsorption capacity at the optimum conditions were 305.4, 63.3, and 50.8 mg/g, for MO, Cd(II), and Zn(II), respectively. Pseudo-second order was more fitted with a R^2 value of 0.9895-0.9982 for MO, Cd(II) and Zn(II) than the pseudo-first order with R^2 values of 0.8541-0.9156, indicating chemisorption process. Additionally, the isotherm adsorption study revealed that Langmuir isotherm data was more fitted with the coefficient of determinations (R^2) value of 0.9981-0.9999 for MO, Cd(II) and Zn(II) than Freundlich with R^2 values of 0.7658-0.8701, indicating a homogeneous adsorbate surface interaction with a monolayer adsorbent active site. Adsorption-desorption experiment demonstrated that the efficiency of E/CS/M/BB towards MO was still retained after eight rounds but decreased for Cd(II) and Zn(II) by 16.8% and 19.5% respectively, indicating the cost efficiency of the adsorbent.

Similarly, Karimi et al. [34] prepared a magnetic-based chitosan/Al_2O_3/Fe_3O_4 (M/CS) nanocomposite adsorbent via ethylenediaminetetraacetic acid (EDTA) functionalization to improve the adsorption as new adsorbent (EDTA/M/CS). FTIR results showed a 1575-1639 cm^{-1} shift in peaks for EDTA/M/CS showing the presence of amino group on M-CS via the vibrational bending of the amide with C=O and $-COO^-$ on the surface of the adsorbent, thus confirming the successful synthesis process. By comparison, the EDTA functionalized M/CS adsorbent revealed that the adsorption capacity increased by about 14.3, 5.6, and 9.1 times towards Zn(II), Cu(II), and Cd(II), respectively indicating that EDTA/M/CS performed better than M-CS adsorbent. The maximum adsorption capacity of 43.93, 109.90, and 43.12mg/g for Zn(II), Cd(II), and Cu(II), respectively at pH 5.3. Finding from the isotherm studies revealed that Langmuir isotherm was mostly fitted into the isotherm data and could adequately explain the adsorption process with R^2 greater than 0.99, indicating a homogeneous adsorbate surface interaction with a monolayer adsorption active site. Additionally, the adsorption kinetics fitted the pseudo-second order with $R^2 > 0.99$ showing a chemisorption process. Furthermore, the thermodynamic study discovered that the adsorption process was exothermic and spontaneous with the values of ΔH, ΔG, and ΔS as -22.7KJ/mol, -10186.1J/mol, and 0.0451KJ/molK, respectively for Zn(II). Besides that, the values were -33.638 KJ/mol, -9797.21 J/mol and 0.0851J/molK, respectively for Cd (II). Additionally, -52.224 KJ/mol, -9129.58 J/mol and 0.1468J/molK, respectively for Cu(II) at 288K. Nasirimoghaddam et al. [36] synthesized a new adsorbent by immobilizing CS-coated magnetite (CS/Fe_3O_4) and applying it for the removal of Hg(II) from industrial aqueous and oily samples. The preparation of Fe_3O_4 was by co-precipitation of Fe(II)

and Fe(III) salts via NH_3 solution before immobilizing chitosan on its' surface to enhance the adsorption of the Hg(II). FTIR characterization results revealed the Fe-O bonds and the -OH and -NH_2 functional groups to confirm the successful synthesis process. The optimized parameters were temperature 289K, pH 6, adsorbent dose 10mg/ml, and 50mg/L initial concentration of adsorbates. The isotherm study revealed that the Langmuir isotherm was more fitted than the Freundlich isotherm with the R^2 value of 0.999 indicating homogeneous adsorbate and monolayer adsorbent surface interactions. The process at 298K was endothermic with ΔH value of +13,169.38KJ/mol, spontaneous with a ΔG value of -60.998Kj/mol, and ΔS as +41.969J/molK. This showed an increase in the randomness process, thus, suggesting that the solid/liquid interface interactions during the Hg(II) and the CS/Fe_3O_4. Furthermore, the adsorption-desorption study revealed that the adsorbent could retain it's 85% potential after a few recycle adsorption processes. Jiang et al. [37] synthesized a new adsorbent of functionalized SiO_2 coated MNPs with CS (Fe_3O_4/SiO_2/CS) to remove Cr(VI) in an aqueous mixture. Three steps were involved in the synthesis process. Firstly, the preparation of Fe_3O_4 by solvothermal reduction procedure, secondly, the preparation through silica coating of the Fe_3O_4 to form Fe_3O_4/SiO_2 and lastly, by immobilizing of chitosan via glutaraldehyde as the cross-linker to form Fe_3O_4/SiO_2-CS to increase the adsorption process. The FTIR characterization results showed the presence of the functional groups of -OH from adsorbed water molecules3436 cm^{-1} Fe-O at 585 cm^{-1} from Fe_3O_4, 1083 cm^{-1} for Si-O, from Fe_3O_4/SiO_2, and -NH_2 at 1640cm^{-1} from chitosan. The BET analysis showed Fe_3O_4 and Fe_3O_4/SiO_2 surface area as 24.0 and 121.0m^2/g, respectively, suggesting that porous silica was coated on top of magnetite to confirm the successful synthesis process. The possible adsorption mechanisms of the adsorbent towards Cr(VI) were reduction and electrostatic processes. The interferences adsorption experiment showed that the adsorbent had a strong affinity for Cr(VI) in the solution containing the ions of Zn(II), Cu(II), Cr(VI), Cd(II), and Ni(II). The researchers found that the adsorption capability of the adsorbent was high (336.7 mg/g) towards Cr(VI), which was enhanced effectively via a simple technique of cross-linking. The pseudo-second order dynamic model for the adsorption methods well-fitted more than the pseudo-first-order kinetics with R^2>0.999, thus indicating a chemisorption process. The Langmuir isotherm model fitted better with the adsorption process than the Freundlich isotherm with R^2 close to unity which showed a homogeneous phase with monolayer active sites. The recent advances in chitosan-based adsorbent materials for heavy metal removal [21-39] are summarized in Table 1.

Alginate-based adsorbents

Alginic acid or else its salt known as alginate is a biopolymer component of polysaccharides found in the colonies of a variety of algae species. It has a copolymer structure made up of layers of β-1,4-associated d-mannuronic acid (M-block) as well as α-1,4-linked l-guluronic acid (G-block) [38]. The existence of a 2 μm thick perforated holes wall of exine internal as well as the exterior surface of alginate, makes it easier for elements and compounds like heavy metals to adsorb. The recent advances in alginate-based adsorbent materials for heavy metal removal [39-44] are summarized in Table 2.

Ren et al. [39] produced new gel beads adsorbent from sodium alginate-carboxymethyl cellulose (SA/CMC) and utilized them to remove Pb(II) in a water mixture. The synthesis was successful via cross-linking of SA and CMC to enhance the adsorption of Pb(II). FTIR showed the functional groups of -OH and -COO in the complete synthesis of SA/CMC were responsible for complexation interactions with Pb(II). The authors verified parameters accountable for maximum adsorption of the Pb(II) and the results demonstrated that the initial adsorbate concentration was achieved at 5mg/L with adsorbent dose of 0.8g, and the temperature of 37 °C, and the vibration time of 18 hours. The adsorption experiment showed that Pb(II) adsorption unto the SA/CMC was greater than 99% under the optimum conditions. In addition, the author's comparative findings revealed that the Pb(II) removal efficiency of SA/CMC was significantly higher than that of traditional adsorbent CMC. Thus, they concluded that the SA could have improved the adsorption procedure possibly due to the functional groups on the SA. Additionally, the Pb(II) adsorption process unto the SA/CMC fitted the Langmuir adsorption isotherm, as well as the adsorption model depicted through a pseudo-second-order kinetic equation. Findings demonstrated that Langmuir R^2 value of 0.718, Freundlich value of 1.96, while the Temkin of R^2 was higher than 0.98. Thus, these demonstrated that both were homogeneous and heterogeneous adsorption sites of the adsorbent as well as both monolayer and multilayer surface sites were involved. The kinetic adsorption model also better fitted the pseudo-second order than the pseudo-first order indicating chemisorption than the physisorption process. Cordova et al. [40] developed a new adsorbent made of alginate (Alg) as a matrix with xanthation (XA) to form adsorbent (XA/Alg) and employed it to remove Cu(II)Zn(II). The purpose of introducing Alg was to enhance the adsorption of metal ions through its suitable functional groups. The important parameters were studied such as the effect of reaction time and findings demonstrated that time ranged (from 4-12 hours), the types of the base suitable to control the pH values were discovered to be (NaOH-KOH), and the quantity of carbon disulphide was (2-10%v/v) to obtain the green materials. NMR methods were used to analyze the XA/SA adsorbent and the evidence of β-removal was found at 5.45 ppm. The findings from the NMR experiment in solid-state revealed that a shoulder was achieved at 182 ppm attributed to the C-S group. The EDS mapping procedure also confirmed the existence of the thiol (S element), whereas XRD showed a semi-crystalline structure. The chemical shifts of δ(C=S) bands were at 863 to 805 cm^{-1}, and ν(C=S) bands were at 662 to 602 cm^{-1}. The findings showed that the maximum adsorption capabilities of Zn(II) and Cu(II) occurred up to 47.30 and 86.40 mg/g, respectively higher than for maximum adsorption capabilities of values were 6.497 and 3.659mg/g respectively for Zn(II) and Cu(II) obtained by Pooladi et al. [29]

Fuks et al. [41] synthesized a new adsorbent by the combination of Fe_3O_4 into calcium alginate gels (CaAlg) to form aggregate magnetic adsorbent material known as alginic ferrogels (Fe_3O_4/CaAlg), utilized for the removal of cationic radionuclides; Am(III), Sr(II), Cs(I) and Eu(III) from aqueous mixtures. The removal of cations of radionuclides was achieved through the direct dosing of the solution mixed with sodium alginate/iron carbonyl with a 2 hours continuous stirring. The purpose of introducing alginate was to improve the adsorption of radionuclides metals through the suitable functional groups of -OH and $-COO^-$ through the modification by CaAlg. The optimized factors were obtained at 15g/L of iron carbonyl suspended in 1 L of an aqueous solution of sodium alginate and the addition of about 20 g $CaCl_2$ to 1 L of the solution comprising the radioactive metals. These findings revealed that the percentage removals of the radionuclides were 30-100%. The author reported

the removal of cations of radionuclides were due to the calcium chloride ions exchange with Cs(I) which was less favorable because of the smaller charge of the ions except that it could be trapped in the adsorbent pores. On the other hand, the ions of Am(III) and Eu(III) could efficiently be removed from the aqueous solution much better than the monovalent Cs(I) and divalent Sr(II) ions. Consequently, the authors concluded that other metal salts could not considerably influence the removal efficiency as much as the roles played by the number of charges on the ions. Lee et al. [42] synthesized a new adsorbent by incorporating Ca/Alg, zinc-ferrocyanide (Zn/FC), and Cyanex 272 to yield an adsorbent composite beads of ZnFC-Cyanex 272-alginate (ZCA), which was then used to remove Cs(I) and Co(II) in water. The Ca/Alg beads were produced through the cation exchange and cross-linking between sodium alginate (Na/Alg) and calcium chloride ($CaCl_2.2H_2O$) in the presence of water. FTIR results showed the -OH, and -COO- in Ca/Alg, -CH stretching vibrations in ZnFC-Cyanex 272 as well as spectral peaks at 1164cm^{-1}, 960 cm^{-1}, representing the P=O and C-O-P stretching vibration respectively: thus, confirming the successful synthesis process. By comparing the adsorbent's performances (Ca-Alg and ZCA), the latter was greater than the former due to the presence of some suitable functional groups of -OH, and -COO- in ZCA adsorbents which were responsible for binding with the metal ions. The maximum adsorption capability for Cs(I) and Co(II) was 71.73, and 34.92 mg/g. respectively. The adsorption procedure fitted both Langmuir isotherm, as well as pseudo-second-order kinetics, to support the adsorption process, indicating the isotherm revealed homogeneous and monolayer surface interactions and a well-fitting chemosorption kinetic process. Additionally, the ZCA composite beads could demonstrate an exceptional selectivity toward Cs(I) and Co(II) despite the presence of competitive cations of K(I), Fe(II), Na(I), and Ni(II). Consequently, the authors concluded that ZCA composite beads could be reused 3 times after the adsorption-desorption studies and could still maintain their excellent potential for the selective removal of Co(II) and Cs(I) in contaminated water.

Song et al. [43] synthesized a new adsorbent of Ca/Alg and applied it for the removal of rare earth metals (i.e., La, Sr, and Li). The purpose of the composite through modification with alginate is to enhance the adsorption process. FTIR characterization showed the presence of -OH, -COO^-, and -C-O functional groups in the Ca/Alg. Findings revealed that the adsorption capacities of Ca-Alg adsorbent towards La(I), Sr(I), and Li(I) were 0.562. 6.695 and 8.625mg/g, respectively. However, the adsorption capacities were generally low because the amount of adsorption depended on the number of the valences of the metal ions which was related to electrostatic interaction. The kinetics model and the isotherm studies were explored for the adsorption process and the findings demonstrated that Li(I) did not fit into both the pseudo-second-order and the pseudo-first-order process at both high and low initial concentrations with the R^2 = 0.781 and 0.825 respectively, while data for Sr(I) and La(I) both matched the pseudo-first as well as the pseudo-second order with R^2 values 0.999 as well as 1.00 respectively. This favored at lower and higher concentrations suggesting that both were physisorption and chemisorption processes. Additionally, the Freundlich isotherm data were more fitted for the adsorption process for La(I), Sr(I), and Li(I) with an R^2 value of 0.981, 0.974, and 0.983, respectively, thus this was more than the Langmuir isotherm data with R^2 values of 0.928, 0.927 and 0.814 respectively, indicated a heterogeneous layer surface interaction. Furthermore, the presence of co-existing ions could not largely affect the adsorption process towards the removal of trace metal ions. Dai et al. [44] developed a unique polysaccharide-based thermos-receptive hydrogel adsorbent material made from SA as well as 2-hydroxy-3- isopropoxy propyl/starch (HIPS) to form (HIPS/SA) and utilized it for the Cu(II) removal. The complex and permeable structure, laden with carboxyl groups, was to provide enough adsorption sites necessary for Cu(II) removal. The FTIR characterization results clearly showed the presence of suitable functional groups of O-H, C-H, C-O-C, -COO- and C=O in SA, HIPS/SA to confirm the successful synthesis process. The BET surface area of HIPS/SA hydrogel was 2.7785 m^2/g, this was much greater than SA alone with 0.284 m^2/g surface area, thus indicating a good surface area for adsorption for HIPS/SA. The conditions for the adsorbent's thermal

reversible responsive swelling/shrinking actions of adsorbent were examined as well as the effects of pH as well as the initial amounts of Cu(II) on adsorption ability. These findings showed that adsorbent dosage of 50 mg, pH 5.5, shaking speed, 200 rpm, temperature, 20 °C, contact time of 48 hours, and initial amounts of 100 mg/L. The maximum adsorption capacities of SA gel, as well as HIPS/SA, were 21.11 and 25.80 mg/g respectively indicating that there was a significant increase in adsorption upon the modification of SA by the HIPS. The adsorption isotherms and kinetics of the adsorbent further demonstrated that the adsorption of Cu(II) onto the HIPS/SA adsorbent which was a better fit for the Langmuir as well as the pseudo-second-order models, with both R^2 as 0.999 and the maximum adsorption capacity for Cu(II) onto the HIPS/SA being 25.81 mg/g. Additionally, the adsorption studies revealed that the adsorbent could still be stable even after 5 cycles with the adsorption capacity of HIPS/SA decreasing from 19.83 to 15.23 mg/g.

Ahmed et al. [45] synthesized a new grafting polymer through the grafting of diphenylamine (DPA) on Na/Alg to form a composite (Na/Alg/g/DPA) adsorbent and applied it to remove Co(II) in wastewater solution. FTIR functional groups of -COOH, -COO-, -C-O, C=C, and C=N. From FTIR, they suggested a polymer structure, thus confirming that the grafting of DPA unto NaAlg in the synthesis process was successful. The adsorption performance of NaAlg-g-DPA was higher than NaAlg due to the existence of suitable functional groups as a result of the grafting of the DPA. The BET surface area of Na/Alg/g/DPA and Na/Alg was found to be 13.164 m^2/g and 2.4459 m^2/g, respectively, indicating that the grafting of DPA onto Na/Alg had greatly increased the surface area for the adsorption process, thus, making the adsorption of Co (II) more feasible. The enhancement of the external area for the one-step manufactured composite was linked to its mesoporous properties, which were crucial in Co(II) adsorption, according to the author's report. Additionally, the authors discovered that the best grafting efficiency was 97.5% at the initial concentration of 0.5M. The results of the kinetic study fitted well into the pseudo-second-order reaction mechanism of Na/Alg/g/DPA with adsorption capacity up to 17.2711 mg/g and an $R^2 = 0.9998$. Consequently, the linear plot, the second order kinetics model had $R^2 > 0.99$, indicating a chemisorption process. Additionally, the adsorption isotherms studies revealed that the Langmuir, Freundlich, and Temkin data were all fitted with a linear plot with the coefficient of determination, $R^2 > 0.9$ which indicated that the adsorption process was both homogeneous and heterogeneous surface interaction. Allouss et al. [46] used an ionotropic gelation approach to produce a new adsorbent from graphene-oxide (GO) combined with condensed carboxymethyl cellulose-Alginate (CMC/Alg) hydrogel nanoparticles as (CMC/Alg/GO) adsorbent and was applied to remove Cu(II) from water solution. FTIR results showed the presence of -OH, and -COOH functional groups in both graphene oxide and alginate to confirm the successful synthesis process and the functional groups were responsible for Cu(II) adsorption. The authors studied the adsorption of Cu(II) particles onto the adsorbent under various experimental settings and discovered that the best-optimized conditions were achieved at an adsorbent dosage of 2g/L, an initial amount of 150mg/L, a contact period of 90 minutes, a temperature of 398K, and a pH of 5. CMC, CMC/Alg, and CMC/Alg/GO were compared for the adsorbent's adsorption performances, thus results also demonstrated that embedded CMC-Alg/GO beads had a superior adsorption capacity to the natural CMC/Alg beads owing to a synergetic influence between the functional units of the GO and the CMC/Alg matrix. The adsorption capabilities at equilibrium for CMC/Alg, and CMC/Alg/GO, were 22.10 and 39.96 mg/g at 1% addition of GO. Subsequently, the adsorption capacity increases to 41.72 and 64.00 mg/g with the addition of 3 and 5% of GO, respectively, indicating that the adsorption capacity is GO dependent. It was clear that the modifications improved the adsorption process when the data were compared. Additionally, the pseudo-second-order adsorption kinetics was well fitted, with R^2 values varying from 0.7974 to 0.989 which was better than the values within the range of 0.953 to 0.995 fittings for the pseudo-first order. Furthermore, both the Langmuir isotherm model and the Freundlich isotherm showed the R^2 values of 0.999, indicating that both physisorption and chemisorption processes were the rate control mechanisms. The intraparticle distribution model was also investigated, with the conclusion that the

adsorption process was a progression of external adsorption as well as intraparticle distribution.

Hassan et al. [47] synthesized an efficient adsorbent by functionalizing a multi-walled carbon nanotube (CNT) ($CNT/CONH_2$) with an amide functional group ($CONH_2$) followed by an imprinted network of sodium alginate (NaAlg) containing hydroxyapatite (HAP) to form the new adsorbent (NaAlg/HAP/CNT). They then applied it to remove Co(II) from wastewater. The purpose of the $-CONH_2$ group addition and the modification was to enhance the metal adsorption process unto the adsorbent. The FTIR characterization revealed the presence of the functional group of -C-N from CNT, -CCOH from NaAlg, and the phosphate group from the HAP to confirm the successful synthesis process. The adsorption conditions were optimized and the findings revealed that the maximum adsorption capacity of Co(II) unto the NaAlg/HAP/CNT adsorbent was 394.5mg/g with a BET surface area of $163.4m^2/g$ greater than those of NaAlg/HAP with $33.1m^2/g$ and NaAlg/CNT with $72.9m^2/g$, indicating a good surface area for adsorption of Co(II). By comparing the adsorption capacities of adsorbents, it was discovered that NaAlg/HAP/CNT with 394.5 mg/g was greater than NaAlg/HAP with 355.2 mg/g and greater than NaAlg/CNT with 354.7 mg/g, indicating that that the adsorption capacities were enhanced through the modifications. Furthermore, the investigated kinetics model was found to be fitted into the pseudo-second-order and the Langmuir isotherm with the R^2 higher than 0.99 indicating a chemisorption process and a monolayer surface, respectively.

The adsorption process was both endothermic and spontaneous. The recent advances in alginate-based adsorbent materials for heavy metal removal [39-47] are summarized in Table 2.

Table 2. Alginate-based adsorbent materials for the removal of metal particles in aqueous mixtures

Adsorbent	Metal Ions	q_{max} (mg/g)	pH	Isotherm/Kinetics	References
SA/CMC	Pb(II)	-	5	Langmuir Pseudo 2nd order	[39]
XA/Alg	Zn(II) Cu(II)	47.30 86.40	7.0	-	[40]

Sporopollenin-based adsorbents

Lycopodium clavatum (sporopollenin, (Sp)) is among the biopolymer materials which can be utilized as an adsorbent with an exceptionally safe biomacromolecule. It exists freely in nature as a segment of the external mass of spores and dust which makes it impervious to attacks by inorganic acids and soluble bases [49]. It possesses an exceptional property that can stay in topographical layers for more than a century while maintaining its full morphological qualities, and this proposed great steadiness of Sp at exceptional requirement. However, the complete chemical structure of the Sp is yet to be discovered, and it also has a stable inter-chain ring structure of aromatic compound containing carbon, hydrogen, and oxygen in a stoichiometry of $C_{90}H_{144}O_{27}$. Moreover, its functional group is the hydroxyl structure making it accessible for modification in huge quantities. Along these lines, the hydroxyl group fills in as anchorage targets for metal atom complexation just as an extension of the needed surface functional group and with the combination of different other materials with high affinity for metal [44]. MNPs can be manipulated with Sp to give magnetic sporopollenin (Msp). These manipulations of Msp have been reported to be utilized in the removal of a wide range of poisons, for example, metal ions pollutants [49].

The various Sp-based adsorbent materials for the removal of heavy metal particles in water solution are summarized in Table 3 [51-56]. Furthermore, Sayin, et al. [51] synthesized a new adsorbent calix[4]arene Sp-based on the adsorbent (SP-Calix) and applied it for the removal of Cr(VI) from an aqueous mixture. The adsorbent was made through the method of immobilization of dihydrazine amide derived from p-test-butylcalix [4] arene on the modified Sp. FTIR characterization. The results showed the presence of the required functional groups of carbonyl and isocyanate to confirm the successful synthesis process. The batch-wise adsorption method of analysis was used to optimize numerous experimental factors and the results were achieved at pH 5, shaking speed 175 rpm, initial concentration 1.0 x 10^{-4}mmol/dm^3, and temperature of 25 °C. Additionally, the maximum adsorption capability was calculated to be 28.07 mg/g. The isotherm study showed that among the three isotherms; Langmuir, Freundlich, and Dubinin-Radushkevich, Freundlich were all found to be the most suitable to describe the adsorption process with the R^2 value close to unity. Meanwhile, the R^2 value for Langmuir was 0.8945. Additionally, the thermodynamic study showed that the value for ΔH, ΔS, and ΔG were found to be +41.01, +222.48, and +30.88KJ/mol which indicated endothermic, randomness, and spontaneous sorption process. Ünlü & Ersoz, [52], synthesized the new adsorbent dithiocarbonate/sporopollenin (DTC/SP) and applied it for Pb(II), Cd(II) as well as Cu(II) metal ions removal. The purpose of introducing sporopollenin was to enhance the adsorption performance of the dithiocarbonate. FTIR results showed the presence of the functional groups of DTC-SP was well captured from the functional groups of DTC and Sp to confirm the successful synthesis process. DTC/SP could adsorb metal ions better than the DTC when comparing the adsorbents, due to the presence of the functional groups of Sp. The mechanism of interaction was that of the DTC/SP chelating exchanger process. The operating pH for Cd(II), Pb(II), as well as Cd(II) metal particles were 7, 5.5, and 4, respectively, and the contact period ranged from 30 min to 7 hours, according to the author's findings. The isotherms studies revealed the maximal adsorption capacities for disclosed Cd(II), Pb(II), and Cu(II) were 7.09, 94.73, and 17.35 mg/g, in that order. The Langmuir R^2 values for the metal ions of Cu(II), Pb(II), as well as Cd(II), were 1.00, 0.9976, and 0.9951, respectively indicating a good fit process, and a homogeneous adsorbate and a monolayer surface interaction. Additionally, the Freundlich correlation coefficients R^2 for Cd(II), Pb(II), and Cu(II) were 0.9225, 0.9949, and 0.9572 in that order, while the Dubinin-Radushkevich(D-RK) R^2 value for Cu(II), Pb(II), as well as Cd(II), were 0.9795,0.9992, and 0.949, respectively. Both Langmuir and D-R isotherms were foreseen by the isotherm with homogeneous and conventional surfaces, i.e., homogeneous, and heterogeneous surfaces of the adsorbate unto the monolayer and multilayer sites of the adsorbent, hence, both Langmuir and D-R isotherms were predicted. Furthermore, the kinetic forecast of the pseudo-second-order process with R^2 values of 0.9975, 0.9996, and 0.9997 for Cu(II), Pb(II), and Cd(II) respectively, outperformed the fit for the pseudo-first order process

with R^2 values of 0.9791, 0.9902, and 0.9548 for Cu(II), Pb(II), as well as Cd(II) in that order. Furthermore, the thermodynamic parameters ΔH^o, $\Delta S^{o,}$ and ΔG^o values were computed as endothermic, randomness, and spontaneous after the graphical reading of the investigational data for the adsorption of Pb(II), and Cu(II), as well as Cd(II) ions to the DTC-SP. On top of this, the mechanism for the process of adsorption was revealed to be an ion exchange process in which the DST/SP is behaving as a chelating exchanger because the functionality present on the DST and adsorption took place through the exchange of valences between the resin and the adsorbent.

Hassan et al. [53] synthesized a new effective adsorbent through APTES functionalized magnetic sporopollenin-based silica-coated ($MSp/SiO_2/NH_2$) and graphene oxide (GO) to form $GO/SiO_2/MSp/SiO_2/NH_2$ and applied for hazardous Pb(II) ions removal from aqueous solution. The purpose of the modification and functionalization of the GO was to hance the adsorption process. FTIR characterization results showed the presence of the -OH, and –COOH which confirmed the successful synthesis process, and these functional groups were responsible for the adsorption of the metal ions. The researchers discovered that the new adsorbent $GO/SiO_2/MSp/SiO_2/NH_2$ at the optimized experimental conditions of pH 6, with a 20 mg amount of adsorbent dosage, initial concentration of 100 mg/L the highest adsorption capabilities realized for Pb(II) was 323.5 mg/g. The adsorption process was studied by utilizing the Langmuir and Freundlich isotherms, and the kinetics with pseudo-first order along with pseudo-second-order models. Findings from this study revealed Langmuir isotherms with an R^2 value of 0.9994 fitted better than the Freundlich adsorption isotherm with an R^2 value of 0.5129. Meanwhile, the maximum adsorption capacity was found to be 323.5 mg/g for Pb(II). Additionally, findings showed that the pseudo-second order proved a better fitted with an R^2 value of 0.9999 for Pb(II) than the pseudo-first-order with R^2 values of 0.4262. In the same manner, the models affirmed a multilayer adsorption process followed by a chemisorption and physisorption model for the targeted metal ion. The thermodynamic study showed ΔH value of +99.901KJ/mol, ΔS value of +0.349KJ/mol, and ΔG value of -6.627KJ/mol indicating endothermic, randomness, and spontaneous process. The authors discovered that the generation studies showed that the potential of the adsorbent only decreased by 8.6% after the 10th round with adsorption capacity maintained at 295m/g thus showing a good recovery, eco-friendly and consequently concluded that the adsorbent shows good future potential to remove lead ions from wastewater.

Ren et al. [54] created a new modified EDTA/chitosan-SiO_2-Fe_3O_4 (EDCMS) adsorbent and used it for the removal of heavy metal ions (Pb(II), Cu(II), as well as Cd(II) from water solution. CMS was created by modifying the surface of chitosan-SiO_2-Fe_3O_4 with EDTA on top of the water/soluble carbodiimide as a cross-linker in a buffer blend. The purpose of EDTA was to enhance the adsorption process. FTIR characterization showed the functional groups of C=O, COO-, and N-H to confirm the successful synthesis process due to the combination of CMS and EDTA via the amide bonds. The most effective optimized conditions for the heavy metal ions removal by the EDCMS were achieved at pH 5, the dosage of 1.0g/L, and contact duration of 360 minutes. The maximal adsorption capacities of EDCMS for Cd(II), Pb(II), and Cu(II) ions were 64,41, 108.98, and 48.55 mg/g, respectively. The Langmuir isotherms investigation supported the sorption process with R^2 values of 0.996, 0.995, and 0.999 for Cd(II), Pb(II), as well as Cu(II), respectively, over Freundlich, with R^2 values of 0.812, 0.912, and 0.947 for Cu (II), Pb(II), and Cd (II) ions respectively. The kinetic study fitted well into the pseudo-second order with R^2 values of 0.999 for Cu(II), Pb(II), and Cd(II) ions, respectively, better than the pseudo-first order with R^2 values of 0.918, 0.980, and 0.906 for Cu(II), Pb(II), and Cd(II) ions correspondingly. Furthermore, both the EDCMS and CMS adsorption kinetics isotherm supported the mechanism of the pseudo-second-order kinetic model, and their equilibrium data were successfully matched with the Langmuir isothermal model. Additionally, at pH 5.0 (25 °C), the maximum adsorption capability of CMS was found to be 2.54, 9.32, and 55.64 mg/g for Cu(II), Pb(II), and Cd(II) ions, respectively, demonstrating the selective adsorption of Cu(II) ions, while the values of EDCMS were 64, 41, 108.98 and 48.55 mg/g, for Cd(II), Pb(II) and Cu(II) ions

correspondingly. The maximum adsorption capacities of EDCMS and CMS towards the removal of metal ions when compared clearly showed that the presence of EDTA enhanced the adsorption process through the modifications. Both EDCMS and CMS adsorption processes were endothermic, and the recycle studies demonstrated that after 12 rounds of reusability, EDCMS decreased by roughly 25% of its adsorption ability for heavy metal ions.

Recently, Bilgic et al. [55], prepared new adsorbent materials from a boron dipyrromethene (BODIPY) derivative which was immobilized on a sensor, then modified on 3-(Aminopropyltrimethoxysilane (APTES) to produce a microcapsule fluorescent sensor adsorbent (Sp/APTES/monoBODIPY) and applied it for Cu(II) the removal and selective sensitive detector. The Cd(II) used was from alkaline mixtures. FTIR results showed the presence of functional groups such as C=C, C=O, and -C=O, Si-O, OH, $-NH_2$ as well as the C-N bond present in both Sp-APTES and Sp-APTES-monoBODIPY adsorbent to confirm the successful synthesis process and the functional groups were responsible for the removal of Cu(II). The adsorbents Sp/APTES/monoBODIPY and Sp/APTES, when compared, in terms of adsorption performance, the former could adsorb Cu(II) better than Sp-APTES due to some suitable functional groups which was confirmed by FTIR. The maximum adsorption capacity of the Sp/APTES/monoBODIPY adsorbent unto Cu(II) was 25 mg/g. The authors reported that both the kinetics model and isotherms study revealed that pseudo-second-order kinetics and Langmuir adsorption were both fitted into the adsorption process with R^2 higher than 0.99.

Ahmad et al. [56] synthesized a new adsorbent of piperazine-functionalized/magnetic/sporopollenin hybrid adsorbent (MNPs/sp/HEP) and applied it used for the removal of Pb(II) as well as As(III) in water. The purpose of the functionalization with the HEP is to enhance the process of metal adsorption. FTIR results showed the presence of the functional groups of -OH. -COOH, C=N, and $-NH_2$ confirmed successful synthesis processes and the functional groups were also mainly responsible for the adsorption of the metal ions. The metal ions removal under optimized parameters was achieved through a batch-wise method with optimum adsorption capacities (q_m) be 13.36 mg/g and 69.85 mg/g for the Pb(II) and As(III), respectively. The experimental data analysis using the non-linear equations for the Langmuir and Freundlich isotherm model was additionally investigated. The findings revealed that the R^2 values of the linear for Pb(II) demonstrated higher for the non-linear plot for the analysis of both isotherms. However, the opposite results are shown in AS(III), where the R^2 values for the non-linear plot for both isotherms were relatively higher than the linear. Hence, AS(III) fitted better with the non-linear plots. The thermodynamic studies of the adsorption process revealed that the removal of both Pb(II) and As(III) ions was spontaneous and exothermic as ΔG and ΔH were both negative according to the findings by the researchers. This proved that the association of the adsorbate at the solid/solution interface was a random process. When comparing adsorbents performance, MNPs/sp/HEP showed a 119% rise in maximum adsorption capacity for Pb(II) as compared to MNPs/sp. This might be due to competition among the Pb(II) and As(III) ions for the insufficient active adsorption sites on MNPs/sp/HEP. Thus, based on the results the new adsorbent MNPs/sp/HEP proved to be an effective material for metal ions removal from aqueous solutions. Sargına et al. [57] synthesized natural polymers as biosorbents from two biomacromolecules and applied them for heavy metals removal. The components of the adsorbent were Cs, a versatile derivative of chitin, and Sp, a biopolymer with outstanding mechanical properties, and great resistance to chemical and biological reactions to form CS/Sp microcapsules which were prepared via a cross-linker. FTIR characterization showed the functional groups of hydroxyls, and carbonyl/carboxyl to confirm the combination of CS and Sp to form CS/Sp microcapsules. The adsorption performance of the microcapsules (CS/Sp) and the natural CS applied for the removal of Cu(II), Cd(II), Cr(III), Ni(II), and Zn(II) ions at various metal ions concentration, pH, amount of adsorbent, temperature, and contact time. The adsorption isotherm model fitted the Langmuir isotherm data and the adsorption capacity of the CS beads was found to be 85.16, 86.56, 51.47, 34.04, and 46.42 mg/g for Cu(II), Cd(II), Cr(III), Ni(II), and Zn(II), respectively. While,

the CS/Sp beads showed greater affinity for the ions at 92.78, 179.85, and 47.54 mg/g for Cu(II), Cr(III), and Ni(II), respectively, values of 16.86 and 16.34 mg/g for Cd(II), and Zn(II) were lower, respectively. Thus, the study revealed that the Sp enhanced ion sorption capacity of Cd(II) and Zn(II). Additionally, these findings from the adsorption isotherm studies revealed that both the Langmuir and the Freundlich isotherm fitted the adsorption process indicating both homogeneous and heterogeneous adsorbate and both monolayer and multilayer adsorbent interaction were involved. These authors stated that sporopollenin itself had an affinity for the metal ions due to the functional hydroxyl, carbonyl/carboxyl, and ether moieties present in its structure. Sargin et al. [58]synthesized bio-based sorbents, chitosan/sporopollenin (CS//Sp) especially by cross-linked chitosan (CS), with glutaraldehyde (GA) and combined with Sp to form (CS/GA/Sp) and applied for the removal of heavy metal. The metal adsorption behavior of chitosan-based sorbents was largely affected by the kind of cross-linking agent and degree of cross-linking. In the study, the authors described the preparation of chitosan/sporopollenin (CS/Sp) microcapsules cross-linked with various amounts of chitosan/glutaraldehyde (GA) ratios. The CS/GA/Sp were modified with 0.3, 0.9, and 1.5 mL of GA solution (in 25% water v:v) for 1.50 g of Cs. FTIR characterization. The results showed the presence of the functional groups of -OH, -C-N, -C=N, and -NH_2 to confirm the successful synthesis process. The adsorption performance of the microcapsules was studied for the removal of Cu(II) at different optimized conditions such as concentrations, contact time, amount of adsorbent, temperature, and pH. These findings showed that the maximum adsorption capacities of Cu(II) removal based on 0.3, 0.9, and 1.5mL GA impregnated CS microcapsules, which were 88.9, 100.4, and 80.7 mg/g, respectively. This indicated that the adsorption process could be best achieved at 0.9mL of GA. The outcomes of the investigation of the equilibrium adsorption isotherm data of the microcapsules demonstrated a better fit to the Freundlich isotherm model than the Langmuir isotherm data. Additionally, the affinity of the CS microcapsules towards Zn(II), Cd(II), Ni(II), and Cr(III) in presence of Cu(II) was revealed upon further investigation. Similarly, the findings revealed that the GA/Cs ratio could greatly affect the metal ions adsorption performance and the physicochemical nature of the microcapsules. Consequently, the results unveiled, implies that when CS microcapsules were cross-linked with 0.9 mL of GA solution, this could give a superior Cu(II) ion adsorption capacity and could be cost-effective sorbents in water treatment. The sporopollenin-based adsorbent materials for the removal of heavy metals in water solution are summarized in Table3 [48-60].

Tannic acid-based MNPs adsorbents

Tannic acid (TA) is a natural organic polyphenol comprising sugar esters. Researchers have been modifying MNP with tannic acid to enhance surface properties and adsorption capacity [61]. Tannic acid, a humic substance comprising carboxyl and hydroxyl functional groups was a well-established metal scavenger, due to the abundant phenolic hydroxyl and carbonyl functional groups on the framework. The complexation and precipitation of polyphenols with polyvalent cations in aqueous mixtures were well understood from the works of the earlier investigator that the nano adsorbent (Fe_3O_4/TA NPs) had possible applications to remove metals from aqueous systems [62]. While some other industrial application of TA is known to be an adsorbent to remove various kinds of chemical species, it is also known to contain hydroxyl groups which show affinity as adsorbents for metal ions recovery [62,63].

Table 3. Sporopollenin-based adsorbents

Adsorbent	Metal Ions	q_{max} (mg/g)	pH	Isotherm/ Kinetics	References
P-t-bCalix/Sp	Cr(VI)	-	1.5	Freundlich	[51]
DTC/SP	Cu(II) Pb(II) Cd(II)	-	4	Langmuir	[52]
MSp/ SiO_2/NH_2	Pb(II)	325.5	6.0	Langmuir	[53]
EDCMS	Cu(II) Pb(II) Cd(II)	-	5.0	Langmuir Pseudo-2nd order	[54]
Sp/APTES/ monoBODIPY	Cu(II)	25		Langmuir Pseudo-2nd order	[55]
MNPS/sp/ HEP	Pb(II) As(III)	-	6.5	Pseudo-2nd order	[56]
CS/Sp microcapsules	Cu(II) Cd(II) Cr (II) Zn(II) Ni(II)	-	-	Langmuir	[57]
CS/GA/Sp	Cu(II)	100.4	-	Freundlich	[58]

Zou et al. [64], used a simple coordination procedure to produce a novel TA-based adsorbent (TA/Zr) and used it for the removal of Pb(II). The purpose of the TA is to introduce some phenolic carboxyl functional groups to enhance the metal ions adsorption process. FTIR characterization results confirmed the presence of some prominent phenolic hydroxyl and carbonyl functional to show the successful synthesis process. Batch adsorption experiments were used to explore the effect of varied initial Pb(II) concentrations on the adsorption capabilities of TA/Zr. The author's findings, disclosed that the maximum adsorption capability was achieved as 99.0 mg/g at 25 °C and an initial Pb(II) concentration of 170 mg/L. The Langmuir, as well as Freundlich models R^2 value of 0.99, which were well fitted into the adsorption process showing monolayer Pb(II) adsorption on the surface of TA/Zr with the theoretical maximum adsorption capacity of 100 mg/g. The results explored for the kinetics of Pb(II) adsorption onto TA/Zr demonstrated that the pseudo-second-order > pseudo-first-order model, indicating that chemisorption was the dominant process. TA/Zr had adsorption selectivity for Pb(II) which was further investigated when mixed with binary solutions such as Zn(II), Cu(II), Co(II), Cd(II), Ni(II), and Pb(II) at a concentration of 150 mg/L. The Pb(II) removal was 64.62 mg/g significantly higher than the removal of other metal ions by the TA/Zr with values of 1.26, 3.68, 4.39, 1.14, 3.94 mg/g, for Zn(II), Cu(II), Co(II), Cd(II), Ni(II), respectively. Therefore, TA contributed substantially more to TA/Zr selectivity than the Zr species. Furthermore, the authors inferred that the presence of phenolic hydroxyl (e-OH) structures on the

surface of TA was responsible for the significant adsorption in which the hydroxyl groups of oxygen atoms synchronized with Pb(II), while hydrogen atoms of hydroxyl groups could be substituted and released as hydrogen ions, in this way showed, a proton exchange mechanism for the selective Pb(II) removal, as confirmed by the results of the characterization and batch adsorption assessments. Huang et al. [65] used a fast and scalable production strategy to produce tannin-based magnetic permeable organic polymers (TA/MOPs) adsorbent for the removal of methylene blue (MB) as well as Pb(II) from water mixtures by using workable tannin acid as construction blocks through an azo connection reaction without losing any phenolic eOH groups. FTIR characterization results showed the presence of some prominent phenolic hydroxyl and carbonyl functional to confirm the successful synthesis process. The results of VSM characterizations showed the value TA/MOPs saturation magnetization which was 17.6 emu/g. This indicated that the amount of MNPs separated throughout the reaction process could be controlled. For the BET surface area of TA/MOPs, results showed the presence of high unique surface areas of 110.7 m^2/g for adsorption process, and plentiful phenolic eOH groups which were capable of providing ultrahigh adsorption capacities and quick adsorption kinetics. The researchers also discovered that MB and Pb(II) adsorption equilibrium capacities of 1696mg/g and 252 mg/g, in that order, could be achieved in 10 min of contact time. The subsequent linear R^2 obtained from the pseudo-first-order model were 0.9425 and 0.9425 for MB and Pb(II), respectively. While the pseudo-second-order model, finely matched better with a high positive R^2 of 0.999 and 0.9908) for MB and Pb(II) respectively. Thus, the rate-controlling step for both Pb(II) and MB adsorption revealed chemical adsorption. The Langmuir isotherm data with an R^2 value of 0.999 was more suitably fitted than the Freundlich isotherm with an R^2 value of 0.9768 which indicated a monolayer chemisorption process governing the interactions of the components. Consequently, the outstanding stability and superparamagnetic attraction properties of the adsorbent could allow 5 cycles with great results without any substantial performance degradation (i.e., the adsorbent still retains over 90% of its adsorption potential), thereby justifying the low-cost efficiency.

Huang et al. [66], formulated an adsorbent from polyethylene polyamine (P/P) and tannic acid (TA) as (P/P/TA), and encapsulated them with Magaly-layered double hydroxide (LDH), to form an adsorbent (LDH-P-P/TA) and to remove Cu(II). The FTIR showed the broad spectral band at 3478cm^{-1} for -OH due to LDH, 3478 cm^{-1} spectra shifted to 3446 cm^{-1} due to the formation of LDH/PP/TA, while spectral bands at 2880-2960 cm^{-1} corresponded to C-H stretching vibration. New bands formed at 1707cm^{-1} and attributed to TA and new bands at 1500 cm^{-1} stand for C=C vibrational band in benzene and 1350 cm^{-1} for C-O stretching vibration for TA acid groups and 1199 cm^{-1} due to TA esters groups thus, confirming the successful synthesis process. The optimized conditions were all investigated as, contact time, solution pH, starting Cu(II) concentration, and temperature. The produced adsorbents LDH, PP/TA, and LDH/PP/TA gave the maximum adsorption of Cu(II) as 23.39, 27.78, and 41.56 mg/g respectively. Therefore, this indicated a progressive rise in the adsorption capacities with modifications. The adsorption ability of Cu(II) was considerably increased when LHD was added to the PP/TA polymer. Furthermore, the adsorption of Cu(II) onto the LDH/PP/TA was fitted into the pseudo-second order with an R^2 value of 0.997, as against the pseudo-first order with an R^2 value of 0.9766. In addition, the calculated qe full term? (qe) was close to the experimental with values of 42.62 and 41.56 mg/g in that order, indicating a good fit. Additionally, the isotherm favored the Langmuir isotherm over the Freundlich isotherm data, with an R^2 value of 0.9897 and 0.8488 respectively. Furthermore, the thermodynamic adsorption capacity was 58.70 mg/g with ΔG = -8.25KJ/mol and ΔH = 22.97KJ/mol, thus, revealing that the adsorption procedure was spontaneous as well as endothermic. The mechanisms of interaction were shown to be primarily mediated by electrostatic and complexation interactions towards the removal of Cu(II). Shi et al. [67], fabricated (TA/CS/MOF) a membrane-type adsorbent by blending and depositing chitosan, TA, and metal-organic structure (MOF, UIO-66) on the surface of polyether sulfone (PES) membrane. The adsorption-desorption of N_2 isotherm

demonstrated the specific surface area of TA/CS/MOF reduced from 598.2m^2/g to 135.77m^2/g after the addition of UIO-66 which reduced the pore volume to confirm the success of the modification in the synthesis process. FTIR characterization showed the presence of -OH, -C-O-C, and -NH_2 to confirm the synthesis process. The SEM images of MOF showed an open-pore surface, while TA/CS/MOF image confirm the successful coating. All these results showed that the MOF contributed a core to the disperse of the tannic acid/chitosan mixture in order to enhance the removal of pollutants. Additionally, under optimized conditions, the findings showed that when the proportion of MOF/Chitosan was combined, at 30%, pH at 3.5, and then the filtration for 200min, the pollutant removal achieved 99%. The improved driving force induced by the concentration polarity in the filtration was assumed to alter the capacity of the adsorbent in the dynamic filtration, which proved a pollutant load-up capacity was 3 times better than that of the static adsorption. The findings from the dynamic filtration process demonstrated that the data fitted both the pseudo-first order and pseudo-second order for most of the adsorption processes for the adsorbate with the $R^2 \geq 0.99$, suggested the process as a chemisorption rate-controlling step. Similarly, the Elovich model fitted the data with the value of $R^2 \geq 0.99$ which showed that the diffusion was also influenced by the adsorption process.

Liu et al. [68], produced adsorbents from, poly(tannin-hexamethylenediamine) (PTHA), by changing the mole proportion of TA as well as hexamethylenediamine (HA) in a one-pot combination to produce a new adsorbent (PEG/PTHA) to remove Cr(VI). The results given were based on the effectiveness of Cr(VI) removal versus all made adsorbents according to the mole ratio formulation. The PEG/PTHA demonstrated an excellent adsorption performance with the mole ratio at TA/HA as 1:12.5. FTIR characterization results showed the presence of some phenolic hydroxyl and carbonyl functional to confirm the successful synthesis process. The adsorption experiment's optimum conditions were achieved at 24 h, pH 2 to 6, and an initial amount of 100mg/L. The process of adsorption for the kinetic equation was demonstrated to conform to the pseudo-second-order isotherm model with an R^2 value of 0.99293 which was better than the pseudo-first-order kinetic, R^2 value of 0.97335. This showed the chemisorption process dominating. Additionally, the highest adsorption capacity for the removal of Cr(VI) was 283.29 mg/g at 30 °C, depending on the isothermal curve appropriately described by the Langmuir model. On top of that, findings from the isotherm analysis revealed that Langmuir isotherm proved superior (R^2 =0.9939) over Freundlich (R^2 = 0.9084) specified homogeneous adsorbate and monolayer as surface interactions. Meanwhile, the authors discovered and stated that the amount of highly toxic Cr(VI) had remained lowered to the less toxic Cr(III) for the duration of the adsorption process. Gao et al. [69], created a new adsorbent from TA/templated mesoporous silica nanoparticles (T/MSNs) by using a simple non-surfactant template technique. The dopamine functionalized T/MSNs to form (Dop/TMSNs) adsorbent, achieved by using a superficial and biomimetic coating approach and used to remove Cu(II). The purpose of functionalization of Dop on top of T/MSNs was to enhance the process of adsorption of the Cu(II) from an aqueous solution. FTIR characterization results showed the presence of some prominent phenolic hydroxyl and carbonyl functional to confirm the successful synthesis process. The results of the adsorption under optimized conditions were achieved at an initial concentration of 100 mg/L, a temperature of 298 K, a contact time of 180min, a pH of 5.5, and an adsorbent dose of 1.0mg/L. Additionally, the kinetic model investigation revealed that the pseudo-second-order model was better preferred (R^2 = 0.995), above the pseudo-first-order model (R^2 =0.827). Meanwhile, the calculated adsorption capacity for the pseudo-second-order model was 45.4 mg/g, close to the experimental value of 42.8 mg/g. Furthermore, the results of the adsorption isotherm model revealed that the Langmuir model had a better fit with an R^2 value of 0.994 as compared to the Freundlich model's R^2 value of 0.948. This implied a homogenous adsorbate process and a monolayer adsorbent active site interaction. Moreover, Langmuir model's adsorption capacity was 58.7 mg/g, which was close to the experimental value of 55.6 mg/g. As for the K(I) and Na(I) concentrations had only a little impact on the adsorption process. The adsorbent's adsorption capacity was maintained at 89.2% efficiency

even after four recycling rounds. Yun Zhang et al. [70], developed a novel adsorbent multi-functional polymer hydrogel (Zr/DETA/TS) with a three-dimensional network structure and used it for the removal of Pb(II), Hg(II), as well as CrO_2(IV) via organic-inorganic crosslinking. FTIR characterization results showed the presence of amino, hydroxyl, carbonyl, and phenolic hydroxyl in the as-prepared composite adsorbent to confirm the successful synthesis process, which was responsible for the metal adsorption process. The peak spectral band at 150cm^{-1} due to N-H bending vibrations of amino in the adsorbent was shifted to 1494 cm^{-1} as well as 1497 cm^{-1} after the adsorption of Pb(II) and Hg(II), respectively, indicated that ionic exchange and electrostatic interactions were the major adsorption mechanisms for Pb(II) as well as Hg(II) removal, while electrostatic attraction, inner-sphere complex, and esterification played a significant role in CrO_2(IV). The optimal parameters for Pb(II), Hg(II), as well as CrO_2(IV), were 200mg/L initial concentration, 780 min contact time, and pH 5, respectively. The Langmuir model adsorption capacity was 384.61, 416.66, and 125.00 mg/g for Pb(II), Hg(II), as well as CrO_2(IV), respectively. The Langmuir model, fitted better with R^2 values of 0.9957, 0.9930, and 0.9949 for Pb(II), Hg(II), as well as CrO_2(IV), than the Freundlich model, with R^2 values of 0.8314, 0.8817, and 0.8435, while the Dubinin-Radushkevich(DRK) isotherm model, with R^2 values of 0.9750, 0.9422, and 0.8940 for Pb(II), Hg(II), as well as CrO_2(IV). The pseudo-second order was also found to be better at fitting the data than the first order, as shown by the kinetic models, which had R^2 values of 0.9995, 0.9999, and 0.9973, respectively. This indicated a chemisorption process over the pseudo-first order model, which had values of 0.9598, 0.9728, and 0.8290 for Pb(II), Hg(II), and CrO2(IV), respectively.

Deng et al. [71], fabricated out of MnO_2(Mn), polyethyleneimine (PEI), and TA, which was a new adsorbent called (Mn/PEI/TA) and used it to remove Cu(II) and Cr(VI) from effluent solution. FTIR characterization showed phenolic hydroxyl groups on the surface of TA and O-N on the surface of functional groups on the MnO_2. This improved the removal of metal ions by complexation. According to the results of the experiment, the maximal adsorption capabilities of the Mn/PEI/TA adsorbent towards Cu(II) as well as Cr(VI) were 121.5 and 790.2 mg/g correspondingly. The physicochemical interaction mechanism in the process of Cu(II) and Cr(VI) co-adsorption on the Mn/PEI/TA was also described using the surface complexation structure model. The complexation, solvation action, electrostatic force, and adsorbate-adsorbate lateral interaction, could be the factors for spontaneous interactions. Although chemical action was the major force significant to adsorption equilibrium, physical electrostatic contact was discovered to be the dominant factor in the primary stage. The scientists then remarked, however, that studying the adsorption on the adsorbent's surface, demonstrated that the Cr(VI) reacted with a few reducing agents. These reducing agents converted it into Cr(III) with the help of functional groups (hydroxylamine-NH_2). The understanding of the adsorption mechanism could have aided in the advancement of heavy metal adsorbents and the addition of PEI/TA considerably aided the adsorption process, demonstrating that the Mn/PEI/TA adsorbent nanocomposite. Consequently, the authors discovered that the results from adsorption-desorption studies revealed that the adsorption capacity was reduced by 12% after recycling 5-times, showing favorable adsorbent for removing heavy metal ions. Zhu et al. [72] prepared TA-based on graphene aerogel adsorbent via the hydrothermal method by incorporating both graphene oxide(GO) and TA in a one-step method to form aerogel composite adsorbent (TRGA) and applied it to the removal of Pb(II) and Cd(II) from wastewater. FTIR results showed the presence of -OH broadband at 1120cm^{-1}, and spectral peaks in 1750, 1695 cm^{-1}, and 1614 cm^{-1}. They were due to the stretching vibration of the ester group and ketone groups. The spectral, C=O. 3383 cm^{-1} peak appeared for -OH groups while the peak at 1695 cm^{-1} and 1614 cm^{-1} disappeared to confirm that GO was present. BET surface area was confirmed to have a value of 122.2 m^2/g with high porosity to enable the adsorption of metal ions. The TRGA maximum adsorption capacity toward Pb (II) and Cd (II) was achieved at 803.84 mg/g and 395.80 mg/g, respectively at pH 4. Findings from the isotherm studies revealed that both Langmuir and Freundlich's isotherm could adequately explain the adsorption process with R^2 values of 0.9924 and 0.9741, respectively.

Ucer et al. [73], developed a new TA immobilized on activated carbon (TA/AC) adsorbent and used it for the removal of Fe(III), Mn(II), Zn(II), Cd(II), and Cu(II)FTIR characterization results. This showed the presence of -COOH and -OH functional groups which were known to be metal ions scavengers. The optimal adsorption parameters were achieved at pH 2-8, a contact period of 60 min, and an adsorbent dosage range of 0.02-2mg. The percent metal ions removed for Zn(II), Cd(II), Cu(II), Mn(II), as well as Fe(III) under optimum conditions were 49.0, 60.1, 89.0, 45.0, and 70.4%, respectively at pH ranging from 5-8. Furthermore, the isotherm adsorption data revealed, that both Langmuir and Freundlich could appropriately explain the adsorption process. Langmuir R^2 values for Zn(II), Cd(II), Cu(II), Mn(II), as well as Fe(III) were 0.989, 0.965, 0.992, 0.990, and 0.966, correspondingly, while Freundlich R^2 values for Zn(II), Cd(II), Cu(II), Mn(II), as well as Fe(III) were 0.978, 0.955, 0.905, 0.989, and 0.935 correspondingly. Furthermore, the order of attraction based on removal by TA/AC and natural carbon was similar, with Mn(II) < Zn(II) < Cd(II) < Fe(III) < Cu(II) and electronegativities values being identical. Furthermore, in separate systems, the adsorption capacity of TA/AC increasing order of Mn(1.13) < Zn(1.23) < Cd(1.51) < Fe(1.77) < Cu(2.23) and in Cu(II) mixed competitive systems, Mn(1.11) < Zn(1.19) < Cd(1.48) < Fe(1.56) also in increased order. Thus, the principal adsorption mechanisms participating in the binding of metal ions were a combination of complex formation, ion exchange, and surface adsorption activities. Findings from the reusability study showed that the adsorbed-desorbed metal ions efficiently ranged from 90.2 to 98.4% by utilizing 0.1 M HCl without damaging the improved adsorbent. In another development, a research conducted by Fan et al. [74] and core workers, a core-shell nano-structured MNPs biopolymer-based composite sorbent was synthesized by immobilizing persimmon-tannin (PT) on top of the overlay of Fe_3O_4/SiO_2 microspheres to produce (Fe_3O_4/SiO_2/PT) adsorbent and applied for the removal of Pd(II), as well as Au(III). The main purpose of PT immobilization of the Fe_3O_4/SiO_2 microspheres is to introduce the presence of some phenolic hydroxyl functional groups to enhance the adsorption of metal ions. FTIR findings showed spectra at 575-589cm^{-1} for Fe-O bond in Fe_3O_4, 794 $cm^{-1,}$ and 1082 cm^{-1} for Si-O-Si bond for coating of SiO_2 on top of Fe_3O_4, 3410 cm^{-1} for -NH due to PT functionalization on top of Fe_3O_4/SiO_2. 3396 cm^{-1} and 1446 cm^{-1} stretching vibrations were for O-H and C-C confirming the presence of phenolic -OH groups from tannin, thereby confirming the successful synthesis of the process. The adsorption capacities of the Fe_3O_4/SiO_2/PT unto Pd(II) and Au(III) under optimized conditions were shown to be 196.46 and 917.43 mg/g respectively, as applied for metal ions removal. The kinetic study revealed that pseudo-second-order with the correlation coefficient R^2 value 0.9969 and 0.9996 for Au(III) and Pd(II) respectively, proved superior over pseudo-first-order with R^2 0.9860 and 0.8712 for Au(III) and Pd(II). Hence, this indicated the chemisorption process. The Langmuir adsorption isotherm showed a better fit with R^2 values of 0.9940 and 0.9937 for Au(III) and Pd(II) respectively than the Freundlich model with R^2 values of 0.9279 and 0.8457 for Au(III) and Pd(II), thus, indicating a homogeneous adsorbate monolayer interaction surface site. The tannic acid-based adsorbent material for the removal of metal in an aqueous solution [61-74] is summarized in Table 4.

Table 4. Tannic acid-based adsorbents

Adsorbent	Metal ions	q_{max} (mg/g)	pH	Isotherm/Kinetics	References
CS /TA	Cu(II) Cd(II)	6810 84.93	9.0	Langmuir	[61]
TA/Zr	Pb(II)	170.0	3.3-3.7	-	[64]

Silica coated MNPs adsorbent

Numerous published works on the applications of the functionalized silica coated MNPs materials utilized as adsorbent raw material for heavy metal ions removal in aqueous media are readily available. For example, Zhang, et al. [75] produced a new MNPs adsorbent material of $Fe_3O_4/SiO_2/NH_2$ core-shell by the sol-gel controllable method and applied it to remove Pb(II) in contaminated natural water. The purpose of the functionalization of the SiO_2 coated MNPs materials was to enhance the adsorption capacity of the adsorbent due to sone suitable functional group. Fe_3O_4, Fe_3O_4/SiO_2, and $Fe_3O_4/SiO_2/NH_2$ were compared for the performances of adsorbents, the adsorption capacities towards Pb(II) which were 6.94, 42.85, 243.9 mg/g, respectively. These progressive increases were due to the adsorption of the -OH groups on $Fe_3O_4/SiO_2/NH_2$ caused by SiO_2 coating of Fe_3O_4 and the $-NH_2$ functionalization of the Fe_3O_4/SiO_2, to form $Fe_3O_4/SiO_2/NH_2$. FTIR characterization results showed the presence of the spectral bands at $1630cm^{-1}$ and $3430cm^{-1}$ corresponding to the O-H vibration from water molecules as well as the presence of NH_2 groups due to functionalization. BET results also showed the surface area of $77m^2/g$ for Fe_3O_4 and $138m^2/g$ for $Fe_3O_4/SiO_2/NH_2$ hence, confirming the coating of SiO_2 on top of Fe_3O_4 with its surface endowed with functionalization due to APTMS. Under optimum parameters for uniform core-shell formation with a relatively high loading amino functionality at 5.45%, with the use of TEOS and APTMS for the sol-gel process, the researchers were able to remove the metal ions were ease with the aid of an external magnet. More findings demonstrated that the adsorbent could effectively remove Pb(II) with an adsorption capability of 243.9 mg/g at 25 ℃. Both the Langmuir model and kinetic data were well fitted into the pseudo-second-order model with R^2 =0.994 against the Freundlich model with R^2 =0.9684. This, indicated homogeneous adsorbate and a chemisorption process, upon the interpretation of the adsorption equilibrium process results. Additionally, the thermodynamic study showed that ΔH = +18.058KJ/mol, ΔS = +73.237KJ/mol and ΔG = -5.233KJ/mol showed endothermic, randomness and spontaneous process.

Zhang, et al. [76] synthesized a novel adsorbent of thiol-functionalized MNPs materials ($Fe_3O_4/SiO_2/SH$) for effluent solutions. The surface-functionalized MNPs were exceptionally viable for the additional removal of Ag, Cd, Pb, Hg, As, and Ti metal ions from water solutions. The purpose of the surface modifications with the -SH group was to enhance the adsorption process through the functional groups. Findings from their experiments indicated that all metals bonded successfully with the -SH functional groups of the ligand, except for As, which binds more to the MNPs. Similarly, the MNPs materials were functionalized in conjunction with mesoporous silica, by further introducing an aminopropyl functional unit to produce the adsorbent ($Fe_3O_4/mSiO_2/NH_2$) and applied for the removal of Cr(III) as a liquid solution and this was achieved with greater recovery. The adsorption capacity of the adsorbent containing just mesoporous silica ($Fe_3O_4/mSiO_2$), was found to show an adsorption capacity of 36.91 mg/g at pH 5.4. However, further functionalization with aminopropyl ($Fe_3O_4/mSiO_2/NH_2$) resulted in the rise in the adsorption capacity to 108.14 mg/g. This showed the $-NH_2$ group enhanced the adsorption process. The mechanisms of interaction between the adsorbent and the metal ions were ascribed to be the coordination of Cr(III) with the amine functional groups ($-NH_2$) combined with the electrostatic impacts of the silica surface. Additionally, the results from the isothermal studies revealed that Freundlich isotherms were better fitted into the isotherm data than the Langmuir isotherms with the R^2 value of 0.99, indicating a heterogeneous solution and multilayer active surface interaction. Sabermahani et al. [77], reported the synthesis of a new adsorbent of polyaniline/maghemite magnetic nanocomposite (PANI/¥-Fe_2O_3/MNC) in which the polyaniline was used as an active agent by the method of polymerization of aniline and applied to remove Pb(II). The purpose of polymerization with aniline was to improve the adsorption process. FTIR characterization results confirmed the presence of some prominent amino-phenol functional groups to show the successful synthesis process. The batch method was used for the adsorption study and the findings showed at optimized conditions were achieved at pH 6.0, adsorbent dosage of 40mg, and the equilibrium contact time was enhanced at

90 min. Additionally, the Freundlich adsorption isotherms were revealed to have a better fit with an R^2 value of 0.97 than the Langmuir isotherm with an R^2 value of 0.80. They found that pseudo-second order (R^2 = 0.984) > the pseudo-first order (R^2 = 0.447). This proved that a chemisorption process more than heterogeneous adsorbate interacting with multilayer active sites.

Similarly, Lin et al. [78], produced a new adsorbent of amino-functionalized SiO_2 coated MNPs ($NH_2/SiO_2/Fe_3O_4$) to remove Cu(II) in water solution. An amino-functionalized SiO_2 magnetite was synthesized with N-(3-trimethoxypropyl) ethylenediamine (TPED) as the surface modifier to enhance the metal removal. The adsorption performances of the adsorbents, Fe_3O_4, SiO_2/Fe_3O_4, and $NH_2/SiO_2/Fe_3O_4$, when compared, was obvious that there was a progressive increase in that order due to the modification which was expected to enhance the adsorption process. FTIR characterization showed that the -NH_2 functional groups were key to the adsorption process. The optimum pH solution was achieved between the range of 5-6, and the maximum adsorption capacity was 10.41 mg/g. Adsorption isotherms studies revealed that equilibrium adsorption data were well fitted into the Langmuir isotherm equations with the R^2 value close to unity than the Freundlich isotherms, indicating homogeneous adsorbate and monolayer adsorbent surface-active sites. Additionally, the kinetic isotherm revealed that the pseudo-second order best explained the adsorption kinetics with the R^2 value close to unity than the pseudo-first order indicating the chemisorption process. The enthalpy energy ΔH was found to be endothermic with the value of +26.92 kJ/mol. The authors discovered that the optimum conditions for adsorption of Cu(II) with the adsorbent $NH_2/SiO_2/Fe_3O_4$ could also be better optimized by using the desorption solvent of a 0.1 M HNO_3 concentration.

Jin, et al. [79], synthesized new magnetic mesoporous SiO_2-coated core-shell nanoparticles (Fe_3O_4/m/SiO_2) adsorbents based on different Fe_3O_4 core sizes. This was to evaluate the impact of the magnetic core sizes on the adsorption capability of adsorbent and to remove Cu(II). Meanwhile, the adsorption capability was discovered to be 84.4m/g for Cu(II). The findings revealed that magnetic core sizes were pH-dependent and have an influence on the magnetic properties of the various adsorbents as well as the structure of the mesoporous silica, specific surface area, and the different interactions with the surface moieties. The adsorption kinetics study for the various adsorptions unto the adsorbent revealed to be fitted to the pseudo-second-order kinetic model. This had well-proven that the adsorption process was a chemisorption process. Nodeh et al. [80] synthesized a new modified magnetic graphene oxide composite adsorbent ($Fe_3O_4/SiO_2/GO$) and intended to remove As(III) and As(V) from ecological samples. The purpose of the modification with the GO was to enhance the adsorption process. Peaks in the FTIR spectrum for O-H at 3400 cm-1, C=O stretching vibrations at 1714 cm-1 for carboxylic groups, C-O vibrations at 1036 cm-1, and C=C aromatic vibrations in GO at 1437 cm-1 all indicated effective synthesis. The findings showed that the $Fe_3O_4/SiO_2/GO$ adsorbent exhibited a superior adsorption capacity towards As(III) along with As(V) with values of 7.51 and 11.40 mg/g, respectively. The adsorbent demonstrated the linearity of 0.05-2.0 ngml-1 and the magnetic solid-phase extraction (MSPE) procedure was used for the pre-concentrations of the metal ions. The Langmuir model was better fitted into the adsorption process with the coefficient of determination; R2 being 0.9992 and 0.9985) for the ions of As(III) and As(V), in that order, than the Freundlich model with R2 0.9256 and 0.9754 .The pseudo-second-order was better fitted with R^2 0.9984 and 0.9968 than the pseudo-first order with R^2 0.8181 and 0.9447 for As(III) as well as As(V), indicating the chemisorption process. The thermodynamic parameters gave correspondingly R^2 0.9990 and 0.9998 as well. The ΔH, ΔS, and ΔG were 29.27KJ/mol, 0.09KJ/mol, and -0.45J/molK for As(III) and 40.75KJ/mol, 0.14KJ/mol, and -2.15KJ/mol for As(V) accordingly indicating endothermic and spontaneous process. Both As(III) and As(V) adsorption on the adsorbent were spontaneously negative when the adsorbent material was applied using the lake, tap water, spring water, and river tap water. The technique could give good relative recoveries of 72.55-109.71% and RSD of 0.1- 4.3 %, with n = 3. The reusability studies showed that the adsorbent could be reused 15 times in

an adsorption-desorption experiment with about 80% potential, to prove that the adsorbent was economically feasible.

Purwanto et al. [81]., synthesized a new adsorbent of a composite of rice husk and ash/activated carbon (AC) made from coconut shell which was subsequently combined with silica gel(SG) and also modified with 3-aminopropyltrimethoxysilane (APTES), through the technique of sol-gel to form (SG/APTES/AC) adsorbent, and was used to remove Pb(II) in aqueous solutions. FTIR characterization showed the functional groups of Si-O-Si from silica gel and -NH_2 from APTES to confirm the successful synthesis process. BET surface area of the SG/APTES/AC adsorbent was 290.23m^2/g at 22°C, which showed a good surface area for adsorption. The results of the investigations revealed that the optimum pH for the adsorption was achieved at 5.0 and the adsorption equilibrium for Pb(II) was achieved within 20 min of the contact time. The Pb(II) adsorption unto the composite adsorbent was well fitted into the Langmuir isotherm model >Freundlich with the R^2 > 0.99 and the maximum and minimum adsorption capacity values were 46.94 mg/g and 29.72 mg/g, respectively.

Ahmad et al. [82] synthesized an adsorbent based on MNPs coated mixture of inorganic-organic material of nanocomposite (MNPs/SiO_2/TSD/TEOS) to remove Ni(II) and Pb(II). Meanwhile, the purpose of the TSD-TEOS was used as a modifier hybrid to enhance the adsorption of the metal ions pollutants. FTIR results showed the spectral peaks at 3405cm^{-1}, 2934 cm^{-1}, 2873 cm^{-1}, 1580 cm^{-1},1475 cm^{-1}, 1317 cm^{-1},1051 cm^{-1},788 cm^{-1}, and 578 cm^{-1} for the bonds of N-H, -CH_3, -CH_2, C-C, C-N, -NH_2, Si-O, Si-C and Fe-O respectively. Extra spectral peaks of 3294 cm^{-1}, 2934 cm^{-1}, 1580 cm^{-1}, 1317 cm^{-1}, and 788 cm^{-1} were observed for N-H, C-H, C-N, NH_2, and Si-C, thus, confirming the successful synthesis process. The researchers discovered that the new adsorbent MNPs/SiO_2/TSD/TEOS at the optimized experimental conditions of PH 5, with a 20 mg amount of adsorbent dosage, the highest adsorption capacity realized for Pb(II) and Ni(II) particles were 417, and 357 mg/g, respectively. The adsorption studies were conducted by utilizing the Langmuir and Freundlich isotherms. The results showed that the Freundlich adsorption isotherm fitted more with the value R^2 of 0.997. This was higher than the Langmuir isotherms with an R^2 value, of 0.871, indicating more heterogeneous adsorbate and multilayer adsorbent active sites interaction. Additionally, findings from the kinetic study showed that the pseudo-second-order proved a better fit with R^2values 1.00 and 0.998 for Pb(II) and Ni(II) respectively than the pseudo-first-order with R^2 values 0.666 and 0.641 for Pb(II) and Ni(II) indicating a chemisorption process. The authors then argued that the newly synthesized adsorbent was different in structure and ability from those most prepared sol-gel-based adsorbents. The results gave a higher adsorption capacity for Pb(II) and Ni(II). Wang, et al. [83] synthesized a new adsorbent of thiol SiO_2 shell coated onto MNPs (Fe_3O_4/SiO_2/SH) by the hydroxylation method of Na_2SiO_3 modified with thiol groups(-SH) and applied to remove Hg (II). The purpose of the -SH group is to enhance the metal adsorption process. FTIR revealed a Fe-O bond with an intense absorption band at 587cm^{-1}, then after the silica coatings, a Fe-O band appeared at 1087 cm^{-1} and for the thiol functionalization, a new spectral band appeared at 2586 cm^{-1} for the -SH bond, thus Fe_3O_4 was successfully coated by SiO_2 and functionalized by the -SH to confirm the success of the synthesis process. The researchers used SiO_2 shells as a protection to the iron core from being corroded or dispersed in acid solution. Their results have demonstrated that the adsorbent coating of the functionalized material, Fe_3O_4/SiO_2/SH showed an excellent adsorption property due to its superior adsorption capability with a rapid adsorption rate. The adsorbent exhibited a good adsorption capacity of 132.0 mg/g owing to the powerful interaction between the -SH group of the adsorbent material and the mercury. They were able to observe that the presence of the -SH groups and was also responsible for the step-up of the adsorption capacities model. The R^2 values were 1.00, 0.920, 0.985, and 0.934 for Langmuir, Freundlich, Temkin, and D-R isotherm models respectively. All R^2 > 0.920 implies that all four isothermal data could be used to explain the equilibrium adsorption process of the Hg(II) unto adsorbent. Additionally, the adsorption mechanisms depended mostly on the electrostatic interactions of the active sites of the adsorbent and the

Hg(II). Furthermore after five rounds of adsorption-desorption studies, the high adsorption capacity of the adsorbent was achieved in the first round and the subsequent values for the second to fifth rounds as 51.1, 42.3, 40.5, and 34.3 mg/g, respectively.

In another related development, Ghorbani et al.[84], a new adsorbent from magnetic-ethylene-diamine-modified graphene oxide (MEDFGO) was prepared to remove Cd(II) and Pb(II). The purpose of the modification with EDTA was to enhance the adsorption process through the $-NH_2$ functional groups. FTIR results showed the functional groups of C-O, C-N from amide, and C-N from amine at 1624, 1400 cm^{-1}, and 1045cm^{-1}, respectively, indicating the interaction between graphene oxide and ethylenediamine and the presence of a peak at 578 cm^{-1} from Fe_3O_4. This confirmed the successful binding of EDFGO and Fe_3O_4. The optimized parameters, namely pH, sorbent dosage, shaking rate, and desorption time, were found to be 6, 33.0 mg, 500 rpm, and 11 mins, respectively. The adsorption capacity of Pb(II) as well as Cd(II) onto the synthesized adsorbent was 10.9 and 10.3 mg/g, respectively. The pseudo-first order and pseudo-second-order equations, both well interpreted the kinetic process with R^2 (0.9102-0.9901) and R^2 (0.9584-0.9935) for Pb (II) and Cd (II), respectively. The Freundlich model data for the metal ions adsorption was better fitted with R^2 0.9719 and 0.9795 for Pb(II) and Cd(II), respectively. The Langmuir model with R^2 0.0100 and 0.9630 for Pb(II) and Cd (II), indicated a heterogeneous adsorbate and a multilayer active sites adsorbent interaction. The thermodynamic parameters were well fitted for both Pb(II) and Cd(II) with R^2 0.9908 and 0.9894 respectively. Meanwhile, the ΔH, ΔS, and ΔG were 37.50KJ/mol, 217.08J/molK, and -39.13KJ/mol and 31.82KJ/mol, 176.12J/molK, and -30.35KJ/mol for Pb(II) and Cd(II) respectively indicated and endothermic as well as the spontaneous process of adsorption. Furthermore, the metal ions removal was discovered to be 99.6 and 99.4% for Pb(II) and Cd(II) respectively recovery after six times of the adsorption-desorption experiment. Santhosh et al.[85] synthesized a new MNPs composite adsorbent of (SiO_2/Co/Fe_3O_4) nanoparticles, amine-functionalized with APTES (SiO_2/Co/Fe_3O_4/NH_2) adorned on graphene oxide by using solvothermal along with sol-gel processes to generate the adsorbent (SiO_2/Co/Fe_3O_4/NH_2/GO) and applied the adsorbent for the removal of organic (black dye 1) and inorganic pollutants (Cr(VI) in effluent solutions. The purpose of the modification with APTES was to enhance the adsorption process through the $-NH_2$ functional groups. FTIR characterization showed the presence of the functional groups of Si-O-Si in SiO_2 coating of Fe_3O_4, $-NH_2$ in APTES functionalization and (epoxides, -OH, and -COOH) groups from GO to confirm the successful synthesis process. The results showed that the synthesis processes were well captured in the characterization methods which showed that the SiO_2/Co/Fe_3O_4/NH_2/GO adsorbent was of good quality. Furthermore, black dye 1 and Cr(VI) had respective adsorption capacities of 130.7 and 136.4 mg/g on the SiO2/Co/Fe3O4/NH2/GO adsorbent, which were well fitted into the Langmuir isotherm than the Freundlich with R2 close to unity. . More so, the results showed that the adsorption was influenced by a maximum value of PH 2. Additionally, the kinetics study interpretation showed compliance with the pseudo-second-order kinetics model with a good fit for both pollutants. Furthermore, the adsorption-desorption studies demonstrated that SiO_2/Co/Fe_3O_4/NH_2/GO could retain its potential with 92% and 65% of Black dye 1 and Cr(VI), respectively even after five rounds to prove its worthiness as a material. Hence, it could be concluded that the material was good for the removal of organic and inorganic pollutants in effluent solutions.

Conclusion

The environmental safety of water supply and efficient management of wastewater remains one of the global concerns. It is discovered that over the last seven years, there have been more notable advances in the development of biopolymer and magnetic-based adsorbents for the removal of pollutants from water and wastewater. The formulation of the adsorbent and the mechanism of the adsorption i.e., chelation, ions exchange, coordination, chemisorption, and electrostatic attraction adsorptions isotherms models, kinetic models, and thermodynamic parameters was applied for the elimination of different heavy metal pollutants in an aqueous environment were specifically discussed. The impact of physicochemical factors on the

performance of these adsorbents was also reviewed. Meanwhile, these magnetic biopolymers sorbents offered a faraway benefit of chemical interaction due to the presence of functional groups like the -OH and -NH_2 groups and magnetic properties for the separation during heavy metal removal. Accordingly, it could be established that the types of functional groups, as well as the surface area presented in the adsorbents, play significant roles in the removal of metals in both aqueous and wastewater environments. It was also discovered in the review that good proportion removal and optimum adsorption capabilities were achieved at optimal conditions. Consequently, the adsorption of these metals was either one of Langmuir, Freundlich, or some additional linear plot adsorption isotherms models. In addition, pseudo-second and first-order kinetics were crucial in determining the nature of the adsorption processes. However, much of the adsorbent produced by the scientists was in an aqueous solution that comprises the heavy metal of concern without the real sample interferences. Therefore, the potential researchers must perform research in real samples as well as in the industrial natural environment.

Acknowledgment

We are grateful for the financial support of the work by Universiti Teknologi Malaysia via the Universiti Teknologi Malaysia Fundamental Research grant (UTMFR, Q.J130000.2554.20H98, reference number PY/2019/02057) and UTMShine grant (Q.J130000.2454.09G30, reference number PY/2020/03555). We would like to acknowledge Ms. Nur Shahz Ereena Zulkifli, Ms. Nur Idayu Mat Ghani, and Ms. Anis Nur Shasha Abdul Halim for their help with language and technical proofreading.

Abstract

Lipid oxidation is the main quandary that causes deterioration of cooking oil quality resulting in off-flavours and an unpleasant odour called rancidity. Oxidative stability can directly affect oil quality and shelf life. Edible oil gets oxidised during processing and storage stages through auto- and photo-oxidations. In addition to this, cooking causes chemical reactions such as hydrolysis, oxidation, and polymerization. Hence, it is imperative to evaluate methods and measures that could maintain the quality of the oil. In addition, it is vital to evaluate the conditions or processes with potentially deleterious effects on oil quality and nutritional benefits to enable avoidance of these negative variables. The rate of oxidation depends on several factors including the presence of oxygen and light, unfavourable storage temperature, fatty acid composition, and cooking conditions and practices. This article reviews the mechanism of auto-oxidation and photo-oxidation, the role of pro-oxidants and antioxidants as well as chemical reactions induced by conventional heating techniques.

Keywords: lipid oxidation, storage conditions, thermal oxidation, oxidative stability, phytonutrient stability

Abstrak

Pengoksidaan lelemak adalah masalah utama yang menyebabkan kemerosotan kualiti minyak masak yang mengakibatkan rasa dan bau (tengik) yang tidak menyenangan. Kestabilan oksidatif secara langsung boleh menjejaskan kualiti minyak dan jangka hayat. Minyak masak akan teroksida semasa pemprosesan dan penyimpanan melalui auto- dan foto-oksida. Di samping itu, proses memasak melibatkan tindak balas kimia seperti hidrolisis, pengoksidaan, dan pempolimeran. Oleh itu, adalah penting untuk menilai kaedah dan langkah-langkah pencegahan bagi mengekalkan kualiti minyak masak. Tambahan lagi, adalah penting untuk menilai keadaan atau proses yang boleh menjejaskan kualiti minyak dan faktor nutrisi untuk mengelakkan pembolehubah negatif ini. Kadar pengoksidaan bergantung kepada beberapa faktor, diantaranya adalah kehadiran oksigen dan cahaya, suhu penyimpanan yang tidak sesuai, komposisi asid lemak, serta keadaan dan amalan memasak. Artikel ini mengkaji mekanisme auto-oksida dan foto-oksida, peranan pro-oksidan dan antioksida serta tindak balas kimia yang disebabkan oleh teknik masakan konvensional.

Kata kunci: pengoksidaan lelemak, keadaan penyimpanan, pengoksidaan terma, kestabilan oksidatif, kestabilan fitonutrien

Introduction

Lipid oxidation

Lipid oxidation is the main process of concern that causes quality deterioration in edible oil that contributes to off-flavors and an unpleasant odor due to oil rancidity. The ability of an oil to withstand oxidation is important, particularly under warm climate conditions in tropical countries, logistics and transportation, unfavorable storage conditions, cooking practices, and extended cooking processes. Oxidative stability is an important indicator of the quality and shelf life of products. Oxidative stability of edible oils is defined as resistance to oxidation during processing, storage, and cooking [1, 2]. The rate of oxidation depends on several factors including the availability of oxygen, the presence of light, and the temperature.

The oxidation process destroys essential fatty acids and promotes the formation of off-flavored and potentially toxic, mutagenic, and carcinogenic new compounds like diacylglycerols, monoacylglycerols, monomers, polymers, free fatty acids, and other oxidative substances. This induces a significant loss of oil quality that promotes changes in functional, sensory properties, nutritional attributes, and safety of oils and food products [3]. The time taken for secondary products to develop from primary oxidation products (hydroperoxides), varies between oils [1]. Oils with significant levels of unsaturated fatty acids are generally more susceptible to the oxidation process [4].

The results of our current review could imply that storage and cooking conditions as well as the choice of cooking oil can have economic ramifications both on a domestic and industrial scale and may potentially be of public health concern. At an industrial scale, current work will enable decisions to be made on storage/transport environments along the logistical supply chain as well as at wholesale and retail sites. The literature search on thermal stability with different cooking techniques and oil selections could serve as a benchmark to educate consumers on appropriate home practices in terms of better heating techniques, oil management and handling, optimum temperatures, and choice of cooking oil to preserve the wholesomeness of the oil. A good quality oil may spoil faster if consumers do not take appropriate measures to control oil integrity. Thus, consumers need to be educated on oil handling during domestic cooking. Such understanding is important to consumers, as any adverse storage and heating conditions will impinge on the shelf life and quality of the oil.

In the following context, the mechanism of auto- and photo-oxidations, the role of pro-oxidants and antioxidants as well as chemical reactions resulting from common heating techniques will be elaborated.

Mechanism of auto-oxidation

Lipid auto-oxidation is a free radical chain reaction, characterized by three stages; initiation, propagation, and termination [1].

Initiation: $RH \rightarrow R\bullet + H\bullet$

During initiation, an endothermic reaction by homolytic cleavage of the covalent bond in the C-H hydrocarbon chain of fatty acid (RH) molecule takes place with the formation of a free hydrogen radical (H•) and fatty acid radical (R•). This reaction may be catalysed the by presence of heat, metal ions, ultraviolet and visible light [1].

Propagation: $R\bullet + O \rightarrow ROO\bullet$

$ROO\bullet + RH \rightarrow ROOH + R\bullet$

Propagation of auto-oxidation generally occurs between oxygen and a highly reactive fatty acid radical (R•) which forms primary oxidative compounds that are highly reactive (peroxyl radical (ROO•)). The unstable peroxyl radical (ROO•) is capable of reacting with unsaturated fatty acids to form a hydroperoxide (ROOH) which is a marker for early oxidation and a newly developed reactive fatty acid radical (R•) that

could initiate further oxidation and a free radical chain reaction. The formation of peroxyl radical (ROO•) and hydroperoxides (ROOH) are dependent on the presence of oxygen and excessive heat [1]. Deterioration starts once the unstable primary oxidative products called peroxides are developed in the oil. This compound is tasteless and odorless.

In the presence of transition metals (like iron (Fe) and copper (Cu) in unrefined oils) and/or at high temperatures, antioxidants in the oils deplete, and unstable hydroperoxides (ROOH) readily decompose to alkoxy radicals (RO) which then form non-volatile secondary oxidation products such as aldehydes, ketones, acids, esters, alcohols, and short-chain hydrocarbons [5]. This reaction occurs rapidly and Fe^{2+} (or Cu^{+}) will degenerate but the regeneration of Fe^{2+} (or Cu^{+}) will be slow.

Fast reaction: Fe^{2+} (or Cu^{+}) + ROOH → Fe^{3+} (or Cu^{2+}) + RO• + OH^{-}
Slow reaction: Fe^{3+} (or Cu^{2+}) + ROOH → ROO • + Fe^{2+} (or Cu^{+}) + H^{+}

Termination: R• + R• → R-R
R• + ROO• → ROOR
ROO• + ROO• → ROOR + O2

In the termination stage of auto-oxidation, sufficiently free radicals interact with one another to form non-radical relatively stable products.

Primary antioxidants like phenols (AH) can promote the termination process hence shortening the propagation sequence in the auto-oxidation mechanism:

Propagation: ROO• + AH → ROOH + A•

Carotenes and vitamin E are extensive molecules (B) with extensively conjugated unsaturation.

Propagation: ROO• + B → ROOB•

The intermediate radicals (A• and ROOB•) are converted to either dimers or substitution products, most importantly these products are free of any undesirable properties [1].

Mechanism of photo-oxidation

Lipid oxidation is hastened by light, especially in presence of photo-sensitizers like chlorophylls [1]. Photo-oxidation generates aliphatic and aromatic oxidized compounds which include ketones, aldehydes, carboxylic acids, fatty acids, esters, epoxides, sulfoxides, sulfones, phenols, anhydrides, quinones, and alcohols.

Sensitizers are aromatic compounds (e.g., fluorescein dyes, methylene blue, and polycyclic aromatic hydrocarbons) that absorb electromagnetic radiation usually from the visible light spectrum. During the photosensitized oxidation process, the sensitizer in the stable ground (^{0}Sen) or singlet state (^{1}Sen) absorbs energy (hv) [that is transferred from light rapidly (in picoseconds)] and becomes excited (^{1}Sen*). This excited-state sensitizer returns to its stable ground state by releasing excess energy as non-radiative heat, electromagnetic radiation (fluorescence and phosphorescence), and other photochemical/ photophysical reactions [6].

Excitation and deactivation of sensitizer: ^{1}Sen + hv ↔ ^{1}Sen*

Reaction of triplet state sensitizers (^{3}Sen*) with substrates; -

Type 1: $^3Sen^* + RH \rightarrow$ (sensitizer H + R•) or ($•R^+ + •Sen^-$)
(Sensitizer H + R•) or ($•R^+ + •Sen^-$) + $^3O_2 \rightarrow$ ROOH

Excited triplet state sensitizers ($^3Sen^*$) can react with the C-H hydrocarbon chain of fatty acid (RH) molecule and form fatty acid free radical which in turn forms hydroperoxide (ROOH).

Type 2: $^3Sen^* + {}^3O_2 \rightarrow {}^1O_2$
$^1O_2 + RH \rightarrow$ ROOH

Excited triplet state sensitizers ($^3Sen^*$) can react with $^3O_2$ to form $^1O_2$. Then, $^1O_2$ reacts chemically or transfers its energy to an acceptor, unsaturated fatty acid, and causes the formation of a hydroperoxide (ROOH).

Pro-oxidants

There are several common physical conditions or environmental states that can promote lipid oxidation. This section will discuss several pro-oxidants that play a role in domestic storage conditions (Table 1) and common heating techniques (Table 2). These environmental parameters and physical conditions modulate the quality of the oil.

Oxygen

Oil degradation upon storage at temperate (-3 to 18 °C) or tropical temperatures commonly occurs due to the interaction of oxygen with fatty acid radical (R•). This involves only the early propagation step of the auto-oxidation mechanism and forms hydroperoxide (ROOH) which is a marker for the early oxidation stage. Daskalaki et al. conducted storage stability studies on virgin olive oils with 1 to 3% headspace (space of a closed bottle). These oils were stored in dark conditions for 15 months at home storage conditions (20±4 °C). It was reported that lower levels of peroxide values with higher retention of polyphenols can be attained with low oxygen (headspace) availability and lower polyunsaturated linoleic acid content [7].

Storage stability of palm, sunflower, and cottonseed oils exposed to light, air, or both light and air were studied for 4 consecutive days. In terms of stability, palm oil, with higher levels of saturation, was most stable followed by cottonseed oil and lastly sunflower oil. Oils exposed to both air and light were found to oxidise fastest. Moreover, the effect of photo-oxidation by light was greater than auto-oxidation by air. To avoid prolonged exposure to light and air, the authors recommend purchasing small packages of oil. In other words, lower oil to volume ratio has shorter exposure and faster use-up of the oil as compared higher oil to volume ratio packaging size [8].

Light

Photo-oxidation involves interaction between a double bond and a highly activated singlet oxygen ($^1O_2$) produced from ordinary triplet oxygen ($^3O_2$). Light has a greater influence and results in a quicker reaction on $^1O_2$ oxidation as compared to auto-oxidation. Exposure to light of shorter wavelengths (<300nm) (higher frequencies) which travels faster and has more energy, therefore leads to a faster oxidation rate of the oil as compared to longer wavelengths (>300nm) [9]. Packaging material and place of storage are therefore crucial to preserve the quality of the oil.

Storage stability of physically refined rice bran oil and binary blends with refined sunflower and safflower oil in different types of packaging (polyethylene terephthalate (PET), laminates, and glass bottles) were studied for 11 months storage period [10]. All the samples were still within limits after 11 months. Blended oils with higher levels of iodine value or saturation exhibited better stability. In terms of packaging, laminate pouches with no light interference were the best with minimum quality parameter changes followed by glass bottles and lastly PET bottles. Laminated pouches and glass bottles are more suitable for longer storage periods since there were no or minimal changes reported with regards to physio-chemical characteristics (peroxide value (PV), free

fatty acid (FFA), color, and p-anisidine value (AnV)) as compared to PET bottles [10].

Nutrient stability of sunflower oils stored in PET clear bottles and exposed to daylight at an ambient temperature of 25 °C were studied for a 10-month storage period [4]. Storage period and PET clear packaging were found to affect the shelf life of oils and result in a drastic loss of antioxidants (total tocopherols (52-64%) and beta-carotene (63-65%)). This implies a protective role of antioxidants against oxidative rancidity. The authors recommend the storage of oils in the dark and at a lower temperature to ensure longer shelf life [4].

Fatty acid composition of oils

Unsaturated fatty acids are more prone to oxidation compared to less unsaturated oils. The iodine value is commonly used as a measure of the relative degree of unsaturation in oil components. Storage stability of sesame oil (control), sesame: rice bran oil blends (80:20 and 20:80), and sesame: mustard oil blends (80:20 and 20:80) were studied for 12 months of storage. Sesame oil has predominantly poly-unsaturated fatty acid (PUFA)-C18:2 (46.74%) and mono-unsaturated fatty acid (MUFA)-C18:1 (37.4%). Blending with rice bran oil resulted in an increase in saturated fatty acid (SAFA)-C16:0 and MUFA-C18:1 as well as a reduction in PUFA-C18:2. Whereas, blending with mustard oil reduced SAFA-C16:0 further. Low SAFA content could be the reason why sesame: mustard oil blends were found to be the least stable based on physicochemical parameters evaluated. Sesame: rice bran oil blends were more stable compared to sesame oil itself [11].

Crude palm oil (CPO), sunflower (SFO), and sesame oils (SO) and their blends binary CPO+(SFO/SO) (3:1, 1:1, 1:3) and ternary CPO+SFO+SO (1:1:1, 2:1:1, 1:2:1, 1:1:2) were tested with regards to storage stability. These oils are unrefined oils purchased from local producers. Traditional processed CPO is obtained by primitive African village methods which involve boiling palm fruitlets, crushing the pulp, and extracting the crude oil. Two series of experiments were conducted. In the first set of experiments, the oils were subjected to heat at 120°C, for 3 hours per day for 60 days in the dark and the second experiment served as a control comparison with unheated oils in the dark for the same storage period. Based on oxidative parameter changes, binary blends of CPO with sesame oil or sunflower oil were most stable compared to the individual oil itself or ternary blends. This oxidative stability can be related to change/increase in saturation as reflected by iodine values [12].

Blends of soybean oil with sea buckthorn oil, camellia oil, rice bran oil, sesame oil, and groundnut oil were stored at accelerated degradation storage conditions of 60°C without the interference of air for 24 days. Blends of soybean oil with sea buckthorn oil responded best, followed by rice bran oil, camellia oil, sesame oil, groundnut oil, and lastly soybean itself. The oxidative stability of the blends increases as the degree of saturation increases [13].

Storage temperature

In a study on shelf-life stability of vitamin A fortified palm oils with varying initial values of PV (< 2, 4, or 9 mEq O_2/kg), oils were flushed with nitrogen in the headspace and stored in amber bottles in the dark at elevated temperatures of 60, 75 and 90°C. It was found that the vitamin A fortified oils in the form of retinyl palmitate oxidized faster in high PV oils with a shelf life ranging from a few days to 3 months based on PV standard (<10 mEq O_2/kg). This is due to the antioxidant nature of vitamin A which reacts against auto-oxidation of the oil. The authors also concluded that it was advisable to fortify oils with low PV value [14].

Following this study, Silalahi et al. studied vitamin A stability in RBD palm olein with PV values of less than 0.5 mEq O_2/kg. Effect of temperature (16-20 °C (cool), 24-29 °C (ambient), or 24-45 °C (seasonal)), as well as packing type (transparent PET bottle, nylon linear low-density polyethylene (LLDPE) (transparent and opaque) pouch or high-density polyethylene (HDPE) jerry can), were compared for 2 years storage period. Vitamin A content reduced to a greater extent at higher temperatures: 45-75% at 24-45°C, followed by 43-49% at 24-29 °C, and lastly 39-45% at 16-20 °C after 2

years of storage period. In terms of packaging material, opaque nylon LLDPE was the most stable followed by transparent PET bottles and lastly HDPE jerrycans. The samples did not have direct exposure to UV or sunlight. However, this deterioration may have occurred due to auto-oxidation by oxygen in the headspace of packaging materials which is highest in HDPE jerrycan followed by PET clear bottles and lastly opaque nylon LLDPE [15].

The solubility of oxygen in crude oil is higher than in refined oil. Crude oils contain transition metals that are reduced in refined oil. These transition metals in crude oil accelerate the oxidation of the oil. Storage stability of crude palm oils produced by either local companies, small producers, or industry was investigated for 3 months storage period at 2 different temperatures (20 and 30 °C). The PV of oils stored at 30°C was higher. Crude palm oil produced traditionally by the small producers had higher levels of FFA, moisture content, deterioration of bleachability index (DOBI), and PV due to poor handling and processing methods (i.e. low level of hygiene, fruitlet bruising during transportation as well as fermentation before threshing, clarification, and storage) compared to local companies and industries [16].

Antioxidants

Antioxidants are the best means of fending off oxidation. Antioxidants can be categorized as natural or synthetic, and differ in their mode of action. Only permitted antioxidants can be used in fats and food according to agreed standards. Butylated hydroxytoluene (BHT) and tert-butylhydroquinone (TBHQ) are common primary antioxidant compounds. The role of synthetic antioxidants (TBHQ, BHT, TBHQ+BHT) or control (without additive) in improving oxidative stability was studied in palm olein, soybean, and linseed oil. The oils were stored at room temperature or 70°C for 168 hours. Based on PVs, palm olein was found to be most stable (22-41% change from baseline), followed by linseed oil (26-43% change from baseline) and lastly soybean oil (320-500% change from baseline) after 168 hours storage period in their natural form. This is attributable to the oil's fatty acid composition, whereby the latter contains a higher amount of polyunsaturated fatty acid (PUFA). Longer storage periods and heat were found to affect the oxidative stability of the oils. In terms of antioxidant stability for palm olein, TBHQ was found to be the best followed by BHT and finally the mix. The mix of BHT and TBHQ was found to be superior for soybean oil and linseed oil compared to BHT and TBHQ by themselves [17].

Oxidative stability of sunflower, corn, extra virgin olive, grape seed, and walnut oils was studied after 5 days of storage at 50 °C. These oils are rich in natural antioxidants such as polyphenols, tocopherols, and vitamin C. Walnut oil was found to have the highest antioxidant capacity and chemical stability followed by olive oil, grape seed oil, corn oil, and lastly sunflower oil. High antioxidant levels were also associated with low PV and FFA content in the oils [18].

Crude oil refining removes toxic and undesirable substances such as mono- and diacylglycerols, pro-oxidants, moisture, FFAs, pigments, volatiles, and contaminants that are detrimental to the flavor, color, stability, or safety of the refined oils. The storage stability of crude and fully refined rice bran oil was studied over 8 months storage period at room temperature with and without the influence of light. Crude rice bran oil was found to have better oxidative stability based on the oil stability index as compared to refined rice bran oil. This is because crude rice bran oil contains a higher level of natural antioxidants such as vitamin E, sterols, and γ-oryzanol that have a synergistic effect with phosphatides. Both the oils were better stored in the dark and sensitive when exposed to daylight [19].

Table 1. Effects of storage conditions on physiochemical parameters of cooking oils

Oil Type	Duration	Storage Conditions	FFA	PV	AnV	TOTOX	extinction coefficients	FAC	Phenolic Compounds	Vitamin E	Carotenes	Antioxidant activity	Rancimat	Summary/ Comments	Ref.
Real storage conditions															
PO vs CSO vs SFO	4 days	Container conditions: 1) Sealed coloured (no light and air) vs 2) Sealed transparent (with light and no air) vs 3) Open transparent (with light and air)	X	X	X									– Stability: PO > CSO > SFO. – Condition stability: 1) no light and air > 2) with light, no air > 3) with light and air	[8]
Cold pressed peanut oil	20 day	Oil without antioxidant addition vs addition of rosemary extract (type Oxy' Less CS) vs ramDOPE vs hpDOPE vs α-tocopherol vs tocopherol mixture vs sage extract vs PG vs BHA		X										– Oxidative stability: PG (best) > rosemary > olive pomace (ramDOPE) > sage extract > olive pomace (hdDOPE) > tocopherol mixture/BHA > control without antioxidants > α-tocopherol	[20]
CPO vs SFO vs SO vs CPO+(SFO/SO) (3:1, 1:1, 1:3) vs CPO+SFO+SO (1:1:1, 2:1:1, 1:2:1, 1:1:2)	60 days	1) Heated at 120°C, 3hr/day x 60days, dark; 2) unheated, dark	X	X										– Storage stability: Binary (CPO+SO> CPO+SFO) > Single (CPO>SO>SFO) > Ternary blends	[12]
CPO (by local company vs small producer's vs industry)	3 months	20 & 30°C	X	X										– Stability: Oils from industry > local company > small producers – Deterioration: 30°C > 20°C	[16]
PO vs SBO vs LSO (TBHQ vs BHT vs TBHQ+BHT vs no additive)	168 hours	RT vs 70°C		X										– Oxidative stability: PO > LSO > SBO – Storage and heat: increase oxidation – Antioxidant stability: i. PO: TBHQ>BHT>mix, ii. SBO& LSO: mix>BHT>TBHQ	[17]
Crude vs refined RBO	240 days (8 months)	Transparent bottles; no exposure to atmospheric oxygen, kept in dark or exposed to daylight at ambient temperature	X					X		X			X	– Oxidative stability: crude > refined RBO – Antioxidant stability: γ-Oryzanol (most stable)> sterol esters > sterols > vitamin E (least stable) – Storage stability: keep in dark > light	[19]
SFO (n=4 with different country of origin)	307 days	Headspace: no protective atmosphere; PET bottles; 21-34°C								X	X		X	– Stability: no difference with different origins. – PET bottles not suitable for long storage period: reduces vitamin E & carotenes. – Advise: store at dark & low temperature for longer storage period	[4]

[a] Abbreviations: AnV: *p*-anisidine value, BHA: butylhydroxyanisole, BHT: butylated hydroxyl toluene, CPO: crude palm oil, CSO: cotton seed oil, DOPE: dry olive pomace extract, FAC: fatty acid composition, FFA: free fatty acid, LSO: linseed oil, PG: propyl gallate, PO: palm oil, PV: peroxide value, RBO: rice bran oil, SBO: soyabean oil, SFO: sunflower oil, SO: sesame oil, TBHQ: tert-Butylhydroquinone, TOTOX: total oxidation value

Oil Type	Duration	Storage Conditions	FFA	PV	AnV	TOTOX	extinction coefficients	FAC	Phenolic Compounds	Vitamin E	Carotenes	Antioxidant activity	Rancimat	Summary/ Comments	Ref.
RBO vs RBO+SAF (20:80) vs RBO+SFO (60:40)	11 months	Packaging materials: bottles (PET vs glass) vs laminated pouches; 25°C	X	X	X			X						– Stability: RBO+SAF > RBO+SFO > RBO. – Stability: Laminated pouches and glass bottles > PET bottles	[10]
SO vs blends SO+RBO vs SO+MO (80:20 & 20:80)	12 months	PET clear bottles at RT	X	X	X	X		X						– Blends of SAFA: MUFA: PUFA at 1:1:1 is recommended to increase stability.	[11]
VOO (Lianolia vs Koroneiki variety)	15 months	Headspace: 1-3%, Dark; 20± 4°C		X					X					– Oxygen exposure: increase in PV correlates with reduction in phenolic compounds and formation of oxidized phenolic compounds	[7]
PO+Vitamin A	16 & 24 months	1) Temperature:16-20°C(cool) vs 24-29°C(ambient) vs 24-45°C (seasonal); 2) Pack type: PET bottle vs nylon LLDPE pouch vs HDPE JC; 3) Packaging type: transparent PET vs opaque nylon vs LLDPE pouch		X							X			– Vitamin A Stability: 16-20°C > 16-20°C > 24-45°C; – Packaging stability: opaque nylon LLDPE > transparent PET > HDPE jerrycan	[15]
Schaal oven test															
Vitamin A fortified palm oil with varying PV values; 2 vs 4 vs 9 mEq O_2/kg		Headspace: flushed with N_2, amber bottles in dark; 60, 75 & 90°C		X							X			– Shelf life of RPO: 3-30days. – Increase in PV causes decrease in vitamin A retention. – Fortification of vitamin A should be done on low PV oils	[14]
SFO vs CN vs EVOO vs GSO vs COC vs WNO	5 days	50°C, light, atmospheric oxygen	X	X								X		– Antioxidant activity decreases as FFA and PV increase	[18]
SBO vs SBO+CAO vs SBO+SO vs SBO+RBO vs SBO+GNO vs SBO+SEBO	24 days	60°C, dark, no headspace		X	X		X							– Stability: SBO+SEA > SBO+RBO >SBO+CAO > SBO+SEBO > SBO+GNO > SBO	[13]

[a]Abbreviations: AnV: p-anisidine value, CAO: camellia oil, CN: corn oil, COC: coconut oil, EVOO: extra virgin olive oil, FAC: fatty acid composition, FFA: free fatty acid, GNO: groundnut oil, GSO: grape seed oil, HDPE: high density polyethylene, LLDPE: linear low density polyethylene, MUFA: mono-unsaturated fatty acid, MO: mustard oil, PET: polyethelene terephthalate, PO: palm oil, PUFA: poly-unsaturated fatty acid, PV: peroxide value, RBO: rice bran oil, RBO: rice bran oil, RT: room temperature, SAF: safflower oil, SBO: soyabean oil, SAFA: saturated fatty acid, SEBO: sea buckthorn oil, SFO: sunflower oil, SO: sesame oil, TOTOX: total oxidation value, VOO: virgin olive oil, WNO: walnut oil.

The addition effect of natural [rosemary extract, sage extract, DOPE-dry olive pomace extract (type hpDOPE and ramDOPE), α-tocopherol and mixtures of tocopherols] and synthetic antioxidants [propyl gallate (PG) and butylhydroxyanisole (BHA)] were evaluated with regards to the oxidative stability (PV) of cold-pressed peanut oil compared to control (oil without antioxidants) for 20 days. Propyl gallate provided the best antioxidant protection, followed by rosemary extract (type OxyLess CS), olive pomace (ramDOPE), sage extract, and olive pomace (hdDOPE), both tocopherol mixture and BHA had equal antioxidant capacity, followed by control oil without antioxidants and the least in the order was α-tocopherol [20].

Chemical reactions during cooking

Cooking oils are an essential part of our daily diet preparations. Some cooking oils are rich in heat-sensitive nutrients that offer varying health benefits. The nutritional content of the oils is affected by different cooking techniques such as deep-frying, pan-frying, conventional oven baking and roasting as well as microwave heating. Table 2 summarizes the effects of several heating techniques under real and simulated cooking conditions on several analytical parameters.

Frying is the oldest method of food preparation. There are different frying techniques namely pan-frying, deep-frying, shallow frying, and stir-frying. The difference lies in the amount of oil used, the latter using lesser oil [21]. The frying technique transfers heat through the convection of oil directly from a heating element [22]. Moving forward in history, the conventional oven revolutionized methods of cooking. The conventional oven operates by transferring heat through convection but uses air as a heat transfer medium [22]. Roasting and baking are common cooking techniques of the conventional oven, which primarily operates by convection of air and secondarily radiation from the oven walls and conduction from the baking pan. The roasting technique requires comparable amounts of fat compared to pan-frying but is highly prone to oxidation as a higher surface area is exposed to convection hot air and for a longer processing time [21]. The microwave oven is a modern technique for heating food through the conversion of electromagnetic energy to thermal energy. A microwave oven heats food faster due to the direct penetration of microwaves into food materials compared to conventional heating on a stove or oven. However, a major hitch to this technique is non-uniform heating that could be influenced by microwave cavity design, food physical properties, and food geometry [23]. Different cooking techniques and operation conditions undoubtedly will impact the physicochemical properties of the oil. The following section will discuss chemical reactions induced by heating which include hydrolysis, oxidation, and polymerization.

Hydrolysis

The FFA concentration is one of the most important indicators of oil deterioration during heating. The formation of FFA is due to the hydrolysis of triacylglycerol (TAG) and hydroperoxide (ROOH) decomposition in oil during heating in the presence of moisture and air. At simulated heating conditions, heating at 180 °C was reported to discourage major triacylglycerol hydrolysis [24, 25, 22]. However, in the presence of a food matrix, the acidity values rapidly increased with frying time probably due to moisture content in the presence of food [26, 27]. The formation of FFA is associated with smoke points [28]. An increase in FFA has an inverse association with the smoke point [3]. The smoke point of fats/oils decreases when the fat begins to break down into FFA, monoacylglycerols (MAG), diacylglycerols (DAG), and volatile compounds [28].

Table 2. Effects of different heating techniques on physiochemical parameters of cooking oils

Heating Technique	Oil Type	Food Matrix	Heating Conditions	FFA	PV	AnV	TOTOX	extinction coefficients	FAC	Polar compounds	Phenolics	Vitamin E	Carotenes	Rancimat	Summary/ Comments	Ref.
DF	EVOO vs VOO (Year 2004) vs VOO (Year 2005) vs refined OO+VOO blend vs SFO	Potatoes	170°C; 27 hr (9h/day); 120min X 10sessions/day; NR	X	X	X		X	X	X				X	Stability: SFO least, OO groups similar	[34]

Heating Technique	Oil Type	Food Matrix	Heating Conditions	FFA	PV	AnV	TOTOX	extinction coefficients	FAC	Polar compounds	Phenolics	Vitamin E	Carotenes	Rancimat	Summary/ Comments	Ref.
DF	11 oils: (1) Singular oils: POo/SBO/CO/SFO vs (2) binary blends POo+ SBO/CO/SFO at (90:10)/(50:50) ratios vs (3) Tertiary blend POo+SBO+CO (40:50:10)	Potatoes	180°C; 8 hr/day x 9 days; 144 sessions; FR											X	Blending unsaturated oils with POo improved oxidative stability.	[31]
DF	RBD PO	chicken	150, 200 & 250°C; 1 day (8 hr/day); 10 min/ sessions (48 sessions)						X						Temperature >200°C causes PUFA isomerization and trans formation. FAC composition of chicken= oxidised oil: proves absorption of harmful compounds.	[45]
DF	15 EVOO samples	Gelatinized maize starch	180°C; 30min / session x 2												Long exposure to heat cause formation of toxic volatile compounds	[49]
DF	Palm products (RBD PO vs SFPO vs DFPO vs RPOo vs PBS) vs HOSFO	Simulation	180°C; 10 days (8 hr day-1), FR	X		X				X		X			RBD PO, SFPO and DFPO most stable	[3]
DF	EVOO Italian vs Portuguese	Simulated	180°C; 3hr		X						X	X			Fluorescence spectroscopy suitable for EVOO quality characterization	[39]
DF	VOO (Lianolia vs Koroneiki variety)	Simulated	180°C; 0-60mins	X	X			X			X				Thermal oxidation: increase in PV correlates with decrease in phenolic compounds & formation of oxidized phenolic compounds	[7]
DF vs PF	EVOO vs SFO+CSO+POo blend	Potatoes	170°C, 12min X 10sessions (1 day); NR	X	X			X	X	X	X	X		X	Stability: deep-fry > pan-fry; Oil stability: EVOO > SFO+CSO+POo blend	[30]
H	VOO (Lianolia vs Koroneiki variety)	Simulated	100°C; 1-4 hr	X	X			X			X				Phenolic compounds stable at 100°C	[7]
H	PO+Vitamin A (45ppm vs 225ppm)	Simulated	180°C; 5 minutes	X	X								X		Low level of oxidised oil is suggested for vitamin A fortification	[15]
MV	EVOO (NE Portugal) vs EVOO (Central Portugal) vs VOO (South Portugal)	Simulated	1000W, 0-15 minutes	X	X			X				X	X		Stability: EVOO>VOO	[25]
MV	4 types of OO	Simulated	1000W, 0-15 minutes	X	X			X			X		X		Microwave is encouraged only for short period of heating	[24]

[a]Abbreviations: AnV: *p*-anisidine value, CO: canola oil, CSO: cottonseed oil, DF: deep frying, DFPO: double fractionated palm olein, EVOO: extra virgin olive oil, FAC: fatty acid composition, FFA: free fatty acid, FR: frequent replenishment, H: heating, MV: microwave oven, NR: null replenishment, OO: olive oil, PF: pan frying, PO: palm oil, POo: palm olein, PV: peroxide value, PUFA: poly-unsaturated fatty acid, RBD: refined bleached deordarised, SBO: soybean oil, SFO: sunflower oil, SFPO: single fractionated palm olein, TOTOX: total oxidation value, VOO: virgin olive oil

Table 2. Effects of different heating techniques on physiochemical parameters of cooking oils (continued)

Heating Technique	Oil Type	Food Matrix	Heating Conditions	FFA	PV	AnV	TOTOX	extinction coefficients	FAC	Polar compounds	Phenolics	Vitamin E	Carotenes	Rancimate	Summary/ Comments	Ref.
MV vs. OVN	ROO vs EVOO	Simulated	MV:500W, 0-30 min		X			X	X						Microwave not significantly higher than conventional oven	[38]
			OVN:1200W, 0-30 min		X			X	X							
MV	SO vs SBO	Simulated	low power: 500W vs medium power:650W vs high power:800W, 0-20 minutes	X	X	X									Stability: SO > SBO; Higher power > degradation	[26]
		chips		X	X	X										
MV	S-LO vs NS-LO	Simulated	1000W, 0-5 min	X	X	X	X	X							Stability: S-LO < NS-LO, PUFA oils not suitable for heat treatment	[36]
MV	Pork lard vs SFO vs RAP vs GNO vs HO-GNO	Simulated	500W, 0-40 min	X				X							Stability: HO-GNO > pork lard > RAP > GNO > SFO. PUFA oil least stable	[33]
MV	POo vs SFO vs POo+SFO blend	Simulated	Medium power setting, 0-20 min	X	X	X	X	X	X	X					Stability: POo > POo+SFO > SFO	[41]
MV	SFO vs CO	Simulated	700W, 0-10 min (Magnetron pause of total heating time: 10% vs 30%)		X	X		X	X			X			Stability: CO > SFO Magnetron pause: 30% better than 10% (higher vitamin E & lesser oxidative compounds	[40]
MV vs. OVN	R-SFO vs R-SFO+GSE (200, 400, 600, 800 and 1000ppm) vs R-SFO+BHT (200ppm)	Simulated	MV: 900W, 0-240 min		X	X	X	X			X				Microwave had higher oxidation values than oven; R-SFO+GSE >600ppm better than SFO+BHT	[37]
			OVN: 1200W, 0-240 min		X	X	X	X			X					
MV vs. OVN	ROO vs EVOO	Simulated	MV: 500W, 0-30 min		X			X	X						Microwave not significantly higher than conventional oven	[38]
			OVN: 1200W, 0-30 min		X			X	X							
MV	4 types of OO	Simulated	1000W, 0-15 min	X	X			X			X		X		Microwave is encouraged only for short period of heating	[24]
DF vs MV vs OVN	RPOo vs POo	Simulated	170°C; 3 hr deep-fat fryer vs microwave oven vs conventional oven	X	X	X	X		X			X	X		Stability: POo>RPOo; POo: stable for all 3 heating techniques; RPOo: not suitable for prolonged heating when carotenes retention is of concern	[22]

[a]Abbreviations:
AnV: *p*-anisidine value, BHT: butylated hydroxytoluene, CO: canola oil, DF: deep frying, EVOO: extra virgin olive oil, FAC: fatty acid composition, FFA: free fatty acid, GNO: groundnut oil, GSE: grape seed extract, HO: high olein, MV: microwave oven, NS-LO: non-stripped linseed oil, OO: olive oil, OVN: conventional oven, POo: palm olein, PUFA: poly-unsaturated fatty acid, PV: peroxide value, RAP: rapeseed oil, ROO: refined olive oil, RPOo: red palm olein, R-SFO: refined sunflower oil, SBO: soybean oil, SFO: sunflower oil, S-LO: stripped linseed oil, SO: sesame oil, TOTOX: total oxidation value

Oxidation

Three types of oxidations take place during the heating process namely autoxidation, thermal oxidation, and photosensitized oxidation. The science behind thermal oxidation is principally similar to the mechanism of auto-oxidation that involves initiation, propagation, and termination. However, the rate of thermal oxidation is faster compared to autoxidation [29]. The induction period is the point where rapid changes occur as a result of oxidation, usually measured by the Rancimat method and expressed in hours. The time taken for secondary reaction products to appear is known as the induction time, induction period, or Oil Stability Index (OSI) [2]. The induction period of the oil was reported to decrease over time with heating [30, 31]. The reduction in the induction period is more prominent in oils containing high amounts of unsaturated fatty acids especially PUFAs [32]. Conjugated dienes are formed corresponding with the formation of linoleic acid hydroperoxide as an early indicator of lipid oxidation [33]. The UV-Vis extinction coefficients K_{232} and K_{270} are other analytical measures that relate to the content of conjugated dienes and trienes in the oil. High PUFA content oils were found to increase these coefficient values faster as compared to monounsaturated and saturated oils subjected to deep-frying [34, 35], pan-frying [30], microwave oven [24,33,36], and conventional oven [37, 38]. Conjugated dienes and peroxides are highly unstable primary intermediate oxidation products of oil which lead to the formation of a complex secondary mixture of volatile compounds such as aldehydes, ketones, hydrocarbons, alcohols, and esters [29]. A reducing trend of PV however was observed by Cheikhousman et al. proving the transformation of unstable primary oxidation products to secondary oxidation products [39]. Peroxides, therefore, are not a good index of oxidation measurement.

Anisidine values (AnV) represent the level of non-volatile aldehydes, primarily, measuring the presence of 2-alkenals and 2,4-alkadienals generated in the fat during the decomposition of hydroperoxides [5]. A progressive increase in AnV was observed with deep-frying [34, 35], microwave [36, 40, 41] and conventional oven [37, 22] heating. The total oxidation (TOTOX) value is an extension of AnV method given as the sum of two times PV and AnV, which is an important evaluation parameter for the overall oxidation state. At low temperatures and a short storage period, the formation of oxidation compounds is slow; hydroperoxides are the major compounds formed. Whereas during heating (high temperatures), the formation of secondary oxidation products is very rapid. Hence, AnV dominates TOTOX value during heating while PV dominates TOTOX value upon storage. Therefore increase in TOTOX value by deep-frying [42], microwave oven [36, 33, 41], and conventional oven [37, 22] is known to reflect a better approximation of the development of oxidative deterioration as it measures both hydroperoxides and secondary breakdown products.

Linoleic acid (C18:2) is highly susceptible to oxidation. The degree of oxidative deterioration is namely evaluated by the ratio of C18:2/C16:0 and is reported to decrease upon prolonged heating by deep-frying [32, 43, 44], pan-frying [30] and microwave oven [40, 41], with a greater degree of saturation. Oil degradation during heating decreases the levels of PUFA, increases the saturated fatty acid content [38, 40, 45, 34, 42], and increases C18 trans [45]. Trans fatty acids are produced from cis-unsaturated fatty acids upon heating of oils at high temperatures and by the hydrogenation process. The chemical structure of the carbon chain of trans fatty acids is more stable than that of cis fatty acids when exposed to heat [46]. The fatty acid composition of the food matrix was found to be similar to the immersed cooking oil during deep-frying, this study implied that harmful oxidative products would be absorbed by the food matrix [45].

Oxidative degradation of oils during heating depends on the fatty acid composition, especially PUFA content as well as the content of natural antioxidants [33]. Minor component losses were also reported by some authors with heat exposure. Antioxidants like polyphenols [30, 39, 7, 24, 37], vitamin E [39, 30, 47, 22], carotenoids [25, 24, 22], vitamin A [15] and chlorophylls [25] were found to degrade upon prolonged heat exposure.

Polymerization

Oil endures hydrolysis, oxidation, and polymerization upon heating, resulting in the formation of decomposition by-products such as non-volatile polar

compounds and triacylglycerol dimers and polymers. The total polar compounds characterize the fatty acid degradation products with higher polarity and molecular weight than initial triglycerides present in the oil with heat exposure. Total polar compounds are a widely accepted indicator to measure fat degradation [21]. Total polar compounds were found to increase with heating time and were greater in oils with a higher degree of unsaturation with heat exposure e.g. deep frying [34], microwave oven [41], and pan-frying [30]. A weak correlation was found between diacylglycerols and total polar compounds, this negates the concern that oils with high natural diacylglycerol content result in a higher rate of formation of total polar compounds upon heating [27].

Polymers are formed in heated oils [33, 47]. These polymers accelerate the oxidation of oil and lead to some physical changes in oil such as an increase in viscosity, color, and foam as well as a decrease in smoke point. An increase in polymers [29] or oil viscosity [48] causes high oil absorption in food. Viscosity was reported to increase with prolonged heating by deep-frying [48, 44] and microwave oven heating [41]. Additionally, prolonged exposure of PUFAs to heat also causes neo-formation of harmful volatile compounds such as acrolein and crotonal [49].

Conclusion

Translating the results of the current review into daily diet application/recommendations for the public's benefit, our research has demonstrated that consumers need to be educated and exposed that cooking oil should be placed away from heat and light to preserve oil quality and phytonutrient content. In addition, it is advisable to keep air to oil interface minimal in a closed handling system for both storage and heating purposes. Polyunsaturated oils are very susceptible to oxidation. Saturated or blended oils are recommended for long cooking processes to maximise the quality of oil and delay the onset of lipid oxidation. Antioxidants are desirable to increase the oxidative stability of the oil, but they degrade at unsuitable storage conditions and with prolonged heating.

Abstract

Wet chemical synthesis has received much attention to develop a wide array of metal oxide nanoparticles (MONPs) due to its low production cost, simplicity, and ability to produce ultrafine products. In recent years, room temperature ionic liquids (RTILs) as a superior solvent, have managed to produce excellent properties of MONPs that are gaining attention due to excellent physical properties such as small particle size, high surface area, and high porosity. To date, the abundance of available data on MONPs can now be used by researchers to establish suitable methods for producing high-performance materials particularly to suit specific applications. However, there is very limited information on the synthesis mechanisms and common characterization methods used in the preparation of MONPs using RTILs. Therefore, this paper aims to provide a comprehensive review on the MONPs synthesis methods using RTILs via sol gel, hydrothermal, microwave assisted, ultrasonic assisted, and precipitation method alongside the characterization by spectroscopic and microscopic techniques. In this article, various fabrication methods to synthesize MONPs with different morphologies and sizes are reviewed. Also, a step-by-step approach on the mechanisms to improve MONPs properties and impacts of RTILs on the formation of MONPs is highlighted. Finally, the potential of MONPs as antibacterial and catalyst are discussed.

Keywords: characterisation, ionic liquid, synthesis, metal oxide

Abstrak

Sintesis kimia basah telah mendapat banyak perhatian untuk membangunkan pelbagai jenis nanozarah oksida logam (MONPs) kerana kos pengeluarannya yang rendah, kesederhanaan dan keupayaan untuk menghasilkan produk ultrahalus. Dalam beberapa tahun kebelakangan ini, cecair ionik suhu bilik (RTILs) sebagai pelarut unggul, telah berjaya menghasilkan ciri-ciri terbaik MONPs yang mendapat perhatian kerana sifat fizikal yang sangat baik seperti saiz zarah yang kecil, luas permukaan yang tinggi, dan keliangan yang tinggi. Sehingga kini, banyaknya data yang tersedia mengenai MONPs kini boleh digunakan oleh penyelidik untuk mewujudkan kaedah yang sesuai untuk menghasilkan bahan berprestasi tinggi terutamanya untuk disesuaikan dengan aplikasi tertentu. Walau bagaimanapun, terdapat maklumat yang sangat terhad mengenai mekanisme sintesis dan kaedah pencirian biasa yang digunakan dalam penyediaan MONPs menggunakan RTILs. Oleh itu, kertas kerja ini bertujuan untuk memberikan ulasan komprehensif tentang kaedah sintesis MONPs menggunakan RTILs melalui sol gel, hidroterma, dibantu gelombang mikro, dibantu ultrasonik, dan kaedah pemendakan di samping pencirian oleh teknik spektroskopi dan mikroskopik. Dalam artikel ini, pelbagai kaedah fabrikasi untuk mensintesis MONP dengan morfologi dan saiz yang berbeza disemak. Juga, pendekatan langkah demi langkah mengenai mekanisme untuk menambah baik sifat MONPs dan kesan RTILs terhadap pembentukan MONPs diserlahkan. Akhir sekali, potensi MONPs untuk menghalang bakteria dibincangkan.

Kata kunci: pencirian, cecair ionik, sintesis, logam oksida

Introduction

Metallic elements can be transformed using various techniques to metal oxides nanoparticles (MONPs) with unique properties such as high surface to volume ratio, reduced surface imperfections, and superior magnetic, optical, electrical, and catalytic capabilities that are correlated to their size and distinct than their bulk materials [1-5]. MONPs are trendy in various applications, namely the health industry [6], textiles industry [7], in the cosmetic industry as antimicrobial agents [8] and the photocatalyst field [9, 10]. The designation of an experimental procedure for the synthesis of MONPs is an important aspect of nanotechnology with a size range of 1 to 100 nanometres (nm) [11]. With these demands, remarkable researches have been performed to prepare a variety of MONPs from d and f blocks elements in the periodic table such as iron oxide (Fe_2O_3) [12], magnesium oxide (MgO) [13], manganese oxide (MnO_2) [14, 15], zinc oxide (ZnO) [16], titanium oxide (TiO_2) [17], copper oxide (CuO) [18], zirconium oxide (ZrO_2) [19], silica oxide (SiO_2) [20], cerium oxide (CeO_2) [21], samarium oxide (Sm_2O_3), lanthanum oxide (La_2O_3) , ytterbium oxide (Yb_2O_3), and scandium oxide (Sc_2O_3). In general, there are two types of strategies to produce MONPs:

i) Top-down method: physical approaches which involve the fragmentation of bulk material into smaller fine particles up to nanoparticle sizes. This method uses several techniques such as ion and ball milling [22, 23], laser ablation [24, 25], chemical vapor, and deposition pulsed-laser deposition [26]. Moreover, this method requires the availability of tools or instruments and a competent operator to perform the specific techniques.

ii) Bottom-up method: tailor-made process using biological method such as plant extract [27, 28], fungi [29], and chemical method such as precipitation [30, 31] , sol–gel [32, 33], hydrothermal [34, 35], and microwave-assisted synthesis [36]. This method offers several advantages including a narrow size distribution, minimal energy usage, low processing temperatures for thermolabile materials, and low cost [37]. Moreover, these methods control the size and structures of MONPs by initiating kinetic energy within the particles to prevent clusters from accumulating [38, 39, 40].

Among the available methods to synthesize MONPs, the chemical method provides promising strategies owing to simpler procedures, ability to control reaction temperature, and high reproducibility [41]. The chemical method involves four main stages which are the formation of precursor, nucleation, growth, and ageing processes that can be controlled to obtain the desired size and shape [42]. To synthesize MONPs using the chemical method, a strong fundamental understanding of the method is required. Chemical methods have gained prominence for the synthesis of MONPs because of their mono-dispersive and non-agglomerative properties, which could be achieved by stabilising MONPs with capping agents especially during the growth stages [43]. This is because Ostwald ripening tends to occur during growth stages as it is a thermodynamically spontaneous process that leads to

agglomeration of the MONPs [44].Therefore, stabilizers or capping agents are needed for the synthesis of small MONPs as a protective layer that shields the particles from each other. Currently, several types of capping agents have been reported for the synthesis of MONPs such as tri-*n*-octyl phosphine oxide, dodecyle amine [45], aniline [46], polyethylene glycol [47], tetraoctyl ammonium bromide [48], hybrid poly(ethylene glycol), polyvinyl alcohols [49], octylamine [50], and room temperature ionic liquids (RTILs) to control the size of the MONPs.

The desired properties of RTILs are in terms of viscosity, conductivity, density, and thermal stability which could be regulated by altering the length of the alkyl chain of cations [51]. The synthesis of MONPs using RTILs has been proven to be environmentally friendly because RTILs can be reused and recycled for another cycle [52, 53]. Furthermore, due to their non-volatility characteristic, RTILs do not contribute to air pollution, and are deemed suitable and safe for industrial applications. The utilization of RTILs as a capping agent in the synthesis of MONPs has gained the attention of researchers due to their ability to produce an aggregation-free-end product, mainly due to the ionic liquid stabilization [54-58]. This is due to: (1) the unique structure of RTILs, cationic-anionic layers from RTILs surrounding the MONPs can generate a great electrostatic force between the MONPs [59], (2) the double-layered RTILs offer electrostatic interactions that can prevent MONPs from aggregating by balancing van der Waals interactions between the MONPs [60], (3) the alkyl side-chains of RTILs stretching far from the MONPs surface lead to a secondary steric stabilization to block the MONPs from approaching each other [61], and (4) the stabilization approach which involves hydrogen bonding from inter RTILs structure and intra RTILs-MONPs surfaces that may improve the synthesis of MONPs [62]. Common RTILs used as capping agents in the synthesis of MONPs involve groups from imidazolium [63], ammonium [30], choline [64], and pyrrole based RTILs [30, 65]. The use of RTILs as a capping agent has been proven to solve the agglomeration problem that usually occurs during the synthesis of MONPs. RTILs have been proven earlier as effective stabilizing agents in the formation of silver NPs [66], cadmium sulphide quantum dots [67], and silver/copper oxide/bentonite nanocomposites [68]. Moreover, RTILs can be used as a capping agent to control the size and shape of MONPs by manipulating the alkyl chain of cations or anions to achieve controllable physical properties [69, 70].

Numerous literature reviews have been published by researchers dedicated to the synthesis of MONPs concerning the utilization of RTILs. In 2011, Abbot et al. [71] provided a critical review on the processing metal and MONPs using RTILs. However, the review covered the role of RTILs in the extraction method to gain high purity metal and MONPs via physical synthesis only. In addition, review articles by Prechtl 2013 [72] and Seitkalieva et al. [73] on the synthesis of MONPs in RTILs covered the catalysis application and did not include a detailed mechanism on the formations of these MONPs in RTILs. Furthermore, there is limited information appertain to the roles of RTILs as a capping agent in the formation of MONPs in the chemical method, especially during the four important stages. In 2017, He and Alexandridis [2] reviewed the utilization of RTILs in MONPs, focusing on the hybrid benefits of MONPs and RTILs in the catalyst, electrochemical, and separation applications, The article only focussed on the emerging applications for the hybrid MONPs dispersed in RTILs. Furthermore, besides the essential contributions of RTILs in a variety of synthesis techniques and their excellent potential, the performances of MONPs in RTILs via chemical method should be emphasized. Therefore, attention must be given to the synthesis of MONPs via chemical method since these materials with smaller size are in great demand in various applications.

The present work will review the progress of the chemical method to synthesize MONPs using RTILs to produce excellent performances of MONPs. Subsequently, the characterization of MONPs involving transmission electron microscopy (TEM), scanning electron microscopy-energy dispersive X-ray (SEM- EDX), X-ray diffraction (XRD), ultraviolet visible (UV-Vis), and Fourier transforms infrared (FTIR) will be discussed herein along with the impacts and influences of RTILs in the MONPs synthesis. This review highlights the applications of MONPs in several sectors including antibacterial, catalysts, and others applications.

A step-by-step approach on the formation of MONPs via RTILs

As an alternative to the conventional organic molecular solvents, RTILs are used as a capping agent in the synthesis of MONPs. A capping agent is defined as an amphiphilic molecule consisting of a polar head

and a non-polar hydrocarbon tail. Both parts depend on the effectiveness of the capping agent, where the non-polar tail interacts with the medium around it, while the polar head coordinates with the metal atom [74]. A brief mechanism on the formation of zirconium oxide (ZrO2) NPs has been explained in our previous study [75]. Figure 1 depicts the reaction of the capping agent towards MONPs during the synthesis where each MONPs is well separated, thus reducing the risk of agglomeration. Typically, the formation of precursor molecules occurs during hydroxylation and hydrolysis reactions, creating a metal of zero charges [37]. Whereby, the metal hydroxides that are formed (formation of M-OH, where M is the metal) then take part in the condensation reactions lead to the nucleation of the solid material [76].

Nucleation is the second step in the preparation of MONPs, where the nuclei or seeds function as a template for crystal growth [1]. For example, the addition of reducing agent sodium hydroxide (NaOH) into the metallic precursor (zirconium chloride, $ZrCl_4$) solution causes the metal ion of Zr^{4+} to reduce to metal atom (Zr^0), creating supersaturated zirconium hydroxide (Zr-OH) that subsequently undergo nucleation [77]. Having said that, it is very important to control the concentration of NaOH in this step as it can indirectly affect the production of MONPs. For instance, if a lot of OH^- is produced in a short period, the metal ions in the solution will quickly precipitate due to the high pH environment, causing the metal ions to only have a minimal contribution to MONPs growth, prohibiting further growth of the MONPs [78]. Following nucleation, MONP's growth continues until the concentration of the precursor reaches equilibrium based on solubility [76]. Diffusion determines the growth rate of the particle; whereby smaller particles have recorded a larger growth rate compared to larger particles.

Next, the change in particle size occurs due to the ageing step that involves coarsening of the particle or also known as the Ostwald ripening process. Ostwald ripening is defined as a thermodynamically spontaneous process where larger particles are more energetically favored than smaller particles. Therefore, smaller particles diffuse in a solution before attaching themselves to the surface of larger particles. This step decreases the amount of smaller particles that are present in the solution. Meanwhile, agglomeration tends to occur rapidly for larger particles because larger particles tend to grow inappropriately due to lower surface energy [79]. The outcomes of the effect of RTILs structure in the MONPs synthesis could be observed through the morphologies and shape of the materials. The impact of the type of RTILs utilized and the exact reaction conditions on the particle size and shape of ZnO NPs were recently described by Alammar and Mudring [80]. It was discovered that increasing the length of the cation alkyl chain results in the creation of nanospheres rather than nanorods. This was explained by the steric effect of the longer alkyl chains of the RTILs with the ZnO NPs surface interaction which inhibit the growth of the particles for their typical creation of nanorods. It was also described that the longer cation chain contributes to smaller particle size with a diameter of 100 nm rather than shorter alkyl chain with a diameter of 400 nm. This was also agreed by other researches that also synthesized ZnO NPs that the length of the alkyl chain affect the morphology, size, and shape due to the steric hindrance [81, 82]. Similarly, the study on CeO NPs synthesis in RTILs reported that an exchange in RTILs cations would lead to a different morphology such that methylimidazolium $(C_3mimOH)^+$ and trishexyltetradecylphosphonium $(P_{66614})^+$ produced spherical-like and nanosheet assembly with particles size smaller than 10 nm.

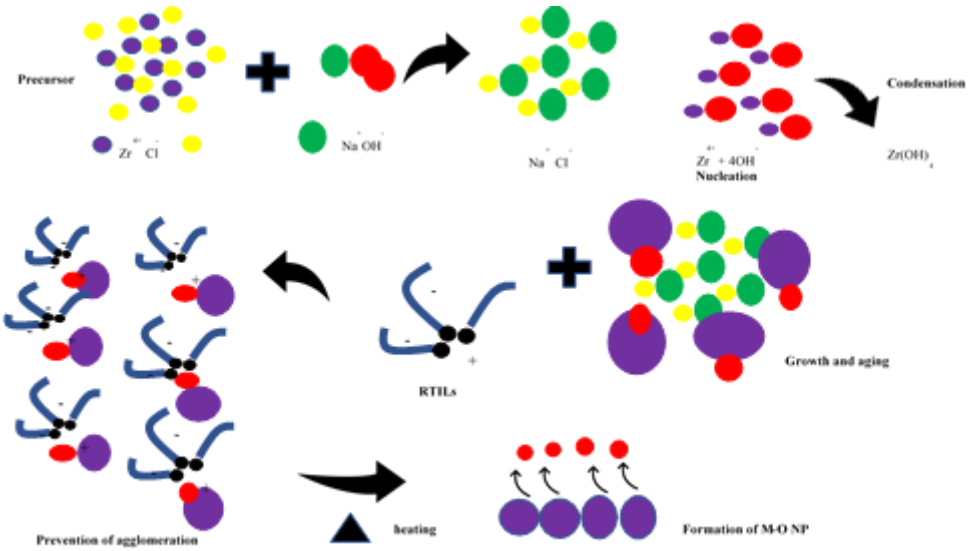

Figure 1. Proposed illustration for the steps in synthesis of MONPs using RTILs as capping agent. Source: [1, 37, 74-82].

Synthesis of MONPs using RTILs

Based on the evidence, the versatility of capping agents allows control over the agglomeration of particles from forming an anisotropic structure [83]. In addition, RTILs have been reported as effective capping agents in the synthesis of MONPs due to their peculiar structural properties. Therefore, the introduction of RTILs as a capping agent into the precursor solution allows the successful synthesis of many MONPs through bottom-up methods such as hydrothermal [84, 85], sol-gel [86], precipitation [30], microwave-assisted [36], and ultrasound-assisted [78] and their application as tabulated in Table 1. Of which, hydrothermal and sol-gel methods are most preferred because they are simpler and milder compared to microwave-assisted which requires special equipment to perform. In addition, sol-gel method is a green synthesize method that enables the recycling of RTILs, thus reducing the amount of chemicals used.

Table 1. Summary on methods and effects of RTILs on structure, properties, and application of MONPs

Method	RTILs	MONPs	Finding	[a]Size (nm) [b]Morphology	Application	Ref.
Sol-gel	Aliquat HTA-1	MnO_2	Good charging and discharging behavior at various current densities.	[a]20 [b]nanorod	Supercapacitor	[33]
	EMIMBr	TiO_2	The ratios of rutile to anatase in the products can be contro lled by altering the RTILs co ncentration.	[a]3.6-5.2 [b]nanorod	n.a	[32]
	$BMIMBF_4$	CeO_2	The formation of MONPs are successfully formed in RTILs acting as a soft-templating agent.	[a]15-20 [b]spherical	Auto-catalytic regenerative	[87]
	BMIMI	ZnO	May act as a template and very impactful on the structure and surface properties of ZnO NPs.	[a]9.13 [b]hexagonal	Antibacterial	[86]
	$BMIMBF_4$	MgO	RTILs formed an extended and lightly structured hydrogen bond network.	[a]30-50 [b]nanorod	n.a	[88]
	$BMIMPF_6$	TiO_2	Important in achieving a longer aging time for the formation of a stable sol-gel network.	[a]5 [b]sponge-like pore	n.a	[89]

Method	RTILs	MONPs	Finding	[a]Size (nm) [b]Morphology	Application	Ref.
	BMIMCl	Si-GO	Higher surface area with high crystalline phase.	[a]20-30 [b]spherical	Removal of heavy metal ions from water	[63]
	Benzimidazolium	ZnO	Good photocatalyst and antibacterial behavior.	[a]96.24 [b]n.a	Antibacterial	[90]
	$BMIMPF_6$	Nd_2O_3	Nd_2O_3-RTILs exhibited bactericidal activity yet at low concentrations and it is more effective drug for biomedical applications.	[a]48 [b]spherical, cubic, cuboic	Antibacterial	[91]
	TMPA-TFSI	Ag/Mn_3O_4/bent	Exhibited non-aggregated and displayed a significant amount of rod and spherical morphologies.	[a]10.4 [b]rod-like	Antibacterial	[92]
	$BMIMPF_6$	SrO/CeO_2	Controlled size of SrO/CeO_2 mixed MONPs exhibit antibacterial and antioxidant activity.	[a]5-55 [b]nanorod	Antioxidant and antibacterial	[93]
	$BMIMPF_6$	Ag-Au/Y_2O_3	RTILs controlled the growth and prevent the agglomeration of metal ions that give higher antibacterial and anticancer properties.	[a]30 [b]nanoflake=like	Biological	[94]
Hydrothermal	$BMIMBF_4$	Yb_2O_3	Less agglomeration due to the use of RTILs in the synthesis.	[a]35 [b] hexagonal, spherical, rectangular	Biological	[95]
	$BMIMPF_6$	Ag-rGO	Higher yields and better control over the diameter of the nanoparticles.	[a]10 [b] n.a	n.a	[96]
	TFSI	ZnO	Exhibited hexagonal shaped ZnO NPs in a very short period of reaction time.	[a]1500-2000 [b]hexagonal	n.a	[34]
	C_{16}MMIMBr	PtAg/rGO	Exhibited enhanced electrocatalytic performance, high methanol tolerant activity, and improved stability.	[a]31.5 [b]flower-like	Oxygen reduction	[97]
	$C_{10}MIMBF_4$ BMIM BF_4	ZnO	Difference alkyl chain length could affect the size of pore channels of hollow structure, the dispersivity and uniformity of ZnO NPs	[a]10 [b]ring-like	n.a	[98]
	C_3MIMBr	ZnO	Successfully synthesized ring-like ZnO NPs and promoted growth of tube-like structure.	[a]500 [b]ring-like hollow	Photoluminescence	[35]
	BDMIMCl	γ-Al_2O_3	Various morphologies successfully synthesis.	[a]90 [b]nanoleaves	n.a	[99]
	$BMIMPF_6$	Sm_2O_3	Particles are separated by distance without agglomeration.	[a]30-50 [b]cubic	Biomedical	[100]
	$BMIMBF_4$	WO_3	RTILs are important in the controlled synthesis of nanostructured materials.	[a]36 [b] spherical	NO_2 sensing	[85]
	HMIMBr	CeO_2– TiO_2	Large specific surface area and uniform pore size.	[a]3-4 [b]spherical	Photocatalytic	[101]

Method	RTILs	MONPs	Finding	[a]Size (nm) [b]Morphology	Application	Ref.
	BMIMCl	Fe_2O_3	Various morphologies of product yield.	[a]39.1 [b] hexagonal	n.a	[84]
	$BMIMBF_4$	TiO_2	Can prevent the production of brookite and favour the growth of the anatase phase.	[a]7.8 [b]n.a	Photocatalytic	[102]
	$BMIMBF_4$	ZnO	ZnO NPs with snowflake shape obtained as the RTILs used acted as a template which improved the sensitivity of NO_x sensor.	[a]600 [b]needle-like	Detection of NOx	[103]
	$BMIMPF_6$	La_2O_3	RTILs acts as a size and shape-directing agent contributes to good antibacterial and anti-inflammatory activities	[a]43 [b]spherical	Biomedical	[11]
Ultrasound-assisted	$EMIMBF_4$	Fe_2O_3	High conductivity with slightly increased viscosity and density.	[a]2-6 [b] quasi-spherical	Liquid marble	[78]
	$HMIMNTf_2$	ZnO	High yield and uniform diameter of small MONPs.	[a]60 [b]spherical	n.a	[104]
	Ionic liquid choline serinate	CeO_2	RTILs provide more stability to the MONPs and acts as cross-linking agent for collagen stabilization.	[a]19.95 [b]n.a	Biomedical	[105]
Precipitation	Poly (N- vinyl pyrrolidone)	ZnO	Increased efficiency in removing water pollutants.	[a]41.4 [b]spherical	Water treatment	[30]
	$BMIMNTf_2$	Fe_2O_3	MONPs exhibited well-controlled size and size distribution.	[a]10.6 [b]spherical	n.a	[31]
Microwave-assisted	$OMIMPF_6$	ZnO	No agglomeration, pure product.	[a]16 [b]spherica	Esterification reaction	[36]

1-ethyl-3-methyl-imidazolium bromide (EMIMBr), neodymium oxide (Nd_2O_3), N-trimethyl-N-propylammonium bis(trifluoromethanesulfonyl)imid (TMPA-TFSI), silver/manganese oxide/bentonite (Ag/Mn_3O_4/bent), lithiated sarcosine-trifluoromethyl sulfonyl imide (TFSI), silver nanoparticles-reduced graphene oxide (Ag-rGO), 1-hexadecyl-2,3-dimethylimidazolium bromide (C_{16}MMIMBr), bimetallic reduced graphene oxide (PtAg/rGO), 1-decyl-3-methylimidazolium tetrafluoroborate ($C_{10}MIMBF_4$), 1-propyl-3-methylimidazolium bromide (C_3MIMBr), 1-butyl-2,3-dimethyl imidazollium chloride (BDMIMCl), gamma-aluminium oxide (γ-Al_2O_3), lanthanum oxide (La_2O_3), Silver and gold decorated Y_2O_3NPs (Ag-Au/Y_2O_3), graphene oxide (GO), silica–graphene oxide nanocomposite (Si-GO), 1-ethyl-3-methylimidazolium bis (trifluoromethylsulfonyl)imide (EMIMTFSI), 1-butyl 3-methyl imidazolium Iodide (BMIMI)., n.a (not availbale).

Sol gel method

Among many available methods, sol-gel is an effective and the simplest chemical method to synthesize MONPs with the desired properties. This method involves various steps starting with the hydrolysis process, followed by polycondensation, gelation, and aging of the metal alkoxide in the presence of acid or base. From this mechanism, a pure and homogenous product would be formed in mild condition before subjected to drying, compaction, and crystallization steps that would improve the chemical homogeneity of the MONPs formed [106, 107]. The reaction of sol-gel through partial hydrolysis of the alkoxide, polycondensation of the hydroxyl, and polymerization of alkoxyl groups are explained using equations as follow [108]:

$$M(OCH_2CH_3)_{10} + x6H_2O \rightarrow M(OCH_2CH_3)_4(OH)_6 + 6CH_3OH \quad (1)$$

$$M\text{-}OH + HO\text{-}M \rightarrow M\text{-}O\text{-}M + H_2O \quad (2)$$

$$M\text{-}OCH_3 + HO\text{-}M \rightarrow M\text{-}O\text{-}M + CH_3OH \quad (3)$$

Fang and Song [87] synthesized CeO_2 NPs via the sol-gel method using cerium nitrate hexahydrate ($Ce(NO_3)_3.6H_2O$) as a precursor dispersed in water. During the synthesis activity, a capping agent of $BMIMBF_4$ was added to control the formation of MONPs. The RTILs in the supernatant solution was collected using a rotary evaporator and was reused in the next synthesis activity of CeO_2 NPs. The recycled

activity indicated that the capping agents used were environmentally friendly. The size of the obtained CeO_2 was between 15 nm to 25 nm after calcined at high temperature for 6 hours. The research was then expanded to study the formation of CeO_2/Chitosan composite. According to the UV-visible spectrum, adding cerium oxide nanoparticles to the chitosan polymer produced a high ability of catalytic oxidative recovery from spectrum shifting, which could be related to the material's tiny size which allowed the penetration into chitosan.

Pandiyan et al. [93] reported a simple and eco-friendly method using RTILs which assisted green synthesis of ceramic SrO/CeO_2 NPs via the sol-gel method. The prepared SrO/CeO_2 NPs were highly crystallized and purified when analyzed using XRD. Based on the investigation, the $BMIPF_6$ improved the surface morphology of the SrO/CeO_2 NPs as compared to the synthesis without BMIM]PF_6. This was due to the material that was uniformly distributed, and the growth and agglomeration activities that was controlled with the presence of $BMIMPF_6$.

Meanwhile, Sundarajan et al. [86] successfully prepared nanocrystalline ZnO NPs using the sol-gel method using 1-butyl 3-methyl imidazolium iodide ($[BMIM]^+ I^-$) as a capping agent. The product was calcinated at 400 ℃ to produce white colored ZnO NPs. To overcome the drawback, $[BMIM]^+ I^-$ was added which acted as a capping agent by adsorbing on the surface and covering the ZnO NPs during crystallization. The calculated average crystal size was found to be smaller with the presence of $BMIM]^+ I^-$ than that without RTILs, indicating the significant role of ($[BMIM]^+ I^-$) in influencing the structure and surface properties of ZnO NPs. During the application of ZnO NPs as an antibacterial agent, it was observed that the bacterial growth inhibition increased due to their small particles size and improved morphology which improved the uniform distribution of Zn^{2+} ions on the bacterial surface, indicating significant enhancement of antibacterial activity. In recent years, Sundarajan et al. [91] reported on the advanced synthesis of neodymium oxide nanoparticles using the sol-gel method by reacting neodymium chloride hexahydrate ($NdCl_3.6H_2O$) and $BMIMPF_6$ at room temperature. The final product was calcinated at a very high temperature (650 ℃) for 5 hours in a muffle furnace. As a result, a material highly improved surface smoothness was obtained due to the excellent roles of the capping agent ($BMIMPF_6$) to control the particles agglomeration as compared to the materials without RTILs. Moreover, they reported that the scavenging activity of Nd_2O_3 NPs synthesized in $BMIMPF_6$ was higher than that of Nd_2O_3 NPs, suggesting that they could be exploited as a viable treatment of diabetes disorders.

On the other hand, a similar method was investigated by Bharate et al. [33] to synthesize MnO_2 NPs in Aliquat HTA-1, whereby 1.5 g of manganese chloride (precursor) was dissolved into 25 mL of distilled water before the addition of Aliquat HTA-1. During the synthesis of MnO_2 NPs, weight ratio of MnO_2 NPs to Aliquat HTA-1 of 1:4 was added amidst the synthesis to ensure that all the particles were capped with the RTILs as it prevents agglomeration, which further prevents anisotropic growth of the particle. The amount of RTILs added was larger than most reported literature that used imidazolium based RTILs. In their work, a comparison study to investigate the effectiveness of RTILs was done where one of the MnO_2 NPs was synthesized without RTILs showing to form spherical shape in contra to nanorods. The RTILs used in this study was also used as an electrolyte during the supercapacitor application where they used 5% of Aliquat HTA.

Hydrothermal method

The hydrothermal method is another choice of method to synthesize MONPs that typically use Teflon-line stainless steel autoclaved reactor with temperature higher than 100°C and pressures above 1 atm [109]. Liu et al. [101] used RTILs to synthesize CeO_2 NPs. It was done by dissolving 0.005 mol of 1-hexadecane-3-methylimidazolium bromide ($C_{16}MIM^+Br^-$) in 15 mL distilled water through vigorous stirring at 40°C for 30 minutes. Then, tetrabutyl orthotitanate (TBOT) and cerium nitrate ($Ce(NO_3)_3$) were added to the solution. In their study, they reported for the first time a facile synthesis of hybrid MONPs of CeO_2–TiO_2 NPs with adjustable Ce/Ti percentages using RTILs, where the molar proportion of cerium (Ce) in the composition varied in the range of 5% to 30%. Upon the completion of stirring for 30 minutes, the pH of the solution was adjusted to 9 -10 using dropwise addition of ammonia solution followed by stirring for 2 hours. Then, the homogeneous sol was transferred to a 100 mL Teflon-line stainless steel autoclave at 100°C for 2 days. The finding from XPS spectra revealed that the Ce^{3+}concentrations decreased from 5% CeO_2–TiO_2 to 30% CeO_2–TiO_2 , indicating that the amount of Ce^{3+} in total Ce declined with the growing amount of CeO_2

NPs.

Zhang et al. [85] investigated the role of RTILs in improving the sensitivity of tungsten trioxide (WO_3) to NO_2 gas. In the synthesis of the material, different concentrations of $BMIMBF_4$ were added amidst the synthesis process. The surface composition of the material was studied using X-ray photoelectron spectroscopy (XPS), which revealed characteristic peaks corresponding to the C, O, W, and N elements in the materials, as well as the appearance of a N 1s peak at 400.2 eV, attributed to imine (=N-) derived from the imidazole ring in RTILs. When compared to WO_3 NPs generated without the addition of RTILs, the as-synthesized WO_3 NPs have significantly enhanced the sensing characteristics of NO_2. The phenomenon could be attributed to the high proportions of surface adsorption oxygen and the residue of C-N from $BMIMBF_4$, thus creating a large specific surface area.

On the other hand, Muthulakshmi et al. [100] used the same hydrothermal method in the synthesis of samarium oxide (Sm_2O_3) NPs. In their work, they utilized 1-butyl 3-methylimidazolium hexafluorophosphate ($BMIMPF_6$) to assist the synthesis route. In their findings, the particle size Sm_2O_3 NPs was between 50 nm and 80 nm as examined using dynamic light scattering method. Due to the superior properties of $BMIMPF_6$ as a capping agent, the particles were found well separated by a certain distance without agglomeration. The consistent particle size distribution and surface charge distribution visible in this finding could possibly explain the stability of Sm_2O_3 NPs produced in $BMIMPF_6$. Subsequently, the stability of the MONPs was proven by a high zeta potential (36.3 mV), indicating high stability of the synthesized Sm_2O_3 NPs. In the recent year, Muthulakshmi et al. [110] described the synthesis of ytterbium oxide (Yb_2O_3) NPs using the same capping agent ($BMIMPF_6$). It was discovered that the large agglomeration of NPs was minimized due to the addition of $BMIMPF_6$ in the synthesis process which was evidenced by using a particle size analyzer. The polydispersity index (P.I.) of the material was calculated to be 0.246 along with the superior electrophoretic mobility (0.000212 cm_2/Vs), indicating a homogeneous particle size distribution and surface charge. Furthermore, the stability of Yb_2O_3 NPs was excellent, making the potential of the material in medicinal field possible.

Microwave-assisted method

The microwave assisted method uses a domestic microwave oven to synthesis MONPs that involves efficient heating method which can significantly decrease the reaction time by the operation of electromagnetic waves between 300 MHz to 300 GHz [54]. For example, Kavya et al. [36] explored the microwave-assisted method to prepare ZnO NPs. 16 g of NaOH was added to 5.5 g zinc acetate dihydrate and 50 mL of distilled water while stirring. The suspension was placed in a microwave oven after adding 2 mL of $OMIMPF_6$ to 3 mL of the prepared solution (2.45 GHz, 850 W). The mixture was then irradiated for 2 minutes to 9 minutes in a loop using 30% of the microwave's output power (on 10 s; off 5 s). The formed spherical shape of the ZnO NPs was discovered to be greatly controlled by the initial production of nuclei by microwave irradiations, and then the subsequent role of the ionic liquid as a growth controller. A small particle size (16 nm) of ZnO NPs was obtained, making them suitable as a catalyst in the esterification between benzoic acid and methanol. The esterification reaction using 5 mol% ZnO NPs as an acid catalyst provided excellent yields in a short reaction time (2 hours), indicating that the produced ZnO NPs have outstanding potential as an alternative catalyst. The microwaved assisted method of MONPs synthesis in addition of RTILs as a capping agent can act as a microwave absorber and improve the induced uniform heating into the solution and maintain thermal homogeneity by an ionic conduction mechanism that lead to the formation of MONPs [42].

Precipitation method

Precipitation method is another synthesis method that is unique, cost-effective, simple, and involves controlling the pH of the medium [111]. The precipitation reaction process consists of five steps[112]:

(1) Dissociation of NaOH: $2NaOH_{(s)} \rightarrow 2Na^{+}_{(aq)} + 2OH^{-}_{(aq)}$

(2) Dissociation of precursor: $M(NO_3)_2{\cdot}XH_2O_{(s)} \rightarrow M^{2+}_{(aq)} + 2NO_3^{-}{}_{(aq)} + XH_2O$

(3) Formation of metal hydroxide: $M^{2+}{}_{(aq)} + 2OH^{-}_{(aq)} + XH2O_{(aq)} \rightarrow M(OH)^2{\cdot}XH_2O_{(s)}$

(4) Formation of colorless solution: $2Na^{+} + 2NO_3^{-} \rightarrow 2NaNO_3$

(5) Drying: $M(OH)_2{\cdot}XH_2O_{(s)} \rightarrow Zn(OH)_{2(s)} + XH_2O_{(g)}$ and

(6) Calcination: $M(OH)_{2(s)} \rightarrow MO_{(s)} + H_2O_{(g)}$

For instance, Atta et al. [30] synthesized ZnO NPs using the precipitation method. In brief, zinc nitrate hexahydrate (0.1 mol) was dissolved in 50 mL water and mixed with 4 g of poly-2-Acrylamido-2-methyl-1- propane sulfonic acid (PAMPSA) or poly-2-Acrylamido-2-methyl-1-propanesulfonic acid/N-vinyl pyrrolidone (PAMPSA/VP) under intense stirring until a clear solution was obtained. Then, 30 mL of NaOH (0.2 M in ethanol) was added to the reaction mixture and vigorously stirred until the pH of the solution reached 12.5. The pH is one of the important factors to be monitored as it has an impact on the product obtained. The number of H^+ or OH^- ions in the sol, which effectively dictates the polymerization of the metal–oxygen bonds, is well recognized to have a substantial influence on the morphology of the produced metal oxide precipitation/solution. The hydrolysis and condensation behavior of the solution during gel formation is affected by the pH of the precursor solution, thus affects the shape but does not affect much on the crystal quality of the MONPs [113]. Therefore, it is important to make sure the solution reach the desired pH to obtain the desired MONPs. Next, to produce a milky solution, the reaction temperature was increased to 45°C for 4 hours before letting it to rest. Then, the cooled reaction mixture was centrifuged at 15000 rpm for 10 minutes. To extract the aggregates and organic impurities, the precipitate was washed several times with distilled water and ethanol before drying for 5 hours at 150 °C.

Ultrasound-assisted method

The ultrasound-assisted method is a method that uses ultrasonic irradiation at frequencies ranging from 20 kHz to 500 MHz in sonochemical technologies to begin or modify chemical processes [54]. This method was described in two different studies to synthesize Fe_2O_3 NPs and ZnO NPs. For example, Zhang et al. [78] described the synthesis of Fe_2O_3 NPs through facile and energy saving (100 mW) ultrasonic decomposition of $Fe(CO)_5$ with 20 ml of $EMIMBF_4$ in a 50 mL round-bottomed flask in an ice bath. The ultrasound probe was placed 1 cm below the liquid surface, where the mixture was ultrasonicated for 1.5 hours at 100 mW. It was discovered that steric forces successfully stabilized the colloidal particles in $EMIMBF_4$, since the bulky structure of molecules/ions $EMIMBF_4$ strongly attached to the colloidal surfaces, allowing them to separate each colloidal surface in some circumstances. The nonpolar alkyl chains acted as a protective group and further inhibit the aggregation of the particles. Similarly, $EMIMBF_4$ enhanced the solvation force in the generation of MONPs, where the multi-layered structure created longer range repulsion and minimized agglomeration.

Whereas, Goharshadi et al. [104] prepared ZnO NPs by dissolving zinc acetate dihydrate into distilled water with dropwise of NaOH solution. The synthesis activity was magnetically stirred under room temperature, resulting in a clear $[Zn(OH)_4]^{-2}$ solution. Before subjected to 40 kHz of ultrasonication for 1 hour, HMIMNTf2 was added into the $[Zn(OH)_4]^{-2}$ solution until white precipitate of ZnO NPs was obtained. The total acoustic power injected into the sample solution was estimated at 50 W by a calorimetry. The white ZnO NPs precipitate was then centrifuged, washed, and dried for 10 hours in a vacuum oven at 40 °C. According to the analysis, both HMIMNTf2 and ultrasound posed a critical role during the formation of ZnO NPs. The obtained ZnO NPs were spherical in shape and well aggregated, consisting of numerous tiny nanoparticles with homogeneous diameters of about 60 nm. This could be possibly explained through the capping agent of HMIMNTf2 which consists of cation $[C6mim]^+$ and anion $[NTf2]^-$. Cation from $[C6mim]^+$ created the electrostatic attraction within the precursor solution comprising a large number of $[Zn(OH)_4]^{2-}$ ions. Due to the high polarization of $[C6mim]^+$, these cation–anion pairs were likely to dehydrate and produce ZnO NPs nuclei. Furthermore, $[C6mim]^+$ ions containing hydroxyl can still adsorb the negatively charged ZnO NPs nuclei's surface to restrict the activities of freshly produced ZnO NPs surfaces, causing the anisotropic development of ZnO NPs to be significantly controlled. The features and comparative analysis of different chemical synthesis methods for MONPs is displayed in Table 2.

Table 2. Comparative analysis of different chemical synthesis methods for MONPs

Synthesis Method	Specific Features	Advantages	Disadvantages
Sol gel method	1. A sol (or solution) grows slowly to form a gel-like system containing liquid and solid phases [114].	1. Possible recycling of RTILs. 2. Made at considerable low temperature below 100 ºC.	1. Product controlled by various parameters; where the final product obtained is affected by concentration of precursor, pH condition, and synthesis time during the sol-gel reaction [115].
Hydrothermal method	1. The action of water at elevated pressure and temperature under a sealed environment in an autoclave [116].	1. Highly nanostructured nanoparticles are controlled over pressure and temperature only [117]. 2. Zero-emission of toxic gases, since the reaction are in the closed system of autoclave [118].	1. Requires expensive equipment (autoclave).
Microwave-Assisted Method	1. Open vessel is simpler than closed vessels [119]. 2. The absorption of microwave radiation by the precursor followed by heat generation through dielectric heating [120].	1. Uniform heating. 2. Possible to use household microwave oven [121]. 3. Use scientific microwave oven. 4. Heats the target molecules directly. 5. Very short reaction time and high efficiency.	1. Requires expensive equipment (microwave oven).

Synthesis Method	Specific Features	Advantages	Disadvantages
Precipitation method	1. Synthesis begins with reaction between metal and alkaline solution or precipitating agent (NaOH, KOH, ammonia etc.) followed by aggregation and precipitate product is collected by filtration or centrifugation [122].	1. Simple. 2. Shape of the particle can be alter by changing the precursor, type of precipitating agent and quantity of organic phase [123]. 3. High crystallinity and homogeneity of product [124]. 4. Cost-effective and scalable [125].	1. pH sensitive. 2. Further thermal treatment is needed [122].
Ultrasound-assisted method	1. Involves energy in the form of heat, light, radiation, electric potential [126]. 2. Formation of bubbles due to the cavitation during ultrasonication [127].	1. More appropriate method for green and sustainable synthetic processes [128]. 2. Minimization of waste [129]. 3. Effective for nanoparticle formation as it yields high product.	1. Require expensive equipment (ultrasonic irradiation). 2. Various reaction parameters including temperature, time, energy input, and pressure must be controlled [126].

Characterization

Morphology and microscopy analysis

Microscopy analysis by transmission electron microscopy (TEM) and scanning electron microscopy (SEM) are carried out to study the morphology of MONPs such as quality, shape, density, diameter, thickness, length, size, and orientation of the as-grown nanostructure [130]. Both use a beam electron to view an image, whereby TEM image is displayed in a two-dimensional projection that passes through the sample while SEM image illustrates the surface morphology of the sample [131, 132].

Scanning electron microscopy

SEM is a microscopy technique that focuses the electron beam to a spot and interacts with the sample which then produces various signals that are combined to form an image. The formation of the image can be used to obtain information about the surface topography and composition depending on the scan pattern chosen [133]. In assessing the physical properties of MONPs, SEM imaging techniques are usually employed to observe their microstructure and morphological properties like size and shape distribution.

A previous study by Mahjoub et al. [134] who synthesized ZnO NPs using chiral ionic liquid (2[N-(n-But)$_4$]+[$C_2H_4(OH)_2(CO_2)_2$]$^{2-}$) (CIL) as a capping agent proved that the absence of CIL resulted in the agglomeration of flower-like ZnO NPs as demonstrated by the obtained SEM image. This shows that CIL plays an important role in morphology of the ZnO NPs. As for the growth of flower-like crystal, when [Zn $(OH)_4]^{2-}$ was decomposed, oxide nuclei developed quickly and served as the growth unit for the formation of ZnO NPs nuclei and epitaxial growth into the flower-like structures. This phenomenon can occur with the help of microwave heating. In general, each Zn^{2+} atom is surrounded by a tetrahedral group of four oxygen ions in hexagonal packing, making the CIL cations and anions easily absorbed on the of O^{2-} and Zn^{2+} surfaces by electrostatic force. However, the amount the CIL extensively affected the morphology of the ZnO NPs as the CIL presence was at 0.3 g, resulting in a narcis-like morphology of the ZnO NPs. A similar finding was also obtained by Kowsari and Karimzadeh [135] who synthesized BaO NPs using CIL, where the amount of CIL added into the MONPs affected the morphology of the product such that a low amount of CIL (0.15 g) formed a heterogenous butterfly-like and cubic like morphology while a higher amount of CIL (0.25 g) formed a cubic like morphology. Instead, they reported that decreasing concentration of CIL reduced the amount of ion carrying the OH group that were responsible for the growth of BaO NPs nuclei to navigate the surfaces forming both cubic and butterfly-like morphologies.

EDX analysis

The elemental mapping using EDX analysis is particularly important in proving the presence of metallic elements and other elements such as oxygen in the sample. This technique can be considered as qualitative and semi-quantitative analysis. The intensity of the peaks in the spectrum indicates the concentration of the respective element since every element has a specific set of peaks in the photoelectron which is determined by photon energy and the respective binding energies [136]. A study on the synthesis of silver NPs using three biodegradables protic ionic liquid (PILs) was reported by Tzani et al. [137], whereby the EDX spectra indicated the composition of the important elements. According to the EDX spectra, the Ag particle was the major element present in the composition with zero interruption from nitrogen element indicating that the NO_3^- ions were appropriately washed and perhaps it did not cap or adsorb in the Ag particles. Indeed, the PILs were successfully washed away using acetone, ethanol, and water. However, it did not interfere with the formation of the Ag NPs [137]. Similarly, a notable evidence of study specifically related to the EDX spectra of CeO_2/ZrO_2 core MONPs synthesized with $BMIMPF_6$ showing a well homogenous composition of cerium (25.95%), zirconium (8.325%), and oxygen (12.07%) due to the washing step during the synthesis using distilled water prior to the characterization technique [138]. However, they also emphasized on the significance of calcination of the MONPs core since the sintering of the particles would give a homogeneity of the MONPs product. Furthermore, another study [95] revealed similar results to the previous study where pure Yb_2O_3 NPs was synthesized using $BMIMPF_6$ in which the elemental composition percentages of ytterbium and oxygen peaks were 85.5% and 10.1%, respectively.

Transmission electron microscopy

TEM is used to observe the size distribution and morphology of the MONPs powder [139]. This analysis provides crystal or surface structure information along with the image up to a few angstrom resolutions. Determination of chemical composition is made possible when TEM is equipped with EDX since the working principle of TEM uses a high energy electron source of around 200 KeV [130]. A thin sample is irradiated with an electron beam of uniform current density passes through the samples to help visualize the size, shape (spherical, flower-like, rod-like or spindle-like structure), and effects of agglomeration [88]. Valuable information on the shape and particle size can provide the potential activity or quantify the distribution characteristics [140]. Moreover, the advantages of TEM include the ability to display the agglomeration of particles under a high-resolution image [141, 142].

As an alternative solvent to improve the properties of the MONPs, RTILs were used as capping agents in several studies [30, 33, 36, 78, 143]. Morphology of ZnO NPs synthesized using (TBA_2($_L$-Tar)) RTILs was elucidated using TEM that proved a flawless rose-like structure and were made up of self-assemble nanosheets with a length and width of several micrometers and a thickness of 30–40 nm with a preferred orientation due to the effect of tartrate anions that reformed the growth mechanism of the ZnO NPs [144]. This confirm that the CIL presence in the synthesis proscribed the 1D growth of the ZnO NPs nanostructures and rearranged the ZnO NPs to form 2D nanosheets that assemble into the hierarchical architectures like "roses." However, the author mentioned, generally the uses of basic imidazolium-based RTILs tends to formed a typical ZnO NPs in nanorods or nanowires structures based on the anisotropic growth of the crystal. In other words, RTILs can be soft templating to the formation of the MONPs structure that can be confirmed by TEM. This finding was found similar in other study where the CIL was acting as template in the formation of ZnO NPs and CuO NPs and the morphology reported a flower-shape with the particle size in the range of 100 – 200 nm for ZnO NPs and a needle-like shape for CuO NPs with a length of 400 – 500 nm and a diameter of 10 – 15 nm. Although the MONPs was synthesized using CIL, there was no significant change in morphology but when the CIL was not added in the MONPs synthesis, the TEM image showed an irregular size and shape. Probably, the presence of RTILs even as a simple additive in water can indeed affect the morphology of CuO NPs. This might be due to the strong electrostatic interactions between anions and cations, as well as π-π stacking and van der Waals interactions involving imidazolium cations perhaps can influence the formation of MONPs that are further characterized using TEM [145].

Moreover, $BMIMPF_6$ is one of the common RTILs used in the synthesis of MONPs to act as capping agent in order to prevent the agglomeration of the MONPs. A Previous study used $BMIMPF_6$ in the synthesis Nd_2O_3 NPs exhibited cubic and spherical shape with a diameter of 48 nm. The synthesis of Nd_2O_3 NPs was reported to exhibit more effective drug delivery for biomedical application [91]. Similarly, Pandiyan et al. also used the same RTILs to control and prevent the agglomeration of metal ions that contributed to nanoflake-like structures of Ag-Au/Y_2O_3 NPs with a diameter of 30 nm. The MONPs obtained were also suitable to be applied in antibacterial and anticancer applications [94]. In addition to this, Veerasingam et al. and Muthulakshmi et al. also reported a size of 43 nm and 50 nm for La_2O_3 NPs and Sm_2O_3 NPs, respectively based on their TEM micrographs. From the TEM image, the crystalite size of La_2O_3 NPs in the absence of $BMIMPF_6$ clearly showed agglomerated particles and while RTILs assisted of La_2O_3 NPs showed agglomeration free particles. Both study reported that $BMIMPF_6$ was able to act as shape-directing agent and the particle were well separated without any agglomeration [11, 100]. It is worth to point out that, $BMIMPF_6$ was suitable in synthesis of various MONPs as this RTIL have weak interaction of cation and anion when interacted with water that enabled the positively charged metal ions to interact with the negatively charged of the RTILs anion to control the growth of the MONPs. From the reported journal, it was noted that a morphology, size, crystal structure, qualitative, and quantitative analysis can all be done using these characterization techniques as this technique provides higher resolution than a light microscope [146].

Besides that, another alternative of RTILs used to prevent agglomeration of the synthesized MONPs was mentioned in previous study by Liu et al. [147] who used 1-hexadecane-3-methylimidazolium bromide (HMIMBr) as a template via the hydrothermal method to produce well-dispersed CeO-TiO_2 NPs. The TEM images demonstrated rod-like shape for 5% CeO-TiO_2 NPs, 10% CeO-TiO2, and 15% CeO-TiO_2 NPs, while

the spherical shape was observed for pure CeO NPs and 30% CeO-TiO_2 NPs at an approximate size of 15 nm. The prepared CeO-TiO_2 NPs was used in the photocatalytic degradation of p-chlorophenol that produced high photocatalytic activity under UV or visible irradiation [101].

Spectroscopic analysis

Fourier-transform infrared

FTIR spectroscopy is a technique used to obtain the absorption or emission spectrum of a solid, liquid or gas in the infrared region, where the spectrum promotes transition between the rotational or vibrational energy level of the ground electronic energy state [148]. Usually, FTIR is used to confirm the bonding and qualitatively detect the presence of functional groups in a nanostructure [139, 149]. FTIR spectroscopy is used to identify functional groups, main vibrational mode, impurities (if any), and determine the purity of MONPs that validates the structural unit and connectivity such as bridging and non-bridging of oxygen in the synthesis of MONPs [150, 151].

The synthesis of MONPs using RTILs has gained interest recently due to the advantages of RTILs. The interpretation of typical peak is still considered as highly divisive due to the difference in opinions expressed by many researchers. A slightly similar peak was almost found on every synthesis MONPs indicating the stretching vibration of O-H bond that are mainly from the alcohol residue. This statement was well supported by a few researchers that synthesized MONPs using RTILs. For instance, Nithya et al. who synthesised CeO_2/ZrO_2 NPs core synthesized using $BMIMPF_6$ reported a broad band at 3426 cm^{-1}. This was similarly found by Veerasingam et al. [11] who observed a broadband at 3453 cm^{-1}. However, Sundrarajan et al. indicated that a broadband located at 3437 cm^{-1} attributed to hydroxyl group of water molecule. Besides that, even though ZrO_2 NPs and CeO_2 NPs have typical absorption peaks at 600 cm^{-1} and 510 $cm^{-1,}$ respectively, the distortion of the peak was reported for CeO_2/ZrO_2 core synthesized using $BMIMPF_6$. The significant peaks were observed at 498 cm^{-1} (CeO_2 NPs) and 416 cm^{-1} (ZrO_2 NPs) mainly due to the effects of zirconia grafting on the cerium surface and was not affected by the $BMIMPF_6$ which enhanced the size and morphology of the MONPs without altering the environment [138]. This finding was then further supported by Fang and Song who synthesized CeO_2 NPs capped by $BMIMBF_4$, the FTIR spectrum manifested a single-phase crystalline CeO_2 NPs with band peaks at 640 cm^{-1} and 673 cm^{-1} representing the Ce-O-Ce stretching vibration. This study reported that the two peaks above 3000 cm^{-1} in the infrared (IR) spectra indicated diagnostic changes in the C-H-F hydrogen bonding between BF_4 anions and the position of hydrogen at 4,5 within the imidazolium ring [87]. This phenomenon revealed that the method employed to synthesize MONPs did not remove all RTILs, hence may require several modifications including calcination temperature and type of method to achieve excellent purity.

It was in contrary to another study that RTILS did not alter the significant functional group of MONPs as none of the RTILs peaks appeared in the FTIR for those MONPs synthesized in RTILs. Based on the results, peaks for Ag-Au doped RuO_2 NPs in $BMIMPF_6$ was determined at 476 cm^{-1} belonging to RuO_2 NPs [152]. Another peak identified in the spectrum corresponded to the hydroxyl group (O-H) indicating the presence of OH bonded alcohol and a phenolic compound that arose from the plant extract used in the synthesis of the MONPs [152]. Furthermore, Sundrarajan et al. [86] provided complementary results for the synthesis of ZnO NPs that reposted the finding of Zn-O stretching vibration at 418 cm^{-1} in the spectra. This study also reported the presence of several other peaks at 2956.97 cm^{-1}, 2404.04 cm^{-1}, 1764.93 cm^{-1}, 1388.00 cm^{-1}, and 1164.38 cm^{-1} indicating the presence of C–O and C–H stretching vibrations from the phenolic compounds within the plant extracts before calcination. While the peak at 1626.95 cm^{-1} maybe due to the presence of intramolecular hydrogen bonds of the ionic liquid. Following the calcination process, the peak at 3500 cm^{-1} remained due to O–H stretching vibration from moisture adsorption. In this study, ZnO NPs were synthesized with the absence and presence of BMIMI but the significant stretching vibration of Zn-O spectra appears at the same wavenumber whereby this indicate that the addition of the BMIMI does not alter the purity of the ZnO NPs. However, uses of another type of RTILs may contribute to peak shifting that may be attributed to changing properties of the synthesis ZnO NPs. For instance, the synthesis of ZnO NPs using chiral ionic liquid reported a strong adsorption peak at 544 cm^{-1} that can be assigned to the Zn–O stretching bonds. With comparison to the typical absorption spectra of ZnO NPs, this peak was shifted to a higher wavelength, and this feature

attributed speculatively to the distinctive structure of ZnO NPs formed in the presence of the RTILs [145].

On the other hand, in another study [99], FTIR was performed to assess the nature of bonds and absorbance of the peak in the prepared Sm_2O_3 NPs. A broad prominent peak was observed at 3444 cm^{-1} which corresponded to O-H stretching vibration, indicating the presence of a water molecule. While the absorption peaks at 1109 cm^{-1} indicated C-O stretching vibration. Also, significant peaks were observed at 749 cm^{-1} and 657 cm^{-1} for Sm-O stretching vibration. In summary, Table 3 lists the functional groups and wavenumber range for the MONPs discussed in this section.

Table 3. Main Functional Groups of MONPs and Wavenumber.

MONPs	Wavenumber (cm^{-1})	Vibrational Mode	Ref.
CeO_2	673	Stretching	[52]
	450	Stretching	[153]
	674 and 545	Stretching	[21]
ZnO	418	Stretching	[86]
	501	Stretching	[112]
ZrO_2	595	Stretching	[138]
	492.73	Stretching	[19]
	473	Stretching	[154]
TiO_2	490	Stretching	[155]

UV-visible spectroscopy

The UV–Vis spectra of MONPs provide significant information regarding their optical characteristics. UV–Vis spectroscopy is also used to investigate the defect energy states induced by various doping agents in MONPs [156, 157]. Besides, for MONPs, UV-vis is commonly used to characterize supported single MONPs and it is widely known that absorption edge energies reduce as oxide domain size increases [158].

Bharate et al. [33] reported that the MnO_2 synthesized with aliquat HTA-1 had a significant absorption at λ_{max} 395 nm that showed smaller bathochromic shift, whereas MnO_2 NPs prepared without aliquat HTA-1 had absorption at λ_{max} 386 nm which could be due to its size and form. The MnO_2 NPs with aliquat HTA-1 had a smaller bathochromic shift than MnO_2 without aliquat HTA-1, which could be due to its size and form. These results show that Aliquat HTA-1, an RTIL, functioned as a surfactant and regulated the size and form of nanoparticles. Similarly, the UV–visible spectra of ZnO NPs showed the excitonic absorption peaks at 222 nm in the presence of BMIMI while 227 nm in the absence of BMIMI. As for the absorption band, it was moved to the lowest wavelength and the blue shift of the quantum confinement effect indicating the production of ZnO NPs [86]. Another study that used $BMIMBF_4$ to synthesize the rare earth MONPs showed that by using UV-Vis spectrum data, the insertion of CeO_2 NPs into the chitosan polymer has a high ability of catalytic oxidative recovery. This can be confirmed by the spectrum shifting from lower to higher and higher to lower energy range with hydrogen peroxide aid. In addition, the valence states of cerium oxide (3^+ and 4^+) on the surface of nanoparticles fundamentally function as an antioxidant, which had been trapping free radicals in the culture medium that was validated using UV-Vis data [52] the sharp absorption band arise from the transition of valence band to conduction band of the MONPs. One can also notice that the absorption band of the maximum wavelength from the UV-vis spectra indicates that the RTILs affected structure formation of the particles as well as the optical properties of the synthesized MONPs. The absorption band showed a blue shift peak due to smaller particles size owing to the use of RTILs as capping agent in the synthesis of MONPs. However, there were studies that show a red shift region when they used RTILs in their synthesis due to the formation of mixed morphology (hexagonal, rectangular, and spherical) of the MONPs product or changing in the shape or structure of the particles such as from spherical to nanarod in the absence and presence of RTILs as a templating agent, respectively [110, 159].

Crystallinity analysis

X-ray powder diffraction

The XRD is a common technique used to study the crystal structures and atomic spacing based on the

constructive interference of monochromatic X-rays. A crystalline sample using XRD consist of three basic elements, namely an X-ray tube, a sample holder, and an X-ray detector [160, 161]. Moreover, XRD is suitable for various types of material such as fluids, metals, minerals, polymers, catalysts, plastics, pharmaceuticals, thin-film coatings, ceramics, solar cells, and semiconductors since it is a non-destructive method [160].

Also, XRD is a fingerprint technique used to study the crystallographic structures, purity, and atomic spacing of the MONPs, whether it is an amorphous or crystal structure based on the constructive interference of monochromatic X-rays and samples. The main distinctive peaks in XRD diffractograms that fit the experimental data of MONPs structure can be used to confirm the presence of MONPs [162, 163]. Meanwhile ZnO/CdO NPs rodlike particles were successfully synthesized by using the hydrothermal method in the ionic liquid medium (4-methylpyridine,2,2,2- trifluoroacetate) and can be clarified using XRD pattern after dried in air at 150 °C. The diffraction peaks were observed at 2θ = 34.0°, 35.0°, 37.05°, 48.04°, 57.03°, 68.02°, 69.00° correspond to (100), (002), (101), (102), (110), (112), and (201), respectively, these peaks are attributed to ZnO nanorod. Therefore, the as-synthesized products have great purity and crystallinity, as evidenced by the sharp and strong diffraction peaks from XRD pattern [163]. In addition to this, the synthesis of ZnO NPs with different pH by aqueous solution growth technique also successfully obtained ZnO NPs using Benzyltrimethylammoiumhydroxide (BTMAH) RTILs at different concentration and various pH. The micro/nanorods were extremely crystalline, as evidenced by XRD patterns with large, high-intensity peaks extending over the 2θ dimension. In this study, crystal planes were only reported at 100, 002, 101, 102, 110, 103, 200, 112, 201, 004 and 202. It was reported that due to the effect of ionic liquid concentration and pH the crystallite size was reduced with good crystallinity [165]. Similarly, Kowsari and Abdpour [166] also reported peaks at 2θ = 34.0, 35.0, 37.05, 48.04, 57.03, 63.04, 65.01, 68.02, 69.00 which corresponded to 100, 002, 101, 102, 110, 103, 200, 112, 201, respectively. The results show that the product is entirely made up of pure phase, with no impurity reflection peaks that indicates the hexagonal wurtzite structures of ZnO NPs when synthesis with functional RTILs, which are consistent with standard JCPDS: 792205 card ICSD#: 067454 [166]. From the reported journals, the synthesis of ZnO NPs using different type of RTILs as capping agents contribute to different crystal systems and a variety of MONPs structures as well as crystallite sizes.

Other than that, in the synthesis of TiO_2 N Ps using $BMIMBF_4$ was also investigated where the crystal plane was observed to be 101, 004, 200, 105, 204 indicated to anatase phase of the TiO_2 NPs without any trace of brookite and rutile phase detected. Based on this study there was a presence of brookite phase during the absence of the $BMIMBF_4$ where the XRD pattern showed a diffraction peak at 2θ=30.8º and disappeared when $BMIMBF_4$ were added amidst the synthesis of MONPs and a sharp diffraction appeared and increased at 2θ=25.4º with increasing amount of RTILs added [102]. A similar observation was also reported by Zheng et al. [32] who synthesis TiO_2 using different concentration EMIMBr and the XRD pattern showed a crystallite phase evolution of the synthesis TiO_2. The absence of EMIMBr gave about a 92% of anatase with minimal brookite phase in the system showing a crystal plane of 101, 004, 200, 105, and 211. The increasing of EMIMBr concentration led to growing of pure rutile phase in the crystal system with crystal plane of 110, 101, 200, 111, 210, 211, and 220. It is worth to noted that, different concentration of RTIL added into the reaction synthesis will provide diversity of crystal system. Therefore, researcher can utilize the amount of RTILs in order to obtain a desired crystal system of the TiO_2 NPs to make sure the suitability of the MONPs products for a curtained application.

Recent and future applications of MONPs synthesized in RTILs

The excellent properties of MONPs that are produced using RTILs as a capping agent were reported in many sectors including water treatment [30], super capacitance [33], catalyst [36], and antibacterial applications.

Antibacterial application

MONPs has drawn researchers interest due to their broad spectrum in antibacterial activities. New developments of antibacterial products or agents are in ominous need due to the resistance of microbial towards antibiotics through mutation process [167]. To investigate the antibacterial activity, the mechanism steps involved between MONPs and microbial are as follows [90, 167, 168, 169, 170, 171]. The MONPs adsorb on the surface of cell wall,

penetrating into the cell, therefore further modify the replication and respiration leading to cell death as reported previously

1. Promote the formation of reactive oxygen species (ROS) from the MONPs that can interact with proteins and/or intercalate between the purine and pyrimidine components that are present in DNA involving further damage in the cell membrane, and
2. Causing a cell death by disrupting the signal transduction pathways of the cells.

Muthulakshmi et al. [110], examined the uniform size of Yb_2O_3 NPs synthesized in the $BMIMPF_6$ as a capping agent during the formation of Yb_2O_3 NPs. The suitable concentrations Yb_2O_3 NPs (150 µg/mL) was added carefully on the plates containing gram positive of *S. aureus* and gram negative of *E. coli* which were cultured in the nutrient agar. After 24 hours, the inhibition zone of Yb_2O_3 NPs synthesized in $BMIMPF_6$ was found to be higher compared to Yb_2O_3 NPs synthesized without $BMIMPF_6$. On *E. coli*, the inhibition zones of Yb_2O_3 and RTIL-Yb_2O_3 NPs were 5 and 8 mm, respectively while the zone of inhibition of Yb_2O_3, RTILs-Yb_2O_3 NPs, on *S. aureus* was at 4 and 7 mm. The effectiveness of inhibition activities of Yb_2O_3 NPs due to formation of uniform size coverage on the bacterial systems, which allow metal cations to be released from MONPs to damage the cell wall by adhering to the bacteria's surface and interacting with cell wall amino acids [39]. A similar investigation has been performed by Sundarajan et al. [91], where $BMIMPF_6$ assisted Nd_2O_3 NPs acting as antibacterial agents pathogenic bacteria like *E. Coli* and *S. aureus*. Even at a very low concentration (10 µg/mL), Nd_2O_3 NPs assisted $BMIMPF_6$ to display a relevant zone of inhibitions indicateing a potential in bactericidal activity.

According to their finding, inhibition zone of gram-negative bacteria (*E. coli*) containing Nd_2O_3 NPs was found at 2 mm while double zone inhibitions were found at Nd_2O_3 NPs- $BMIMPF_6$ (4 mm). Similar observation was reported for the zone of inhibition of the Nd_2O_3 NPs (5 mm) against *Staphylococcus aureus* where the zone inhibition was found larger using Nd_2O_3- $BMIMPF_6$ (7 mm).

Likely, Sundrarajan et al. [86] examined an inhibition zone of ZnO NPs against gram negative of *E.coli* by different methods such as the zone of inhibition, growth curve and biofilm formation. In their finding, the improved morphologically material exhibited very good antibacterial activity against the gram-negative. The ZnO NPs (50 µg mL^{-1}) without RTILs after calcination produced maximum diameter of inhibition zone (2.2 cm) while a same concentration of ZnO NPs synthesized in BMIMI produced larger inhibition zones with a diameter of 3.2 cm, indicating stronger antibacterial activity. Furthermore, upon test on *E. coli* bacterium's biofilm architecture on glass, the control demonstrated biofilm bacterial strains' significant adhering capacity after incubation. However, confocal fluorescence micrograph revealed that ZnO NPs in BMIMI were more effective and active in reducing adhesion and biofilm formation, and that they inhibited bacterial growth better than ZnO NPs without BMIMI. These effective bactericidal capabilities could be attributed to the tiny particle size and enhanced shape of the synthesized material, which allowed for uniform distribution of Zn^{2+} ions on the bacterial surface, resulting in substantial antibacterial activity.

Another MONPs nanocomposite have been synthesis for biological activities has been studied by far to inhibit the growth of *Staphylococcus aureus* (Gram-positive) and *Escherichia coli* (Gram-negative) bacteria such as Ag-Au/Y_2O_3 NPs in $BMIMPF_6$ [93], Ag-Au doped RuO_2 NPs synthesized in $BMIMPF_6$ [151], silver/manganese oxide/bentonite nanocomposite synthesized in N-trimethyl-N-propylammonium bis(trifluoromethanesulfonyl) imide [91]. Different physiological features including shape, size, charge, and morphology have a significant impact on the antibacterial activity of MONPs aided RTILs. Small particles have a larger surface area than bulk material, allowing them to pass through the bacterial wall more quickly. MONPs with a smaller crystalline size are more effective at releasing ions and inhibiting bacterial growth by entering cell membranes and reacting with sulfhydryl inside the cell membranes. As a result, the MONPs break the membrane and render proteins inactive, causing the bacterial cell to die [94].

Catalyst

Researchers are interested in developing photocatalysts with a mesoporous shape to produce high photocatalytic activity and promote quick intraparticle molecular transfer. To acquire higher photocatalyst characteristics, bigger surface area particles are necessary to improve light harvesting and adsorption for reactant molecules. For example, Liu et

al., [102] described the synthesis of TiO_2 NPs in $BMIMBF_4$ where the addition of $BMIMBF_4$ encouraged the formation of anatase TiO_2 NPs. The material was very thermally stable which enabled the preservation of anatase phase even after calcination at 900 °C. The photocatalytic activity of TiO_2 prepared with $BMIMBF_4$ was higher than that of the sample prepared without RTILs attributed to a larger surface area, good anatase crystal mesostructured and small particles size of synthesized material.

Subsequently, Liu et al. [147] investigated the photocatalytic activity of CeO_2–TiO_2 NPs produced in $C_{16}MIMBr$ for the degradation of p-chlorophenol aqueous solution under UV and visible-light irradiation using well-crystallized CeO_2–TiO_2 NPs. During the research, they discovered that 10% CeO_2–TiO_2 NPs had the maximum photoactivity under UV and visible light irradiation, with degradation rates of 95.3% and 57.5%, respectively. This activity was supported by the greater surface area, higher Ce^{3+} concentration, highest surface hydroxyl group concentration, and strongest light absorbance due to the smaller particle size (11–16 nm) formed in the synthesis. Meanwhile, Kayva et al. [36] reported the use of ZnO NPs synthesized in $OMIMPF_6$ (capping agent) to reduce the agglomeration via microwave irradiation method in esterification. Due to its good reproducibility, ZnO NPs as the smart material acts as a solid acid catalyst in the esterification process as it can be used up to four cycles. The authors discovered that the catalysts managed to enhance the percentage yield of primary alcohol to almost 80%.

Other applications

According to Atta et al., ZnO NPs are environmentally friendly nanocomposites for water treatment applications due to their antimicrobial and superior properties. In their work, poly-IL (PIL) based quaternary ammonium salts of 2–acrylamido-2-methyl propane sulfonic acid homopolymer and its copolymer, N-vinyl pyrrolidone, were used as capping agents to control the shapes and sizes of ZnO NPs. The prepared ZnO NPs were successfully crosslinked to 2–acrylamido-2-methyl propane sulfonic acid-co-acrylonitrile nanocomposites, which were used as adsorbents for methylene blue dye, as one of the efforts to reduce a hazardous organic pollutant found in water. The enhanced properties of ZnO NPs showed high removal rates than that used without ZnO NPs [30]. Bharate et al. [33] synthesized MnO_2 NPs in IL for supercapacitor application as an electrode material. The study revealed that MnO_2 NPs displayed different morphology in the presence of nanorod-shaped RTILs and the absence of spherical-shaped RTILs. As for the supercapacitor study, cyclic voltammetry and charge-discharge analysis were performed using an electrode modified with MnO_2-capped RTILs. The electrode generated substantial pseudo-capacitance reaching a maximum value probably due to the supercapacitor assembled with RTILs capped MnO_2 NPs, as positive and negative electrodes, resulting in high specific capacitance and better rate capability. Based on the available literature, remarkably excellent properties have been reported in studies of MONPs synthesized in RTILs in various fields. Therefore, the synthesis of other materials could be now investigated in the RTILs to obtain improved physiological properties.

Conclusion

In conclusion, he synthesis of MONPs commonly involve chemical methods which include sol-gel, hydrothermal, ultrasound-assisted, precipitation, and microwave-assisted. This paper provided a comprehensive review of the common techniques of preparation and characterization of MONPs using RTILs. In general, the MONPs could be prepared using various RTILs by chemical method followed by calcination and characterization to get the desired structure and morphology of the MONPs. SEM/EDX and TEM were used to study the structure and morphology of the synthesized MONPs, whereas XRD was used to study the crystallinity and purity of the synthesized MONPs. Meanwhile, FTIR and UV-VIS were used to study the shifting of the functional group of the MONPs and the maximum wavelength shifting of absorbance of the synthesis MONPs. Based on the studies, various structure and morphology of the MONPs have been reported and can be tailor-made using different RTILs for the synthesis of specific MONPs. On the other hand, the impacts of RTILs on the formation of MONPs which reduces the agglomeration during the growth steps was also extensively discussed in this review. Moreover, this review recapitulated the applications of MONPs synthesized using RTILs with enhanced properties in antibacterial, catalyst, and other applications. For example, in antibacterial application, the inhibition zone of bacteria for MONPs that were synthesized using RTILs were doubled rather than the MONPs that were not synthesized using RTILs. In short, this review would be beneficial for manufacturers custom-made materials of MONPs using RTILs with effective properties. Finally, it is hoped that this review will not

only exhibit the recent progress in the synthesis of MONPs using RTILs, but also embark further research to explore insightful and green methods for the preparation of MONPs.
